10^6 cells in response to K562 compared with zero in Percoll fraction 5, the only fraction tested. Immunofluorescence assays with monoclonal antibodies revealed that fraction 2 cells were enriched fivefold in the following NK markers compared with unfractionated lymphocytes: 60% HNK−1$^+$ (NK specific[5]), 52% OKM1$^+$ (ref. 6), 38% mac−1$^+$ (ref. 7) and depleted severalfold in the following non-NK markers: 15% OKT3$^+$ (T cells)[8] and 3% Ia$^+$ (B cells + monocytes + activated T cells)[9]. In addition, fraction 2 cells were >50% large granular lymphocytes (LGL), a morphological marker of human NK cells[4], and <0.1% granulocytes as judged by morphology in Giemsa-stained cytocentrifuge preparations or by immunofluorescent staining with a monoclonal antibody specific for human polymorphonuclear leukocytes (PMN). Over 50% of fraction 2 cells bound to ox erythrocytes coated with rabbit IgG anti-ox erythrocytes antibody (EA$^+$) which is another NK characteristic, whereas <0.1% phagocytosed the erythrocytes to which they were attached. In addition, <0.1% of the cells expressed the Mo2 marker[10] specific for human monocytes and <0.1% stained cytochemically for acid esterase. Therefore Percoll fraction 2 cells were contaminated with few (<0.1%) granulocytes or phagocytic macrophages and over half expressed NK markers and morphology. The few T cells in the preparation were probably not important since Percoll fractions 5 and 6 consisted of 90% T3$^+$ cells and did not generate significant chemiluminescence. When monocytes (purified by plastic adherence) or granulocytes (isolated on Ficoll–Hypaque followed by hypotonic shock of the cell pellets) were incubated together with Percoll fraction 2 cells at a cell dose approaching 1% contamination (10^4 cells ml^{-1}), the chemiluminescence response to K562 was not altered. In addition, 10^4–10^5 monocytes or PMN alone gave an insignificant response (< 10 × 10^3 c.p.m. above background) to K562 over the 10-min period of the chemiluminescence assay. Furthermore, 10^{-8}M phorbol-12-myristate-13-acetate-4-*O*-methyl ether (PMA) caused no chemiluminescence in Percoll fraction 2 cells although Percoll fraction 1 cells and purified monocytes or granulocytes generated >4 × 10^6 c.p.m. within seconds after addition. It is unlikely, therefore, that monocyte or PMN contamination can account for the response of the NK-enriched populations. Furthermore, we[11] as well as others[12] have shown that PMN- and macrophage-mediated cytoxicity of certain tumour cells is inhibited by catalase but not SOD, whereas NK-mediated cytotoxicity can be inhibited by SOD but not catalase as shown below. Finally, pretreatment of fraction 2 cells with monoclonal anti-HNK-1 antibody and complement, a procedure known to selectively remove NK cells[5], reduced the chemiluminescence, cytochrome *c* reduction, conjugate formation and cytolytic response against K562 by 56–75% (Table 1, expt *a*). It is likely, therefore, that most of the these responses are mediated by NK cells.

We then asked if the generation of chemiluminescence was

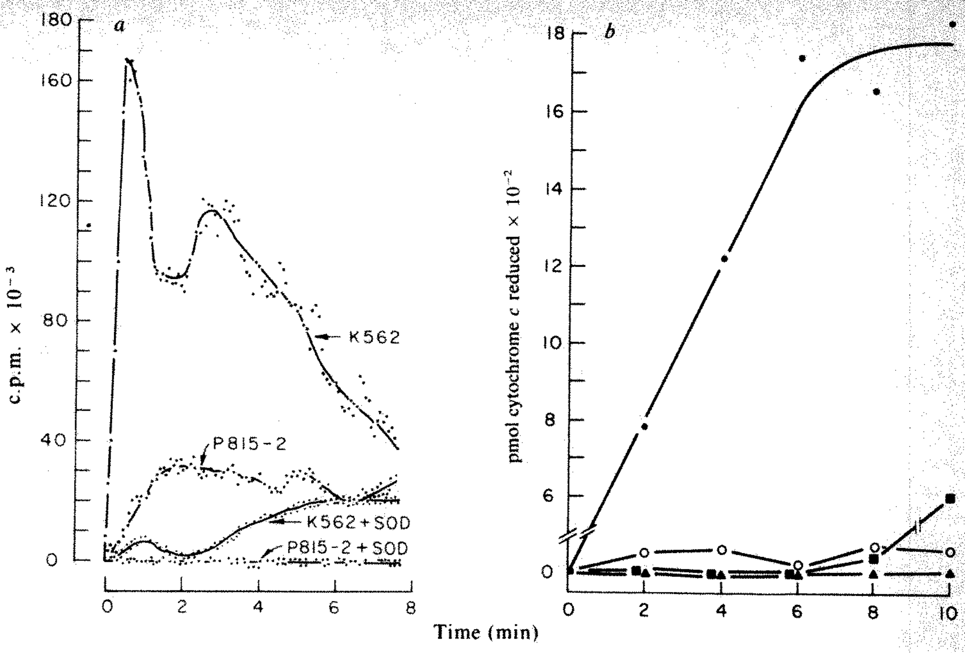

Fig. 1 Chemiluminescence and cytochrome *c* reduction in large granular lymphocytes (LGL) induced by NK-sensitive tumour cells. Peripheral blood was treated for 30 min at 37 °C with carbonyl-iron and a magnet to remove monocytes. Mononuclear cells were isolated by centrifugation on Ficoll-Hypaque (1.077 g cm^{-3}) and were further depleted by adherence on autologous serum-coated plastic dishes for 1 h at 37 °C. The non-adherent lymphocytes were layered on a five-step, discontinuous, Percoll density gradient and centrifuged for 30 min at 20 °C as described by Timonen and Saksela[4] and elaborated in Fig. 2 legend. Fraction 2 cells were enriched fivefold in cytolytic activity against K562; 60% of fraction 2 cells were LGL as detected morphologically in Giemsa smears, whereas <0.1% phagocytosed antibody-coated erythrocytes. *a*, 10^6 Percoll fraction 2 cells were dark-adapted for 30 min in 1.0 ml of 10% luminol-saturated, fetal calf serum in plastic scintillation vials. 10^7 tumour cells, medium alone, or tumour cells + 100 μg superoxide dismutase (280 U) was added in 0.1 ml volumes and mixed. Chemiluminescence was measured at ambient temperature (20 °C) in an LKB liquid scintillation counter in the out of coincidence mode. Values represent c.p.m. above background, measured in successive 5-s intervals. Luminol alone gave 35×10^3 c.p.m. and fraction 2 cells + luminol gave a stable background of 50×10^3 c.p.m. throughout the 8 min of the assay. This experiment was repeated 10 times with similar results and in replicate samples within each experiment the area under the curves varied <3%. *b*, 10^6 fraction 2 cells were combined with 10^7 K562 cells (●), 10^7 P815-2 cells (○), 10^7 K562 cells + 100 μg per ml SOD (280 U) (■), 10^7 P815-2 cells + 100 μg per ml SOD (280 U) (▲) in 1 ml of balanced salt solution (BSS) containing 0.2% bovine serum albumin in 10 μM KCN, 200 U catalase (Sigma; thymol-free) and 0.01 mM cytochrome *c* (Sigma, type III). After varying periods of incubation at 20 °C the reaction was stopped at 0 °C. Supernatants were measured spectrophotometrically at A_{550}. Maximum, reducible cytochrome *c* was determined with an excess of sodium dithionite. Absorbance readings were converted to pmol cytochrome *c* reduced after subtracting a small background response (<500 pmol) by tumour cells alone. Fraction 2 cells gave zero background over the 10-min period of assay. This experiment was repeated five times with similar results and values for replicate samples at each point varied <10%.

triggered in NK cells by a selective membrane binding event. As shown in Table 1, expt *b*, the degree of chemiluminescence correlated well ($r = 0.96$) with the degree of target cell binding in a survey of five different cell lines. One of the lines was a clone from K562 cultures which had been induced to differentiate in the presence of haemin[13]. Cell-free culture supernatants of K562 were inactive but plasma membrane vesicles also triggered chemiluminescence (Table 1*c*). Vesicles from a NK-insensitive target (P815) were not effective. The directionality of the response was indicated by the fact that mild glutaraldehyde fixation of NK cells abolished the chemiluminescence response to untreated K562 cells although conjugate formation was not markedly altered. Glutaraldehyde-fixed targets, on the other hand, stimulated a normal response in unfixed NK cells. It is likely therefore that target–effector binding stimulates the effector, rather than target, to generate chemiluminescence.

We emphasize that target-cell binding may not be a sufficient stimulus for release of oxygen species. Hence, stably low NK responders, selected from 600 screened normals, exhibited normal frequencies of HNK-1$^+$ NK cells and normal target cell binding but failed to generate normal levels of chemiluminescence, cytochrome *c* reduction or cytolysis (Table 1*d*). Furthermore, genetically NK-defective, Chediak-Higashi (CH) patients[14] also had normal frequencies of HNK-1$^+$ NK cells, normal target-cell binding and normal levels of chemiluminescence but markedly deficient cytolysis. Therefore, the generation of chemiluminescence may be necessary but not sufficient for cytolysis.

The generation of oxygen intermediates, particularly the superoxide anion, O_2^-, may be necessary for cytolysis because SOD (100 μg ml^{-1}, 280 U) inhibited 90% of chemiluminescence and cytochrome *c* reduction and consequently reduced cytolysis by 75% in a short-term (<2 h) ^{51}Cr-release assay (Table 1, expt *e*). Target-cell binding was not effected by SOD and denatured SOD did not inhibit chemiluminescence, cytochrome *c* reduction or cytolysis. Catalase was also non-inhibitory, as shown, although similar concentrations prevented monocytes from generating chemiluminescence and mediating cytotoxicity against L5178Y in parallel experiments (data not shown). In contrast to the inhibitory effects of SOD, both human α- and β-interferon were shown to augment chemiluminescence in parallel with cytotoxicity (Table 1*f*). Target binding was not effected.

Other cell subpopulations have also been shown to generate oxygen intermediates. Thymocytes stimulated with phytohaemagglutinin generated a peak chemiluminescence response of 15×10^3 c.p.m. per 10^8 cells[15] which compares with a peak NK response of 170×10^3 c.p.m. from only 10^6 Percoll fraction 2 cells in the present study (Fig. 1). Neutrophils (10^7) and mononuclear cells (5×10^7) generated up to 30×10^3 c.p.m. and 10×10^3 c.p.m. respectively, in response to opsonized bacteria[16]. Neutrophils stimulated with PHA generated 800 pmol cytochrome *c* reduced per min per 10^6 cells[17] compared with 200 pmol cytochrome *c* per min per 10^6 NK-enriched cells stimulated with K562 (Fig. 1). Therefore the NK cell response to K562 targets is similar to the response of other cell types to various stimuli.

In comparison with our findings with NK cells, alloimmune killer T cells in mice were not inhibited in function by any concentration of SOD tested (100–1,500 μg ml^{-1})[18]. Therefore killer T cells may function by a SOD-resistant mechanism[18] and monocyte-mediated cytolysis is catalase-sensitive and SOD-resistant[12]. The SOD-sensitive triggering of cytolysis in NK cells may be a unique phenomenon.

In conclusion, these results suggest that human NK cells are triggered to release oxygen intermediates including O_2^-, by contact with NK-sensitive targets. Although these oxygen species appear to be involved in cytolysis, their function may be to activate a subsequent step in the cascade of events leading to target cell destruction.

We thank I. Louwman and A. Wade for assistance and Drs Toru Abo and Charles Balch for the HNK-1 antibody. This

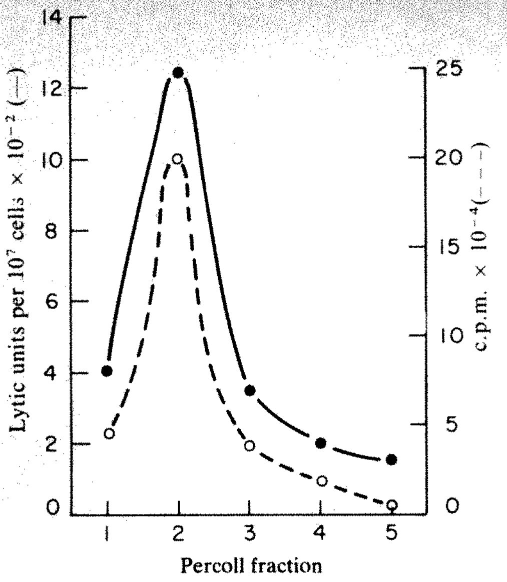

Fig. 2 Correlation between NK enrichment or depletion and chemiluminescence. Peripheral blood lymphocytes were prepared as outlined in Fig. 1 legend and layered on a five-step discontinuous Percoll (Pharmacia) density gradient[4]. The top layer consisted of 40% Percoll (v/v) diluted in medium and adjusted to 285 mosmol with a refractive index of 1.3432. Each 2-ml layer varied by 2.5% Percoll. The gradient was loaded with 10^8 lymphocytes and centrifuged at 550 g for 30 min at 20 °C. Cell yields were as follows ($\times 10^{-6}$): fraction 1, 13.3; fraction 2, 7.5; fraction 3, 48.4; fraction 4, 24.4; fraction 5, 8.3. Cytolysis was measured in a 4-h ^{51}Cr-release against K562. Values are expressed in lytic units per 10^7 lymphocytes where one lytic unit is the number of lymphocytes required for 20% lysis. To measure chemiluminescence, 10^6 lymphocytes in luminol were stimulated with 10^7 K562 cells as described in Fig. 1 legend. Values represent the c.p.m. above background in the first peak. A similar curve was generated using a calculation based on the area under the entire curve for cells from each Percoll fraction. Unfractionated lymphocytes yielded 240 lytic units per 10^7 cells and 3×10^4 c.p.m. This experiment was repeated five times with similar results.

Note added in proof: Recent experiments reveal partially depressed NK-mediated cytolysis in strictly anaerobic conditions, which confirms an oxygen-dependent component in the cytolytic pathway.

Adenosine-induced slow ionic currents in the *Xenopus* oocyte

Ilana Lotan, Nathan Dascal, Sasson Cohen & Yoram Lass

Department of Physiology and Pharmacology, Sackler School of Medicine, Tel-Aviv University, Ramat-Aviv 69 978, Israel

Adenosine and its 5′-phosphorylated congeners evoke specific membrane-mediated responses in excitable tissues[1,2]. Available data suggest that inhibition of the target cell occurs due to hyperpolarization[3,4], and in some preparations a compound effect of ATP (excitation and inhibition) has been found[5,6]. However, the ionic mechanism of the purinergic-mediated response has not been studied by standard intracellular voltage-clamping techniques. Recently, we have discovered purinergic receptors in the *Xenopus* oocyte, a well defined giant cell amenable to rigorous electrophysiological[7] and biochemical[8] studies. We report here that in these cells, adenosine-induced slow membrane responses consisted of an early depolarizing (D) transient current carried by Cl^- ions, followed by a steady hyperpolarizing (H) current involving K^+ ions. The relative potency sequence for the D current was ATP ≃ ADP > AMP ≃ adenosine; this order was reversed for the H current.

Fully grown oocytes (stages 5 and 6)[9] were dissected from an ovary of *Xenopus laevis*, mounted in a 1-ml Perspex bath and continuously perfused at room temperature with Ringer's solution (mM): Na^+, 116; K^+, 2; Ca^{2+}, 1.8; Cl^-, 128.6; Mg^{2+}, 1; Tris, 5. In a standard experiment the oocyte was impaled with two microelectrodes and the cell was clamped at −50 mV. The cell was then exposed to one of the active compounds and the induced membrane current recorded on a paper chart (YEW 3022).

Typical responses to 4×10^{-5} M adenosine and 4×10^{-5} M ATP are shown in Fig. 1. The basic response consists of an initial 'fast' inward current of 10–30 s duration (D), followed by a long-lasting outward current (H). The relative potency sequence for the H-response was: adenosine ≃ AMP > ADP ≃ ATP, whereas that for the D response was: ATP ≃ ADP > AMP ≃ adenosine. In some preparations, adenosine failed to evoke the D response and the H response was the only current recorded. In these cells, the latency of the H response was 25–40 s, well beyond the 'dead time' of the perfusion system (5–10 s). The latency of the D response was the same as the perfusion 'dead time'.

Voltage–current curves were obtained using a ramp command voltage. The reversal potentials of the D and H responses, measured as described in Fig. 2 legend, were [mean (mV) ± s.e.m. (number of cells)] −21.86 ± 2.34(7) for the D current and −102.7 ± 3.6(7) for the H current. A plot of the D reversal potential as a function of the log external Cl^- concentration showed a strict Nernst relationship (Fig. 3*a*), which suggests

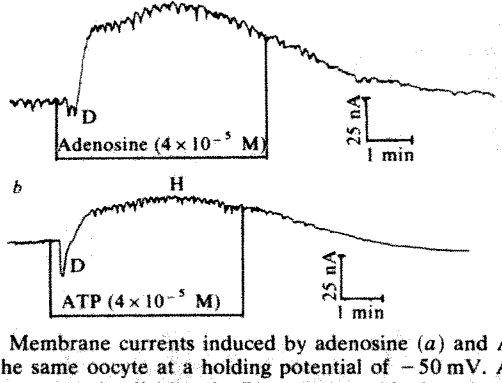

Fig. 1 Membrane currents induced by adenosine (*a*) and ATP (*b*) in the same oocyte at a holding potential of −50 mV. ATP was more potent in eliciting the D response, and adenosine was more potent in eliciting the H response.

0028–0836/82/310572—03$01.00

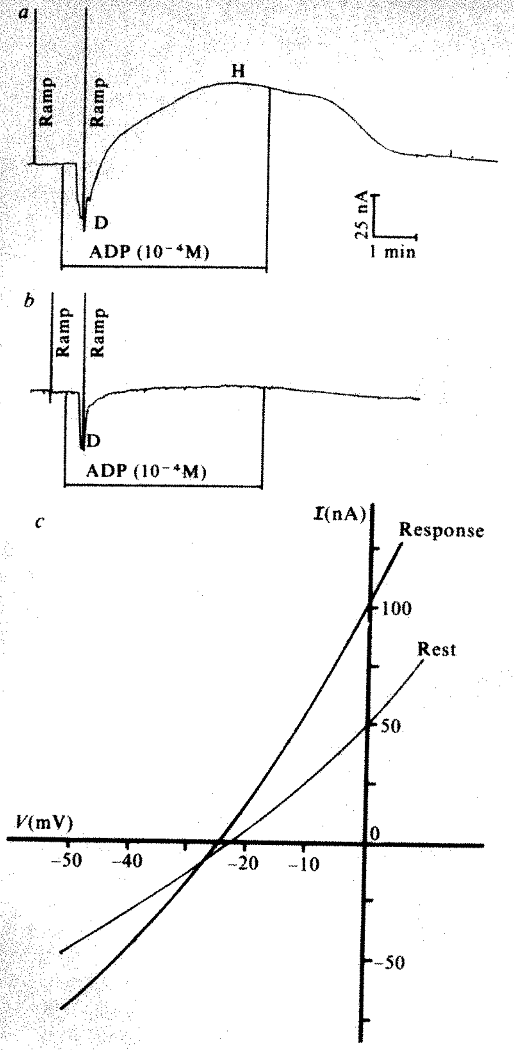

Fig. 2 *a*, Oocyte response to 10^{-4} M ADP at a holding potential of −50 mV. *b*, Blocking of the H current by tetraethylammonium (3×10^{-2} M) in the same cell. Two ramp-like changes of the holding potential (duration 0.8 s) were applied, one just before application of ADP and a second at the plateau of the D current. The voltage electrode was connected to the *x* axis of the *x–y* plotter, the current electrode to the *y* axis, and the voltage–current relationships were plotted automatically (*c*). The reversal potential of the D current was obtained from the cross-over point.

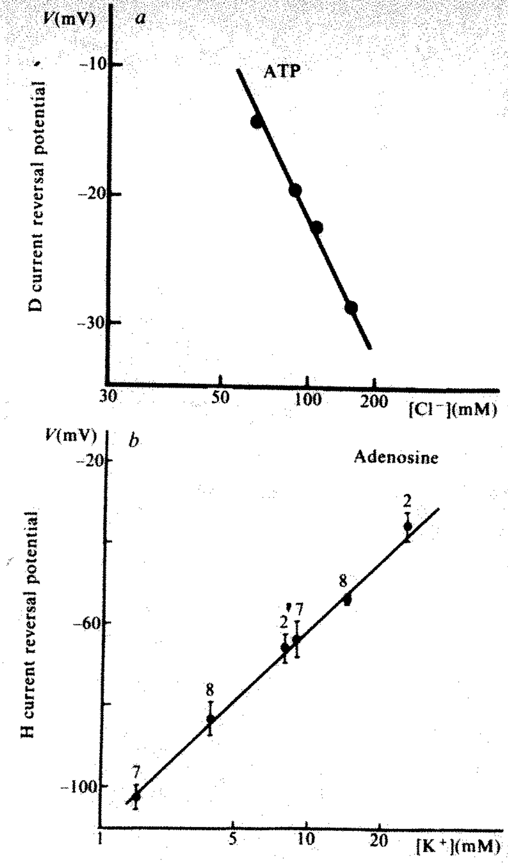

Fig. 3 *a*, Relationship between the D current reversal potential and bath Cl⁻ concentration in the same oocyte. SO_4^{2-} was substituted for Cl⁻ and tonicity was kept constant with sucrose. A strict Nernst relationship was obtained with a slope of 58 mV for a 10-fold change in Cl⁻ concentration. *b*, Reversal potential of the H current plotted against bath K⁺ concentration in several oocytes. KCl was replaced by $MgCl_2$, with the Cl⁻ concentration kept constant, and tonicity balanced by sucrose. In control experiments, increased Mg^{2+} had no effect on the H current reversal potential: again a strict Nernst relationship was obtained.

that the D current is carried by Cl⁻ ions. The involvement of Cl⁻ in mediating the oocyte membrane depolarization has already been postulated[7]. A similar Nernst plot showed that the H current is carried by K⁺ ions (Fig. 3*b*). Moreover, tetraethylammonium (3×10^{-2} M) almost completely abolished the H current (Fig. 2*b*), with no effect on the D current. Based on the measured reversal potential and the Nernst equation, the intracellular concentrations of K⁺ and Cl⁻ were calculated to be (mM) 117.0 and 54.0, respectively. The value for K⁺ correlates well with intracellular [K⁺] measurements (102 ± 2 mM) for *Rana pipiens* oocytes[10].

The spontaneous membrane current fluctuations shown in Fig. 1*a* were observed in ~20% of the cells. The reversal potential of the fluctuations was the same as the D current reversal potential. Thus Cl⁻ may be involved in generating these currents. In most cases, ATP increased the amplitude of the fluctuations (Fig. 1*b*).

The purinergic response was preserved after complete removal of the follicular cells, which normally envelop the oocyte. The follicular cells were removed by shaking for 2.5 h in collagenase (2 mg ml^{-1}, dissolved in Steinberg solution (mM): 58 = Na⁺, 1 = K⁺, 1.8 = Ca²⁺, 69.6 = Cl⁻). The oocyte was then returned to normal Ringer's for 1 h and tested for the presence of purinergic responses. The same cell was fixed, embedded in paraffin, sectioned and stained with haematoxylin-eosin. In eight oocytes examined morphologically, the follicular cells were completely removed but the purinergic response was preserved; the H current, however, was rather reduced.

These results demonstrate a compound membrane response to adenosine, generated by two distinct ionic mechanisms having different relative potency sequences for the purinergic agonists. Further pharmacological characterization of the oocyte purinergic response was achieved using theophylline. Figure 4 shows selective and reversible blocking of the H current by 5×10^{-5} M theophylline. This blocking action was tested in the range 10^{-6} M–10^{-4} M theophylline, and was found to be dose dependent. The D current was augmented, probably due to the removal of the H current, and remained unaffected even at 10^{-4} M theophylline. The reported heterogeneity among

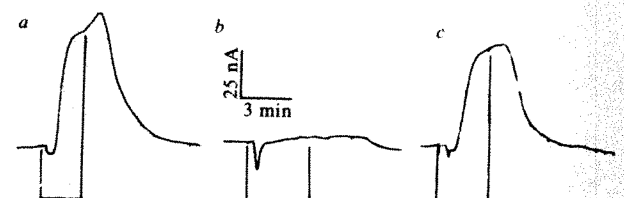

Fig. 4 Selective blocking of the H current by theophylline. *a*, Control response; *b*, a response of the same oocyte after 20 min incubation in 5×10^{-5} M theophylline; *c*, a response of the same oocyte after a 20 min wash period in normal Ringer's.

purinergic receptors[11-14] might represent the biochemical and pharmacological basis of this diversity in electrophysiological response. More specifically, the H current is probably mediated by the P1-receptor type[15].

The oocyte response to adenosine is qualitatively similar to muscarinic cholinergic responses described previously[7,16]. However, the adenosine response was not blocked by atropine (10^{-5} M), which suggests that the various membrane receptors may have the same biochemical mechanism, possibly mediated by cyclic nucleotides[17], for opening 'slow' ionic channels in the oocyte membrane.

Presence of cyclic nucleotide–Ca^{2+} independent protein kinase in bovine brain coated vesicles

A. Pauloin, I. Bernier & P. Jollès

Laboratory of Proteins, University of Paris V, CNRS ER 102 and
INSERM Unité U-116, 45 rue des Saints-Pères,
F75270 Paris Cedex 06, France

Coated vesicles, which are membrane vesicles enclosed by a polyhedral protein lattice, are involved in many cellular events[1-6], including intracellular membrane transport and protein secretion, in which they must be able to undergo repeated membrane fusion and fission. The icosahedral lattice of protein surrounding the core of coated vesicles is composed predominantly of clathrin, a 180,000 (180 K) molecular weight protein, and other 30 K and 36 K polypeptides[7,8]. In native conditions, the basic subunit of the coat consists of a trimer of clathrin with probably three polypeptides of 30K and/or 36K (refs 9–11). Additional minor proteins of 100K and 55K have been reported in purified coated vesicles[12]. We describe here the presence of cyclic nucleotide- and Ca^{2+}-independent protein kinase activity in coated vesicles. This protein kinase phosphorylates specifically a unique 50K protein which can be co-purified with clathrin and seems to be an integral protein of coated vesicles.

Coated vesicles were isolated from fresh bovine brain according to a slightly modified procedure of Keen *et al.*[13] The highly enriched upper 5% sucrose solution of the second gradient was used for the final purification using a self-generated density gradient centrifugation of Percoll (Pharmacia). We verified the homogeneity of this material by submitting samples from the upper and lower opalescent Percoll zones to agarose gel electrophoresis. The lower Percoll fraction corresponds to the more slowly migrating agarose zone which contains smooth vesicles and membrane fragments while the upper Percoll fraction corresponds to the faster migrating agarose zone which contains only coated vesicles and empty coats (see Fig. 1 and ref. 12). Aliquots of coated vesicles obtained after the different purification steps were incubated in presence of [γ-^{32}P]ATP. Figure 2 shows an analysis by SDS-polyacrylamide gel electrophoresis of the radiolabelled and stained proteins.

Many proteins are phosphorylated in the grey matter homogenate but only one 50K phosphoprotein, which is poorly stained by Coomassie blue, can be co-purified with clathrin. The pattern of radioactive proteins indicates that neither clathrin nor the 30–36K polypeptides are phosphorylated. We verified the presence of both the 50K protein substrate and its specific kinase in coated vesicles after agarose gel electrophoresis[12]. Following the electrophoresis, the different supernatants from the centrifuged broken agarose gel fractions (see Fig. 3 legend) were incubated with [γ-^{32}P]ATP. The 50K radiolabelled protein co-purified with clathrin (Fig. 3). Using radiolabelled ATP, a slight phosphorylation of a 100K band could be observed in our experimental conditions, but not after the incubation of coated vesicles just purified by Percoll centrifugation: this unexpected observation is now being investigated. Fig. 3 shows not only the association of the 50K protein substrate with coated vesicles but also that the kinase activity is a constitutive part of the vesicles. Phosphorylation of the 50K protein occurred without cyclic AMP or cyclic GMP in the reaction mixture, and addition of 40 μM cyclic AMP or cyclic GMP did not modify the phosphorylation (Fig. 4, lanes 6, 7).

The presence of calmodulin in coated vesicles[14] and the dependence of the phosphorylation of many proteins on calmodulin and Ca^{2+} have been described. We therefore investigated whether Ca^{2+} and calmodulin had any effect on the *in vitro* phosphorylation of the 50K protein. The addition of 1 mM EGTA or 10 μg exogenous calmodulin or calmodulin inhibitors, such as 1 mM dibucaine[15] or 50 μM trifluoperazine[16], to the reaction mixture had no effect on the 50K polypeptide labelling (Fig. 4, lanes 1–4). Furthermore, the isolation of coated vesicles in Ca^{2+}-depleted MES buffer (see Fig. 2 legend) did not modify the purification of either clathrin or 50K protein, or the phosphorylation of the latter (data not shown). Note that a high concentration of trifluoperazine (400 μM) blocks the phosphorylation of the 50K protein but allows that of the 100K coated vesicles protein (Fig. 4, lane 5). Dibucaine (10 mM) induced the same effect (data not shown).

The 50K phosphoprotein and its kinase are not membrane contaminants or traces of smooth vesicles, as they cannot be eliminated even by agarose gel electrophoresis, which is considered to be the most powerful purification technique. Recently, Pfeffer and Kelly[17] reported further data on minor components of coated vesicles. Using permeation

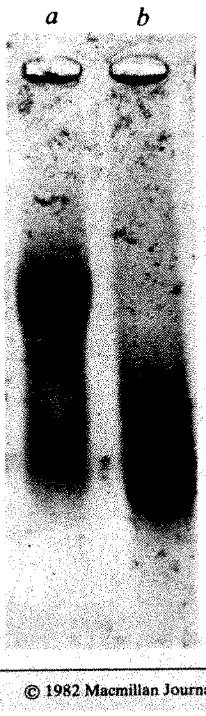

Fig. 1 Coomassie blue-stained 0.15% agarose gel of lower (*a*) and upper (*b*) fractions from Percoll gradient centrifugation.

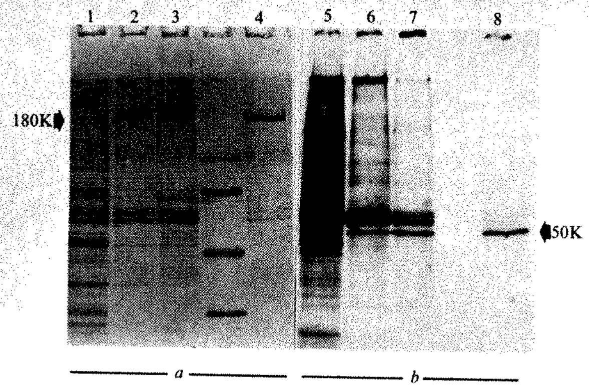

Fig. 2 Comparison of the protein gel patterns after Coomassie blue staining (*a*) and autoradiography (*b*) of the coated vesicles purification steps. The purification procedure was carried out at 4 °C. Bovine brains were cleansed of meninges and the white matter removed by dissection. The grey matter was homogenized in 1 vol of a 2-(*N*-morpholino)ethanesulphonic acid (MES)–Ca^{2+} buffer: 0.1 M MES, *p*H 6.5, 0.1 mM EGTA, 2 mM $MgCl_2$, 1.1 mM $CaCl_2$, 0.2% NaN_3, 50 µg ml^{-1} phenylmethlsulphonyl fluoride (PMSF). The homogenate was centrifuged at 20,000*g* for 30 min in a Sorvall GSA rotor. The resulting pellet was subjected twice to the same procedure. All the supernatants were pooled and centrifuged at 100,000*g* for 1 h in a Beckman 60 Ti rotor. The soluble fraction was removed and the pellet was resuspended in the MES–Ca^{2+} buffer. Coated vesicles were purified by two successive sucrose gradients[13]. The highly enriched upper 5% sucrose solution of the second gradient was used for the final purification using a self-generated density gradient centrifugation of Percoll (Pharmacia). A 2-ml aliquot of the coated vesicle preparation in 5% sucrose was mixed with 3.96 ml Percoll, 0.44 ml 2.5 M sucrose and 15.6 ml 0.25 M sucrose in the MES–Ca^{2+} buffer. After centrifugation at 100,000*g* for 15 min, the upper opalescent zone contained the highly purified coated vesicles. The reaction mixture (15 µl) for phosphorylation tests was made in ice and contained 12 mM Tris-HCl, *p*H 7.5, 32 mM KCl, 2 mM $MgCl_2$, 2.3 mM 2-mercaptoethanol, 0.2 A_{280} aliquots of coated vesicles obtained after various purification steps, 0.1 mM ATP and 10 µCi [γ-^{32}P]ATP. It was incubated for 12 min at 30 °C as previously described[21]. The reaction was stopped by addition of 30 µl SDS-gel electrophoresis sample buffer and the polypeptide composition was analysed by SDS-polyacrylamide gel (5–10%) electrophoresis according to Laemmli[22]. The electrophoresis was carried out at 20 mA for 6 h at constant current until the Bromophenol blue as tracking dye was eluted. Autoradiography was done by exposing the stained gel to Royal X-Omat Kodak film. Lanes 1, 5, grey matter homogenate; 2, 6, middle zone of first sucrose gradient; 3, 7, upper 5% zone of second sucrose gradient; 4, 8, upper opalescent zone of self-generated density gradient of Percoll. The following proteins were run in parallel as molecular weight markers: phosphorylase *b* (94K), bovine serum albumin (67K), ovalbumin (43K) and carbonic anhydrase (30K).

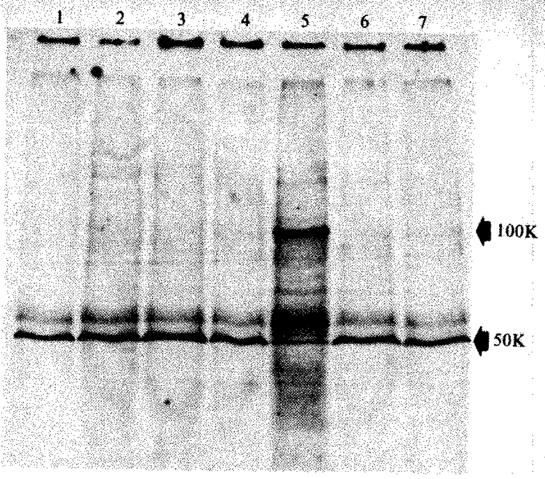

Fig. 4 Effect of cyclic nucleotides and Ca^{2+} inhibitors on the coated vesicle protein ^{32}P-labelling. The following substances were added to the phosphorylation reaction mixture: lane 1, 1 mM EGTA; lane 2, 10 µg calmodulin; 3, 1 mM dibucaine; 4, 50 µM trifluoperazine; 5, 400 µM trifluoperazine; 6, 40 µM cyclic AMP; 7, 40 µM cyclic GMP. Following the incubation, the phosphoproteins were analysed on a 10% SDS-polyacrylamide gel and visualized by autoradiography.

chromatography, they also identified a thin 50K protein band in their highly purified preparations.

Dissociation and reassembly of coat structures seem to be reversible, and both energy[13,18,19] and phosphorylation independent. In comparison, membrane transport, secretion and internalization generally require more complex control. Thus, before internalization, the coated pits act as a molecular filter, selecting some proteins and excluding others. Although the molecular mechanisms remain uncertain, proteins selected to enter the cell are supposed to interact directly or indirectly with clathrin[20]. Such a selection might depend on a phosphorylation step. If the 50K protein is involved in regulation, one or a few molecules per coated vesicle would be sufficient. This would explain its presence in trace amounts in coated vesicles preparations.

This work was supported by INSERM (Unité U-116) and CNRS (ER 102). We thank Dr G. Petrissand and Dr Feure for providing the bovine brains, Professor C. Chany for the use of his laboratory and Dr M. F. Dubois for supplying the [γ-^{32}P]ATP.

Injection of subunits of cyclic AMP-dependent protein kinase into cardiac myocytes modulates Ca^{2+} current

β-Adrenergic stimulation of the heart is thought to increase cardiac muscle contractility by activation of cyclic AMP-dependent protein kinase and concomitant increase in the phosphorylation of certain proteins (for refs see refs 1–6). Electrophysiological studies have shown that the stimulation of cardiac β-adrenoreceptors[7], the external application of cyclic AMP or its analogues to Purkinje fibres[8], or the injection of cyclic AMP into single myocytes[9] can increase the slow inward current (I_{si}) during the plateau phase of the action potential (AP). In heart muscle this current is mainly carried by Ca^{2+} (refs 10, 11) and it has been suggested that cyclic AMP-dependent phosphorylation of some component of the calcium channel increases the amount of Ca^{2+} which enters the cell during depolarization[10]. We have investigated this hypothesis by examining the electrical responses of isolated guinea pig ventricular myocytes to pressure injections of subunits of the cyclic AMP-dependent protein kinase. We report here that injection of the catalytic subunit (C) resulted in a lengthening of the action potential duration (APD) and an increase in the height of the plateau as well as the amplitude of I_{si}. By contrast, the injection of regulatory subunit (R) shortened the APD of fast and slow response APs, an effect which was reversed by adrenaline.

Isolated ventricular cells[12] stimulated at 0.33 Hz through the injection electrode had a resting potential of approximately −80 mV and stable action potentials of 150–300 ms duration. Injection of C prolonged the APD measured at 80% repolarization (APD_{80}) from 130 to 315 ms and increased AP amplitude by about 20 mV without affecting the resting potential (Fig. 1*A*). These changes occurred during the 60 s injection period and were still present 20 min after the cessation of injection pressure (Fig. 1*B*). Visual inspection of the cells revealed that the injection of C also produced a dramatic increase in the force of contraction. After the injection of C the addition of adrenaline (0.5 μM) to the bathing solution had no effect on the AP or force of contraction. The injection of buffer A (see Fig. 1 legend) or of C inactivated by incubation at 60 °C for 30 min had little or no effect on the configuration of the AP. These controls confirm an earlier conclusion that injection-related increases in intracellular volume and pressure have minimal effects on the AP[9]. Thus, it is highly likely that the molecular basis of the changes observed after C injection is quite similar or identical to that found after stimulation of the β-adrenoreceptor by adrenaline[7] or after the intracellular application of cyclic AMP[8,9]. Similar changes of the AP have been observed after C injection into bag cell neurones obtained from the abdominal ganglion of *Aplysia*[13].

The experiments suggested that C altered the AP configuration by increasing the Ca^{2+}-dependent I_{si}. Therefore, I_{si} was determined in cells in which the membrane potential was clamped by current being supplied through a second microelectrode. In five experiments, changes in I_{si} in response to depolarizing clamp pulses were recorded before and after the pressure injection of C through the voltage-sensing electrode. Figure 2*A* shows that the injection of C increased the inward current from 2.2 to 6.0 nA. This increase in current was not reversed when the pressure was terminated but was completely abolished by the addition of the Ca^{2+} channel blocker, D-600 (Fig. 2*B*). The time constant for inactivation of I_{si} was 17 ms before the injection of C, and 15 ms after C injection. The similarity of these time constants suggests that C does not alter the time during which the voltage-dependent Ca^{2+} channel is open. The recording of Fig. 2*A* suggests that injected catalytic subunit slightly increased the outward current.

The present experiments indicate that elevation of the intracellular concentration of free C increases I_{si} during the plateau phase of the AP. As free C is an active phosphotransferase, its injection probably results in enhanced phosphorylation of cytosolic and membrane proteins. Therefore, phosphorylation of certain membrane proteins may be intimately involved in the hormonal regulation of I_{si}. However, the results do not eliminate the possibility that in physiological conditions in the absence of hormones either the phosphorylation of certain membrane proteins is not important for the opening of the Ca^{2+} channel, or these proteins are phosphorylated by a protein kinase other than C. The latter point arises because the injected subunit might phosphorylate proteins usually not accessible to C.

To establish whether C is involved in physiological conditions, we examined the effects of the regulatorys subunit, R. The rationale for this experiment was that, as far as is known, the only function of R is to bind C and thereby inhibit its phosphotransferase activity[6]. The pressure injection of R into isolated ventricular cells decreased the APD_{80} from 240 to 130 ms and the AP amplitude by about 15 mV (Fig. 3*A*). Both decreases were slowly reversed after the termination of injection, suggesting the occurrence of some compensatory regulation, presumably cyclic AMP production. However, a compensation of the inhibitory effects of R on the AP was no longer observed after multiple injections of R. On the other hand, the AP depression produced by R was reversed by the addition of adrenaline (0.1 μM) to the bathing solution. Finally, the injection of heat-inactivated R had no significant effect on the configuration of the AP. It is therefore quite likely that the R-induced depression in the AP was brought about by inhibition of the phosphotransferase activity of free C. To substantiate an effect of R on I_{si}, the resting membrane potential of some cells was decreased to −50 mV by increasing the extracellular K^+ concentration, $[K^+]_O$, to 22 mM (Fig. 3*B*). The fast sodium channel is inactivated in this condition and the upstroke of the AP is mainly carried by I_{si} (slow response AP). In this condition, R injection had the same effect as discussed above.

The data strongly support the hypothesis that injection of catalytic or regulatory subunit of cyclic AMP-dependent protein kinase affects the phosphorylation of one or several proteins and thereby alters Ca^{2+} influx. Changes in the AP and I_{si} caused by the injection of free C are indistinguishable from those produced in ventricular myocytes by extracellular adrenaline[14]

0028-0836/82/310576—03$01.00

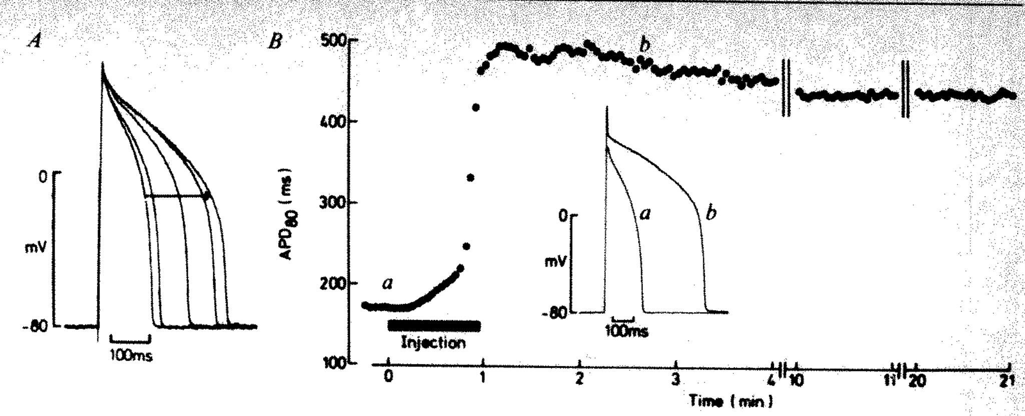

Fig. 1 Injection of the catalytic subunit (C) prolongs the action potential and increases the amplitude. *A*, a microelectrode containing C (9.6 mg ml^{-1}) was impaled into a myocyte and C was injected by pressure (4 bar, for 60s). The injection prolonged the AP from 130 to 315 ms. The arrow indicates the direction of change. *B*, the same procedure as in *A* was used. The injection pressure was gradually increased from 2 to 5 bar during 60 s. Injection of C prolonged the AP from 170 to 490 ms. The inset shows an AP before (*a*) and 1.5 min after (*b*) the injection of C. A different cell from that used in *A* is shown. Cells were isolated from the ventricle of adult guinea pig hearts as described previously[12] and were incubated in Tyrode solution containing 150 mM NaCl, 5.4 mM KCl, 1.8 mM $CaCl_2$, 1 mM $MgCl_2$, 10 mM glucose and 5 mM HEPES, *p*H 7.4. Injection experiments were carried out at 37 °C in a Perspex chamber perfused with the same Tyrode solution. Cells were visualized on a TV screen after 1,000-fold magnification. Glass microelectrodes containing 2 mM HEPES *p*H 7.2, and 150 mM KCl (buffer A) and having a resistance of 100–150 MΩ were used for pacing the cells at 0.33 Hz, recording the membrane potential and pressure injection of proteins or buffer. The volume injected was of the order of 1 pl and that of the cells 30 pl (the injected volume was estimated by measuring the size of the drop released by pressure into oil (×250 magnification)). APD was taken as the time between the beginning of the stimulating current pulse and 80% repolarization, and AP amplitude was measured 30 ms after the stimulating current pulse. Homogeneous preparations of catalytic subunit (C) and cyclic AMP-free regulatory subunits (R) of cyclic AMP-dependent protein kinase II were prepared from fresh bovine heart muscle as described earlier[17,18]. Proteins used for injection were chromatographed on a Biogel-P6 column (2.5 × 9 cm) equilibrated in buffer A. Fractions containing protein were pooled and concentrated by vacuum dialysis against buffer A at 4 °C. Dialysis was continued after the concentration step for at least 18 h with several changes of buffer. Thereafter, denatured protein was removed by centrifugation and the clear supernatant containing active subunits at a concentration of 5–10 mg ml^{-1} was stored in aliquots at 4 °C. For control experiments aliquots of the dialysis buffer were always used. The purity of all proteins used was better than 95%. During this investigation, we used five and three different preparations of C and R (free of cyclic AMP), respectively. No apparent differences between these preparations were observed.

or intracellular cyclic AMP[9], suggesting that all three agents affect the AP by the same basic mechanism. This is not surprising because each agent increases the intracellular concentration of the active species of cyclic AMP-dependent protein kinase. A previously proposed mechanism for the enhancement of I_{si} is that adrenaline and cyclic AMP increase the number of Ca^{2+} channels which are opened by depolarization[10]. Some evidence has been obtained (see Fig. 3) that in the absence of hormone, C is involved in the regulation of I_{si}, although a complete suppression of the plateau phase of the AP by injection of free R has not been observed. This might suggest that cyclic AMP-dependent phosphorylation of membrane proteins is not an absolute requirement for the ability of Ca^{2+} channels to open on depolarization. However, the data do not rule out the possibility that in the absence of hormone, cyclic AMP-dependent phosphorylation of some membrane protein(s) occurs and that this covalent modification is a necessary condition for depolarization-activated Ca^{2+} channels. The data are also compatible with the existence of two types of Ca^{2+} channel or with two states of one Ca^{2+} channel. One type or state would allow voltage-dependent Ca^{2+} influx in the absence of protein phosphorylation, while the other would allow this only after phosphorylation of a specific membrane protein.

The positive inotropic effect of adrenaline, injected cyclic AMP or C on the heart is at least partially mediated through

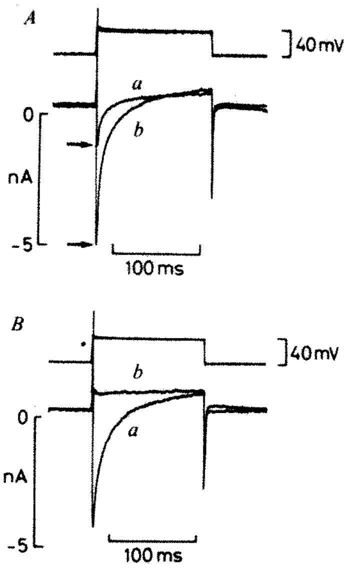

Fig. 2 *A*, injection of C increases I_{si}. Two microelectrodes, one containing C (16 mg ml^{-1}) and a second containing 2 M KCl (20–30 MΩ resistance), were impaled in a single cell for voltage clamp. Depolarizing clamp pulses from −50 mV (holding potential) to −10 mV were applied continuously at a rate of 0.33 Hz throughout the experiment. Superimposed potential (top) and current (bottom) traces before (*a*) and after (*b*) the injection of C (3 bar; 30 s) are shown. Arrows indicate peak I_{si} which was increased from 2.2 to 6.0 nA. The peak amplitude of I_{si} was measured as the difference between peak inward current and the current amplitude 100 ms after the pulse. *B*, the calcium channel blocker D-600 (10 μM) abolishes the effect of injected C on I_{si}. The same procedure as in *A* was applied to a different cell. The injection of C (9.6 mg ml^{-1}) into the cell resulted in a large I_{si} (*a*) which was blocked within 60 s by the addition of D-600 to the bathing solution (*b*). For further details see Fig. 1 legend.

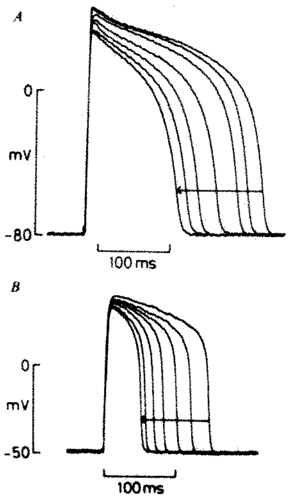

Fig. 3 Injection of the regulatory subunit (R) shortens the action potential. *A*, injection of cyclic AMP-free R (0.1 mg ml^{-1}) at 3 bar for 30 s shortened the AP_{80} within 30 s from 240 to 130 ms. The arrow indicates the direction of change. *B*, in a different cell slow response APs were recorded after increasing extracellular KCl to 22 mM. Injection of R (0.1 mg ml^{-1}) at 5 bar for 15 s shortened the AP from 150 to 50 ms. The control AP and successive APs during the injection are shown. The arrow indicates the direction of change. The upstrokes of APs are blurred by the stimulation artefact. For further details see Fig. 1 legend.

their effect on the slow Ca^{2+} channel. It can be estimated from the data of Fig. 2 that I_{si} measured after C injection amounts maximally to 1.3×10^{-16} mol of Ca^{2+} entering the cell during each depolarization. Taking into account an average total cell volume of 30 pl and a cytosolic space of ~50% of the total cell volume, this indicates that the intracellular Ca^{2+} concentration was elevated by 1.3 μM during depolarization. This crude estimation could indicate that more than just the trigger calcium enters isolated cells through maximally phosphorylated Ca^{2+} channels.

The nature and localization of the proteins phosphorylated by injected C have not been determined. Studies in intact hearts stimulated by adrenaline indicate a rapid phosphorylation of a sarcolemmal protein of molecular weight 27,000 (ref. 15). Several groups have shown that a 22,000 or 11,000 molecular weight peptide is phosphorylated by an endogenous cyclic AMP-dependent protein kinase in purified sarcolemmal membranes[1,3,4]. In addition, some evidence has been obtained that *in vitro* phosphorylation of this peptide is associated with an increased Ca^{2+} uptake by sarcolemmal vesicles[16]. Thus, there is a growing body of evidence supporting the concept that cyclic AMP-dependent protein kinase and phosphorylation of distinct membrane proteins are intimately involved in the regulation of I_{si} of myocardial cells.

The DNase I sensitivity of *Xenopus laevis* genes transcribed by RNA polymerase III

J. Coveney & H. R. Woodland

Department of Biological Sciences, University of Warwick,
Coventry CV4 7AL, UK

Since the initial discovery that the DNase I sensitivity of the globin genes in different cell types correlates with globin gene expression[1], this relationship has been shown to hold true for a variety of genes, including the genes for ovalbumin[2], conalbumin[3], α- and β-globin in chicken[4,5], several heat-shock proteins in *Drosophila*[6,7], the r-chromatin of *Tetrahymena*[8] and the viral polyoma minichromosome[9]. Although genes transcribed by RNA polymerases I and II have been studied extensively, the genes transcribed by RNA polymerase III have not. We have therefore investigated the DNase I sensitivity of transfer RNA (tRNA) and oogenetic 5S RNA genes in the liver and erythocyte nuclei of *Xenopus laevis*. The oogenetic 5S genes are not transcribed in any known somatic cell[10,11], and tRNA genes are transcribed in the hepatocyte but are inactive in the erythrocyte. We show here that, although in these two cell types the correspondence between DNase I sensitivity and gene transcription holds good for globin and the ribosomal genes, the tRNA and oogenetic 5S genes are DNase I sensitive in both liver and erythrocyte nuclei. Thus for the genes transcribed by polymerase III the correspondence of sensitivity and expression breaks down.

There are two types of 5S ribosomal gene in *X. laevis*: oocyte specific ($5S_{ooc}$) and somatic ($5S_{som}$)[10,11]. The $5S_{ooc}$ genes are a family of about 20,000 genes per haploid genome[12], interspersed with an equal number of 5S pseudogenes, representing residues 1–101 of the normal 120 bp gene[13]. Transcripts of the pseudogene *in vivo* have never been detected, but their occurrence remains a possibility[14]. The $5S_{ooc}$ genes are transcribed exclusively during oogenesis, whilst in other cells it is the $5S_{som}$ genes (of which there are fewer, about 400)[15] which are used[10,11]. This number is far too small for the somatic genes to be detected by the straightforward hybridization experiments described here. A rough calculation of gene number from Fig. 1*a* (11,000–21,000 copies of the gene per pseudogene repeat per haploid genome, depending on the amount of vector sequences involved in the hybridization) confirms that, in effect, we measure only $5S_{ooc}$ genes in these hybridizations. Figure 1*a* and Table 1 show that the $5S_{ooc}$ genes are sensitive to DNase I in both liver and erythrocyte nuclei. No 5S genes are transcribed in erythrocytes, which have lost all RNA polymerase III molecules during maturation[16], nor are the $5S_{ooc}$ genes believed to be transcribed in hepatocytes[17]. In the latter cells, the $5S_{som}$ genes should provide all the 5S RNA. These genes are hidden by the 50 times more numerous $5S_{ooc}$ genes.

Equally surprising is the finding (Fig. 1*b*) that certain of the tRNA genes, which are transcribed in the hepatocyte but not in the erythrocyte, are equally sensitive in both types of nucleus. The probe used contains two $tRNA^{Met}$ genes and one each of the tRNAs accepting phenylalanine, tryosine, asparagine, alanine, leucine and lysine[18]. The complete 3.18 kilobase (kb) unit is repeated about 100 times per haploid genome[19]. The probe probably reveals all of these tRNA species present in the genome, but some of them may be pseudogenes and never expressed. Even if this were the case, it would not alter the conclusion that these tRNA genes are hypersensitive to DNase I, even when they are not expressed.

Thus in blood and liver cells, many, and perhaps all, genes transcribed by polymerase III seem to be DNase I sensitive, regardless of their transcriptional activity. Maternal $5S_{ooc}$ genes have not been active since oogenesis, a period of at least 2 yr. In the case of the paternal $5S_{ooc}$ genes, it is not known whether they were even active during gametogenesis, but this seems unlikely as the accumulation of vast numbers of ribosomes, transcribed in part from the $5S_{ooc}$ genes, which is a feature of oogenesis, does not occur during spermatogenesis. Thus this half of the $5S_{ooc}$ gene complement may have been inactive for as much as 4 yr (two life cycles).

Table 1 Degree of hybridization of various probes to DNase I-digested erythrocyte and liver nuclei as a percentage of binding to undigested DNA

	% Probe binding			
		Ribosomal		
DNA	$5S_{ooc}$	tRNA	DNA	Globin
Total, undigested	100	100	100	100
Erthrocyte nuclei;				
5% DNase I digestion	34.9	51.0	100	42.5
Liver;				
5% DNase I digestion	39.5	47.8	54.5	100

The data are calculated from the experiments shown in Figs 1 and 2. The saturation values were calculated by fitting straight lines to double reciprocal plots using linear regression by least squares.

0028-0836/82/310578—03$01.00

It might be suspected that these results reflect an artefact in the preparation and digestion of the nuclei, and therefore that many other genes would also show unexpectedly high nuclease sensitivity. However, measurement of the concentrations of several other genes in the same DNA samples yielded the predicted results. For example, ribosomal genes are not transcribed in erythrocytes[16], nor is RNA polymerase I present in their nuclei, but the opposite is true of liver. As expected the ribosomal DNA from liver was more sensitive to DNase I digestion than bulk DNA, but equally resistant in erythrocytes (Fig. 2*a*). Globin genes are active in the immature erythrocyte of *Xenopus*, but not in the adult cell. The latter, however, contains RNA polymerase II molecules tightly bound to the chromatin[16] and in avian erthrocytes the frozen polymerases are to be found on the globin genes[20]. In this sense the globin genes could be regarded as 'active genes', which correlates with the observation that in avian erthrocytes, globin sequences are preferentially digested by DNase I[1,4,5]. The same is the case in human erythrocytes (Fig. 2*b*), but not hepatocytes, which do not synthesize globin. Our results confirm those of others[1-7], and show that the crude approach of DNase I solubilization is capable of detecting different DNase I sensitivity in genes active in one cell type and inactive in another.

The results of Figs 1 and 2 show a single time point of digestion and leave open the posibility that the inactive tRNA or 5S genes show different kinetics of digestion from active genes. Figure 3 shows that this is not the case; in fact, $5S_{ooc}$ genes demonstrate even greater sensitivity to DNase I than do the active ribosomal genes of liver.

It has been argued[1,21] that any gene that has been transcribed at a given stage of the life cycle of an organism remains DNase I sensitive, even if the gene becomes inactive later. This argument could be used to explain the sensitivity of the tRNA genes in the erythrocyte nuclei. It is harder, however, to sustain this argument in the case of the $5S_{ooc}$ genes, which show a similar DNase I sensitivity. It would mean that any gene active in oocytes (and this would probably amount to ~15% of the DNA[22]) would always be in the sensitive state, even when it passed through the male for one or more generations (as 50% of the $5S_{ooc}$ genes have done). The insensitivity of ribosomal genes in the erythrocyte nuclei is also inconsistent with this idea, since these genes must have been active in erythroblasts. It seems more likely that the genes transcribed by RNA polymerase III have a different structure from other genes, at least in their inactive state, with the result that they are always DNase I sensitive. The difference might simply relate to their very small size and tandem repetition. Several RNA polymerase

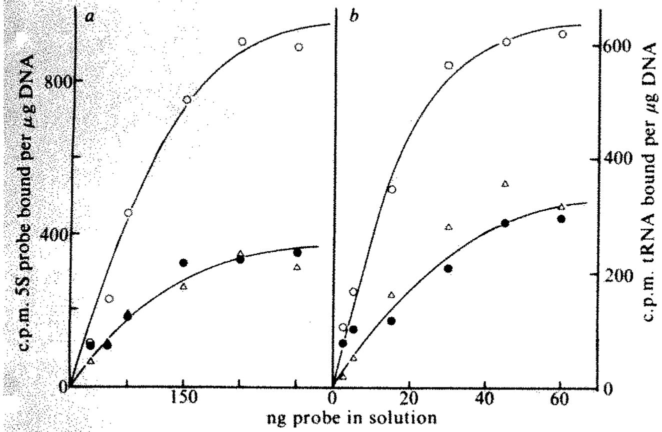

Fig. 1 DNase I sensitivity of 5S (*a*) and tRNA (*b*) genes in erythrocyte and liver nuclei. Erythrocyte nuclei were prepared according to the method of ref. 26 and the liver nuclei by the method of Scribler and Weber[27]. Nuclei from the two tissues were digested with pancreatic DNase I (20 μg ml^{-1}) for 5 min, which is sufficient to release 5–10% of the DNA from the nuclei. The nuclei were pelleted by centrifugation for a few seconds in an Eppendorf microfuge and their DNA extracted according to the method of Weintraub and Groudine[1]. The alkali-denatured DNA was loaded onto nitrocellulose filters[28] and hybridized with nick-translated recombinant DNA[29] containing the relevant gene sequences. This procedure will not detect a hypersensitive site[30] in the way that a blot-transfer hybridization of electrophoresed DNA would, but it gives a more quantitative assay of the DNase I sensitivity of the genes as a whole[5]. The $5S_{ooc}$ probe used was pXlo31 which contains a single repeat of the 5S gene plus a pseudogene[31]. It was labelled with ^{3}H-dCTP to a specific activity of 5.5×10^5 c.p.m. μg^{-1}. The tRNA probe used was λt210, which contains two copies of tRNA$_1^{Met}$ and one copy each of tRNA^{Phe}, tRNA^{Leu}, tRNA^{Lys}, tRNA^{Asp}, tRNA^{Ala} and tRNA^{Tyr} (refs 18, 19) it was labelled with ^{3}H-dCTP to a specific activity of 3.9×10^6 c.p.m. μg^{-1}. Undigested liver DNA gave a result identical to that for erythrocyte, so the data are not shown. ○, Undigested erythrocyte DNA; △, digested erythrocyte DNA; ●, digested liver DNA.

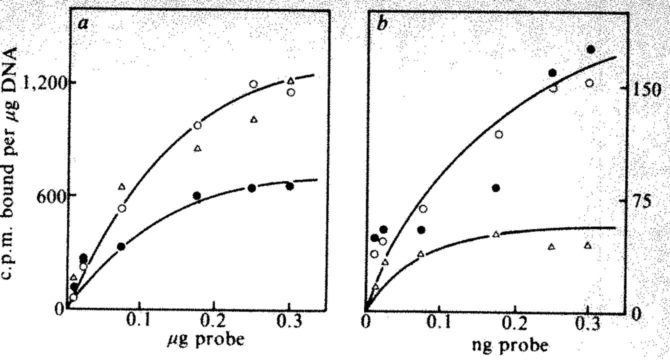

Fig. 2 DNase I sensitivity of ribosomal RNA (*a*) and globin (*b*) genes in erythrocyte and liver nuclei. The DNA samples and procedures were as for Fig. 1. The ribosomal probe used was pXlr101, constructed by Dr R. Reeder; it contains a complete repeat of the 40S precursor plus non-transcribed spacer. It was nick-translated with ^{3}H-dCTP to 2.2×10^5 c.p.m. μg^{-1}. The globin probe was labelled with ^{32}P-dGTP to 1.1×10^7 c.p.m. μg^{-1}. It was a gift from Dr R. W. Old, and contains an~300 bp sequence complementary to a globin mRNA. ○, Undigested erythrocyte DNA (liver gave identical results); △, DNase I-digested erythrocyte DNA; ●, DNase I-digested liver DNA.

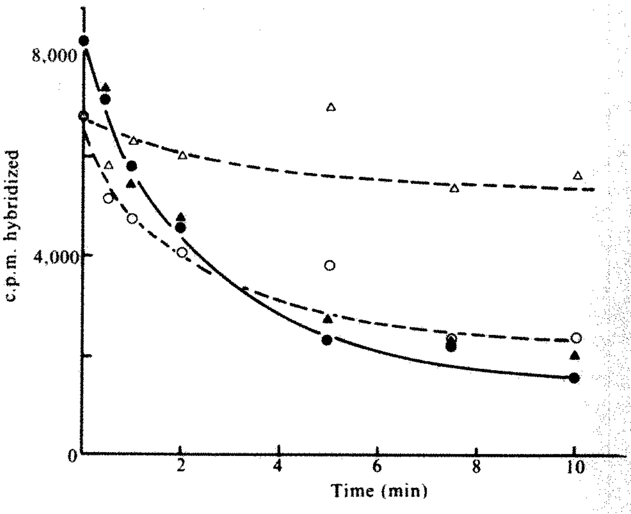

Fig. 3 Time course of DNase I digestion. Erythrocyte and liver nuclei were digested with 20 μg ml^{-1} DNase I for increasing periods of time, the reaction was stopped by the addition of SDS and EDTA to a final concentration of 0.5% SDS, 12.5 mM EDTA, and the DNA extracted as previously described. One μg DNA from each time point was loaded onto duplicate nitrocellulose filters, which were hybridized in a final volume of 200 μl with either 250 ng ^{32}P-pXlr101 or 200 ng ^{32}P-pXlo8 for 24 h before washing and counting. pXlr101 and pXlo8 were labelled with ^{32}P-dCTP to a specific activity of 5.6×10^7 and 3.6×10^7 c.p.m. μg^{-1} respectively; pXlo8 contains three copies of the gene–pseudogene 5S repeat[32]. Further details are given in Fig. 1 legend. Erythrocyte ribosomal genes; ○, liver ribosomal genes; ▲, erythrocyte 5S genes; ●, liver 5S genes.

II-transcribed genes have been shown to be associated with sites hypersensitive to DNase I[3,6,7,23] and for some genes these sites are always sensitive, regardless of the activity of the genes[6]. For genes in which small units are tandemly repeated this might be a serious problem. We have therefore examined the $5S_{ooc}$ repeat unit by digesting the DNA samples of Fig. 3 with the restriction enzyme *Hin*dIII, running the digested DNAs on agarose gels, transferring them to nitrocellulose and probing with pXlo31. *Hin*dIII cuts once within the $5S_{ooc}$ gene/pseudogene repeat, yielding a 700 bp fragment. If a hypersensitive site were present it would act like another restriction site, giving a defined fragment or fragments smaller than 700 bp. The 700 bp repeat disappeared with the expected kinetics and without revealing discrete smaller fragments (data not shown). Thus it does not seem that our results can be explained by the presence of specific hypersensitive sites. Another possible explanation of the $5S_{ooc}$ sensitivity is that the location of these genes at the telomeres of several chromosomes[24] confers special nuclease sensitivity on them. This possibility could be tested by studying a species, such as *Rana temporaria*, in which the 5S genes are not telomeric[25]. In any case, the tRNA repeat studied here does not have a telomeric location. (See G. Fostel, M. L. Pardue and S. G. Clarkson, quoted in ref. 18.) Whatever the reason for the phenomenon, it appears that ready DNase I solubilization cannot be used as an indication of activity in genes transcribed by polymerase III.

Is avian adeno-associated virus an endogenous virus of chicken cells?

G. J. Dawson*, V. J. Yates, P. W. Chang & J. J. Oprandy

Department of Animal and Veterinary Science,
University of Rhode Island, Kingston, Rhode Island 02881, USA

The adeno-associated viruses (AAV) are defective parvoviruses which produce infective progeny only in cells co-infected with a 'helper' adenovirus (Ad)[1]. Both human and simian AAV have been recovered from human and simian primary cell cultures following their inoculation with 'AAV-free' Ad. Whereas some studies have suggested that AAV exists in a latent state in these cells[2,3], others have indicated that the AAV genome is capable of establishing and maintaining a latent state in defined laboratory conditions[4–7] which mimic the situation proposed for the 'latent' AAV recovered from human and simian tissues. Here, avian adeno-associated virus (AAAV) was consistently recovered from limiting dilutions of purified and unpurified avian Ad stocks propagated in embryonating chicken eggs derived from two independently raised flocks of White Leghorn (WL) chickens but not when these Ad stocks were propagated in duck cells. These observations suggest that AAAV is a latent endogenous virus of at least some flocks of WL chickens.

Infectious AAV has been vertically transmitted *in utero* in both naturally occurring and experimentally induced infections of hens[8,9] and in experimentally infected mice[10]. An advantage of using chickens for virological studies is the availability of specific -pathogen-free (SPF) embryonating eggs derived from WL chickens which had not been exposed to avian Ad or to AAAV. By using SPF embryos, the possibility of an *in utero* infection with either infectious Ad or AAAV was eliminated. Antibodies to avian Ad or AAAV were not detected either in the SPF chickens during serological surveys conducted by the producer or in the yolks of SPF embryos we tested using the virus neutralization test and the enzyme-linked immunosorbent assay[8,11]. (We had previously demonstrated that yolk antibody levels to avian Ad and AAAV were similiar or identical to those present in hens experimentally infected with these viruses[11].)

Two avian Ad strains, CELO virus (serotype 1) and Irish strain 506 (serotype 4), were treated with antiserum to AAAV and inoculated in chicken embryo kidney (CEK) cells prepared from SPF embryos. Various dilutions of the cell lysate were inoculated into sets of 10-day-old embryonating eggs. The allantoamniotic fluids were collected and tested for AAAV as described in Table 1. legend. AAAV was detected in all inoculated eggs by the second passage, even though these Ad stocks were pretreated with AAAV antiserum of high titre. Because our antiserum may not have neutralized all of the AAAV, the CELO virus stock was purified as indicated (Table 1, experiment 2). Three successive isopycnic centrifugations were performed[12,13] to separate possible contaminating AAAV (buoyant density 1.38 and 1.42 g cm^{-3}) from CELO virus (buoyant density 1.34 g cm^{-3}). AAAV was not detected when this purifed stock was examined by electron microscopy. Two thousand CELO virus particles were counted without detecting a single AAAV particle. However, AAAV was detected in all embryos infected with purified CELO virus (Table 1, experiment 2). In some cases, the allantoamniotic fluids of eggs inoculated with higher dilutions of CELO virus (for example, eggs inoculated with a 10^{-9} dilution of CELO virus) had Ad antigens but not AAAV antigens until the second passage. These results suggested that several cycles of viral replication are needed to produce enough AAAV to be detected by the agar gel precipitation test. Similar results were obtained when the above experiment was repeated using embryonating eggs from a second flock of WL hens housed in isolation at the University of Rhode Island Experimental Farm.

Our findings were of great concern because the usual means of assaying AAAV involved inoculating embryonating eggs with CELO virus and various dilutions of AAAV. In previous studies the incubation period was limited to 96 h when the CELO virus inoculum was 10^4 plaque-forming units (PFU) per ml. AAAV was only detected when added to this system; eggs inoculated with CELO virus alone did not produce detectable AAAV antigens. In the present study, AAAV was invariably produced in embryonating eggs when either the incubation time

Table 1 The detection of AAAV in Ad stock virus

Avian Ad	Virus dilution	Detection of AAAV (no. positive/total eggs tested)		Detection of avian Ad (no. of positive/ total eggs tested)	
		First passage	Second passage	First passage	Second passage
Expt 1					
Irish strain 506 (serotype 4)	10^{-6}	2/3	3/3	3/3	3/3
	10^{-7}	1/2	2/2	2/2	2/2
	10^{-8}	0/3	3/3	2/3	3/3
	10^{-9}	1/4	2/4	2/4	2/4
	10^{-10}	0/4	0/4	0/4	0/4
CELO virus (serotype 1)	10^{-6}	3/4	4/4	4/4	4/4
	10^{-7}	2/3	3/3	2/3	3/3
	10^{-8}	1/3	3/3	1/3	3/3
	10^{-9}	0/3	1/3	0/3	1/3
	10^{-10}	0/4	0/4	0/4	0/4
Expt 2					
Purified CELO virus (serotype 1)	10^{-6}	4/6	6/6	6/6	6/6
	10^{-7}	2/4	4/4	4/4	4/4
	10^{-8}	1/3	3/3	3/3	3/3
	10^{-9}	0/4	4/4	4/4	4/4
	10^{-10}	0/3	3/3	2/3	3/3
	10^{-11}	0/4	2/4	1/4	2/4
	10^{-12}	0/4	0/4	0/4	0/4

In experiment 1, Ad stocks were mixed with an equal volume of 1:10 dilution of hyperimmune rabbit antiserum to avian AAV for 30 min before inoculating monolayers of CEK cells made from SPF embryos. (Rabbit hyperimmune serum to AAAV, prepared as described elsewhere[13], had a neutralizing titre of 1:2,560 when 250 ID_{50} AAAV was used as the challenge virus.) After an adsorption period of 1 h, the supernatant fluid was decanted and the cell sheet was rinsed three times with sterile phosphate-buffered saline (PBS). At 72 h post-infection, the tissue culture fluid was clarified, diluted in sterile PBS and inoculated into the chorioallantoic sac of 10-day-old SPF embryonating eggs. At 120–144 h post-infection the allantoamniotic fluids were collected, concentrated with polyethylene glycol and tested for AAAV and Ad antigens using the agar gel precipitation test performed as previously described[8]. Second passages were performed by inoculating SPF 10-day-old embryonating eggs with 0.1 ml allantoamniotic fluids from the first passage and testing for viral antigens by the agar gel precipitation test at 96 h post-infection. In experiment 2, the CELO viral stock was purified by performing three successive isopycnic density gradient centrifugations; in each case viral suspensions were centrifuged at 45,000 r.p.m. (210,000*g*) for 22 h. Discrete CELO viral bands of buoyant density 1.34 g cm^{-3} were collected after each centrifugation and tested for avian Ad and AAAV as described above.

Table 2 Detection of AAAV in chicken and duck embryos

Inoculum	Virus propagation system	Presence of AAAV (no. positive/total no. tested)
Ad*	Duck eggs	0/6
Ad + AAAV*	Duck eggs	5/5
AV	Chicken eggs	5/5
Ad + AAAV	Chicken eggs	5/5

Viruses were propagated in DEK cells for two passages and inoculated into either duck or chicken 10–11-day old embryonating eggs. The AAF from these inoculated eggs were collected at 120 h post-infection and tested for AAAV using the agar gel precipitation test[8].

* Ad = 10^5 ID_{50} units of purified CELO virus were used as inoculant. AAAV = 10^5 ID_{50} units of purified avian adeno-associated virus were used as inoculant.

was extended to 120–168 h or when collected material was passaged in a second set of eggs.

To provide further evidence that AAAV was not present as discrete virions in the purified CELO virus stock, 10^5 50% infectious doses (ID_{50}) CELO virus were grown in duck embryo kidney (DEK) cells and then passaged twice in embryonating duck eggs before being tested for AAAV. If AAAV were present as discrete virions in limiting dilutions of the purified CELO virus stock, a dose of 10^5 CELO virus would also contain at least 10^5 ID_{50} AAAV. AAAV was not detected in duck eggs inoculated with purified CELO virus stock before being propagated in DEK cells (Table 2). Therefore, duck cells can support the growth of both viruses, but AAAV was only detected when added to the inoculum.

We tentatively conclude that AAAV did not have its source in the CELO virus stock but rather may be present in these chicken cells as an endogenous virus.

If AAAV is latent in chicken embryos, it is likely that all Ad propagated in chicken cells would eventually become contaminated with AAAV. It was previously reported that AAAV was detected in 6 of the 11 Ad strains which had been propagated in CEK cells[14]. (The origin of these viral stocks has been described in this report.) The Ad strains had been purified by isopycnic density gradient centrifugation and fractions with a buoyant density of 1.34 g cm^{-3} were examined by electron microscopy. Recently, this experiment was repeated, and fractions with densities of 1.38 and 1.42 g cm^{-3} were examined. AAAV was found in four of the five Ad strains (CELO, 506, 685 and AP-1) previously reported negative. The other Ad strain was not available.

We have previously reported that individual plaques (clones) of CELO virus propagated in SPF CEK cells produced AAAV when inoculated into embryonating eggs (Table 3)[15]. As the CELO virus stock was diluted to contain 100 PFU ml^{-1} and then treated with a 1:10 dilution of rabbit anti-AAAV antiserum, our results provide additional evidence that AAAV may be endogenous to chicken cells.

The concept of vertically transmitted latent AAAV is further supported, though indirectly, by field studies, Avian Ad infections in the field are commonly accompanied by AAAV[16]. In fact, antibodies to AAAV so commonly precede detectable antibody to Ad during field infections that we have suggested rapid screening for precipitating antibodies to AAAV as a reliable means of detecting avian Ad infections[16].

A second possible explanation of our findings is that the information for AAAV is contained in the Ad virion either as separate DNA strands or as a hybrid with Ad DNA. There are no available data to support this hypothesis but it is an interesting possibility especially when one considers that the CELO virus genome is several million daltons larger than Ads of man or ducks[17].

Several studies have shown that AAV can enhance or inhibit Ad replication *in vitro* and modify Ad pathogenicity *in vivo*[18–23]. Our present study raises questions as to the role of

Table 3 The detection of endogenous AAAV in the embryonating eggs of a specific-pathogen flock of hens following the inoculation of eggs with single clones of CELO virus.

Clone no. (plaque no.)	Detection of AAAV* (no. positive/total tested)		Detection of avian adenoviral antigen* (no. positive/total tested)	
	First passage	Second passage†	First passage	Second passage
1	1/4	4/4	4/4	4/4
2	2/4	4/4	4/4	4/4
3	0/3	3/3	2/3	3/3
4	1/3	3/3	3/3	3/3

Individual plaques were picked from a monolayer of CEK cells prepared from SPF chicken embryos infected with 100 PFU CELO virus. The inoculum was reacted with rabbit antiserum to AAAV for 30 min before infecting the cells. After an absorption period of 1 h at 37 °C, the cell sheet was washed with PBS before adding nutritive agar.

* Individual plaques were crushed and dissolved in 2 ml PBS; then 0.2 ml of this virus suspension was inoculated into 10-day-old embryonating eggs from SPF chickens. The allantoamniotic fluid was collected at 120 h post-infection and tested for avian adenoviral antigen using the agar gel precipitation test.

† 0.1 ml concentrated amnioallantoic fluid from the first passage was inoculated into 10-day-old embryonating eggs; the fluid was collected at 96 h postinfection and tested for viral antigens using the agar gel precipitation test.

a possible endogenous virus in modifying the pathogenicity of a second virus.

Our preliminary results suggest that AAAV may be transmitted in the germ line of chicken cells, This is the first report indicating that a DNA virus can be transmitted in this fashion. Further studies should provide interesting data as to whether AAAV is endogenous in WL and other strains of chickens. It would also be valuable to determine if the AAV of other animals are carried as endogenous viruses.

Evolutionary selection for perfect hairpin structures in viral DNAs

Uwe R. Müller* & Walter M. Fitch†

Several recent discoveries[1] have pointed to nucleic acid secondary structure as an additional dimension in gene expression[2]. Further evidence for the formation of hairpins in RNA is the fact that cruciforms exist in negatively supercoiled DNAs[3–5]. As potential binding sites for proteins, these structures have been proposed to play a part in the regulation of various crucial reactions, such as replication[6,7], transcription[8], or RNA processing[9]. As any random nucleotide sequence can self-anneal with an approximately 50% chance of forming some Watson–Crick-type base pairs[10], it is difficult to assess which, if any, of all possible hairpin-like secondary structures may be biologically relevant. We have computed the expected distribution of perfectly base-paired structures as a function of loop size and stem length and compared it with the distribution observed in the complete genome of eight DNA viruses from animals, plants and bacteria. We report here that hairpins having six or more consecutive base pairs in the stem are not distributed randomly along the genome, occur much more often than chance would predict, and are particularly over-represented in regions that appear to have regulatory significance. The average loop size was found to decrease with an increase in stem length. These results support our previous hypothesis that these structures are biologically relevant[11].

The sequenced genomes of bacteriophages ΦX174 (ref. 12), G4 (ref. 13) and fd (ref. 14) and of the eukaryotic viruses simian virus 40 (SV40)[15] and polyoma[16] were searched by computer for invert repeat DNA sequences, which can form hairpin (or cruciform)[2]-like secondary structures. The search was restricted to those hairpins with perfectly base-paired stems (no G–T pairing, no interruptions) and loop sizes of at least 3 but not more than 20 nucleotides. Occurring naturally in a circular form, these genomes were aligned for comparison according to functional similarities among their genetic maps. The start codon of the first gene following the structural gene block was used as a cleavage point for the icosahedral viruses (SV40, polyoma, ΦX174 and G4) and the linearized genomes were plotted on a per cent scale (Fig. 1). In this alignment the leftward 40–45% of each genome contains all the non-structural genes, while the remainder carries all the structural genes and intercistronic regions[2]. The genome of filamentous phage fd was linearized beginning with the start codon of gene II, the product of which (an endonuclease)[17] is functionally homologous to the G4 and ΦX174 gene A products[18]. In this arrangement the largest intercistronic region containing the origin of replication[19] occupies the right end of the genome and aligns with the largest intercistronic regions of SV40 and polyoma, which also contain the replication origins[15,16].

The positions of potential hairpins plotted on these genetic maps, revealed a remarkable similarity in their distribution. As shown in Fig. 1, the major hairpins are not randomly distributed, but consistently more concentrated in the right half of each genome, that is, the portion encoding the intercistronic regions and structural genes. Despite considerable variation in the total number of major hairpins between these genomes, there are always more in the right half than in the left (Table 1). In the case of SV40 and fd, the discrepancy between the left and right halves is even more pronounced when only hairpins with ≥7 base pairs in the stem are considered (Table 1).

Although intercistronic regions occupy only 4% (ΦX174) to 13.7% (SV40) of the total genome, they contain 20–40% of all major hairpins and, when corrected for differences in length, between 2 and 8 times as much secondary structure as translated regions (Table 1). Furthermore, the largest (or at least one of the largest) hairpins can always be found in an intercistronic region (Fig. 1). It appears that most of the hairpins occur in the two largest intercistronic regions of each genome, and the structural gene block between them.

The genomes of hepatitis B virus (HBV)[20] and cauliflower mosaic virus (CaMV)[21] have been cloned and sequenced and only two genes and their products have been described for each agent. For HBV, one of the surface antigens (S antigen) has been identified as the major envelope protein(s)[22], and its gene has been localized in open reading frame 7 (ref. 20; Fig. 2). The core antigen (gene 8) was found to be a DNA-binding protein[23]. The identified gene products of CaMV are capsid protein (gene 4)[21] and the inclusion body protein (gene 6)[24]. Both circular genomes were linearized such that the major capsid (or envelope) protein gene (gene S and gene 4, respectively) would align with the major capsid protein genes of the other icosahedral viruses (VPI and F). For CaMV it was also possible to place the start codon of gene 6 (a non-structural protein)[24] to the extreme left and an intercistronic region at the right end. In the case of HBV, the stop codon of gene 8 was localized at the extreme left, thereby aligning this gene with the DNA-binding protein genes of the other viruses. In this arrangement, the gap on the L-strand is in approximately the same position as the gap in the CaMV α-strand (Fig. 2). As shown in Fig. 2, the similarities in gene arrangements among all virus genomes analysed are congruent with similarities in the distribution of DNA secondary structure. Both the hepatitis and CaMV DNAs have the potential for these structures concentrated in the right half of the genome, although for CaMV this is only true for hairpins with seven or more base pairs in the stem (Table 1). Furthermore, the largest (CaMV) or one of the two largest hairpins (HVB) are localized at the right end,

0028-0836/82/310582—04$01.00

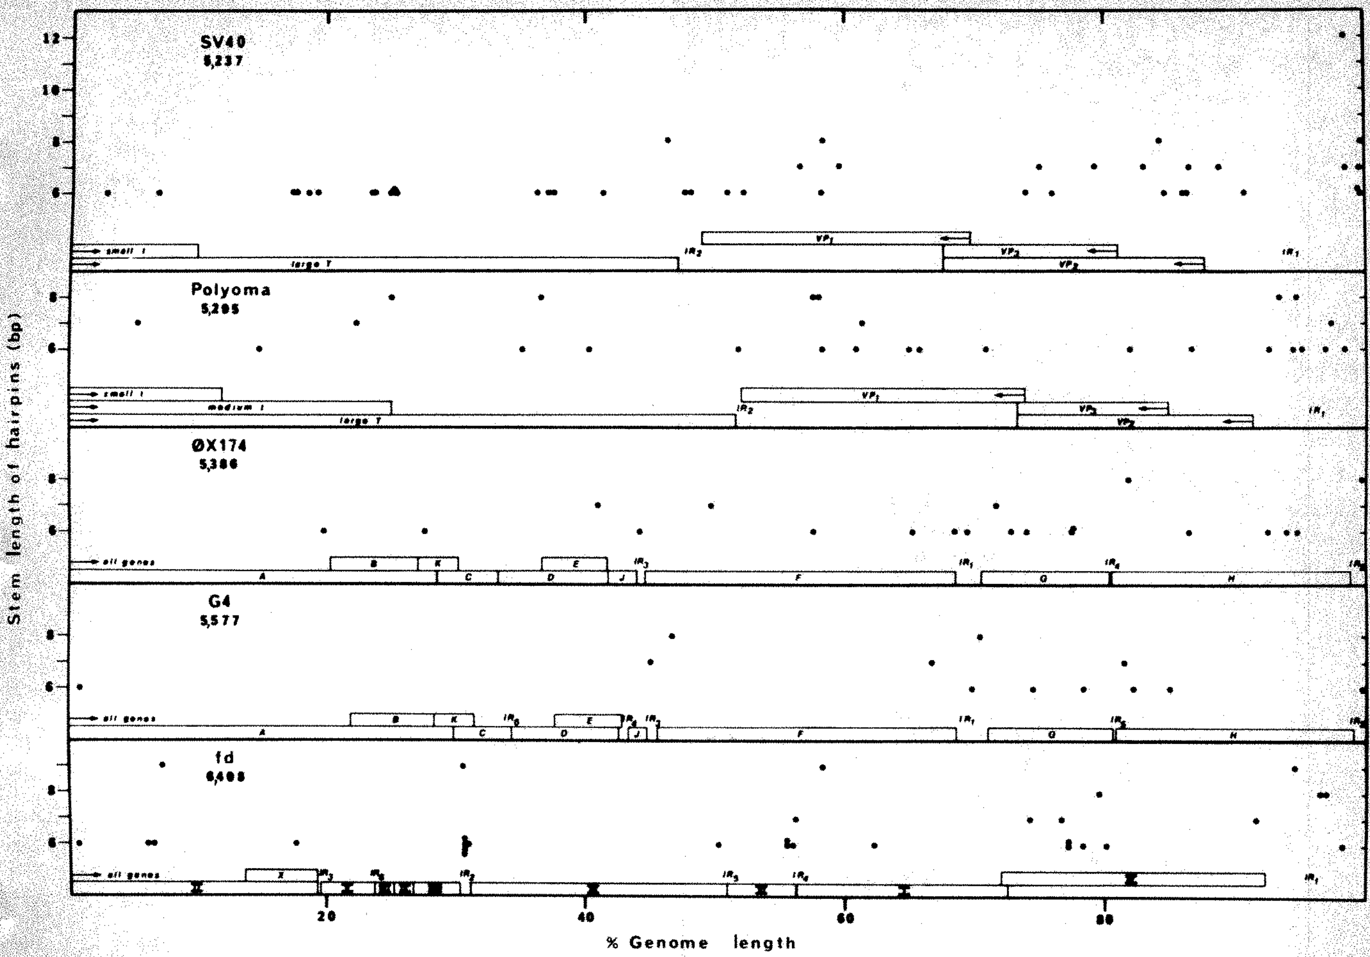

Fig. 1 Distribution of hairpins in the genomes of SV40, polyoma, ΦX174, G4 and fd. The genomes were linearized as described in the text and plotted on a per cent scale. The length in base pairs and name of each genome are indicated. The positions of perfect hairpins (as defined in the text) with ⩾6 base pairs in the stems are indicated by dots. Genes have been labelled according to the original literature and the arrows indicate the direction of transcription. Intercistronic regions (IR) have been labelled sequentially according to size.

which is also characteristic of most of the other genomes. Despite these similarities, the relatively small size and number of hairpins in the intercistronic regions of CaMV make this genome rather unusual compared with the others (Fig. 2 and Table 1).

For comparison, the sequence of the *Escherichia coli* plasmid pBR322 (ref. 26) was analysed and then linearized such that the intercistronic region containing the largest hairpins was placed to the right side (Fig. 2). In this arrangement the observations made for the viral genomes hold true also for this DNA (Table 1), supporting the generality of our findings.

The possibility of a non-uniform distribution of the four nucleotides and consequently an artefactual concentration of hairpins in one region of the genome makes a statistical evaluation of our findings necessary. The detailed mathematical approach and the computer program will be published elsewhere. Briefly, a program was written to compute E_n, the expected number of perfect hairpin structures with stem length n and loop sizes of 3–20 nucleotides, as a function of the total length and composition of the sequence; F_n is the number actually observed in a specific genome of that length and composition. The ratio of observed to expected numbers, Q_n, for a

* RH and LH refer to right and left half of the genome, respectively.

† IR and TR refer to intercistronic regions and translated regions, respectively. The values were corrected for the length of the regions.

stem length $\geq n$, is the ratio of the two sums

$$Q_n = \sum_{i=n}^{15} F_i \Big/ \sum_{i=n}^{15} E_i$$

Thus, values for $Q_n > 1$ show more structures of stem length $\geq n$ than expected by chance alone.

Using this approach we analysed the known intercistronic and translated regions separately. The results indicate an intrinsic difference between them (Fig. 3). While short hairpins are found in both regions with the expected frequency ($Q_n \simeq 1$), larger hairpins are definitely over-represented in intercistronic regions with an excess ranging from approximately 4-fold ($n \geq 6$ bp) to 2,000-fold ($n \geq 12$ bp). For translated regions the curve is shifted by about 2 bp, and hairpins with 8 or 9 base pairs in the stem are over-represented. Note also that the uneven distribution of hairpins between structural (late) and non-structural (early) genes in icosahedral viruses (Table 1) is matched by a difference between these regions with regard to Q_n values (Fig. 3). Of particular interest here are the non-structural genes of ΦX174 and G4. Hairpins with 5 or more base pairs in the stem are under-represented in these regions with a Q_n for $n = 6$ as low as 0.38 (ΦX174) or 0.16 (G4) (data not shown). The situation is reversed, however, in the filamentous phage fd, which has an over-representation of hairpins in the non-structural genes, but an expected frequency in the structural genes[25] (data not shown).

As thermodynamic considerations favour the formation of secondary structures having small loops[27], we determined the average loop size for the hairpins of all eight genomes with stem length $n \geq 4$ bp. For $n \leq 5$, the loop sizes average ~11.5 nucleotides, indicating a random distribution between the minimum and maximum values allowed in this study. For stem length $n > 6$ bp a preference for smaller loop sizes was discernible. Compared to the average loop size of 11.18 for hairpins with $n = 4$, the 12 hairpins with $n > 8$ averaged 7.9 bases in the loop, and the 2 with $n > 10$ both have a loop size of 3.

We have demonstrated that the potential to form perfectly base-paired hairpin structures with six or more base pairs in the stem is non-randomly distributed and generally larger than expected in viral DNA genomes. This, together with the preference for small loop sizes, implies an evolutionary selection and therefore a function. Their predominance in intercistronic regions strongly supports the speculations[2,11] that they have evolved as regulatory loci expressing their functions via DNA (or RNA) secondary, rather than primary, structure. Furthermore, it may be argued that secondary structure may also be needed in translated regions and can evolve whenever compatible with the coding requirements. The difference between structural and non-structural genes in this regard cannot be easily explained, but is probably not an intrinsic feature of the genes themselves, as the fd genome shows, but rather a function of their location in the genome, for example, their proximity to the origin of replication.

Though we do not claim that a given loop size or the absence of G–T (or G–U) pairing is fundamental to the biological significance of a hairpin, we are certain that the type of secondary structure on which we have focused here either has some biological role or is at least part of a more complex structure which may be universal to all genomes, as is the genetic code itself.

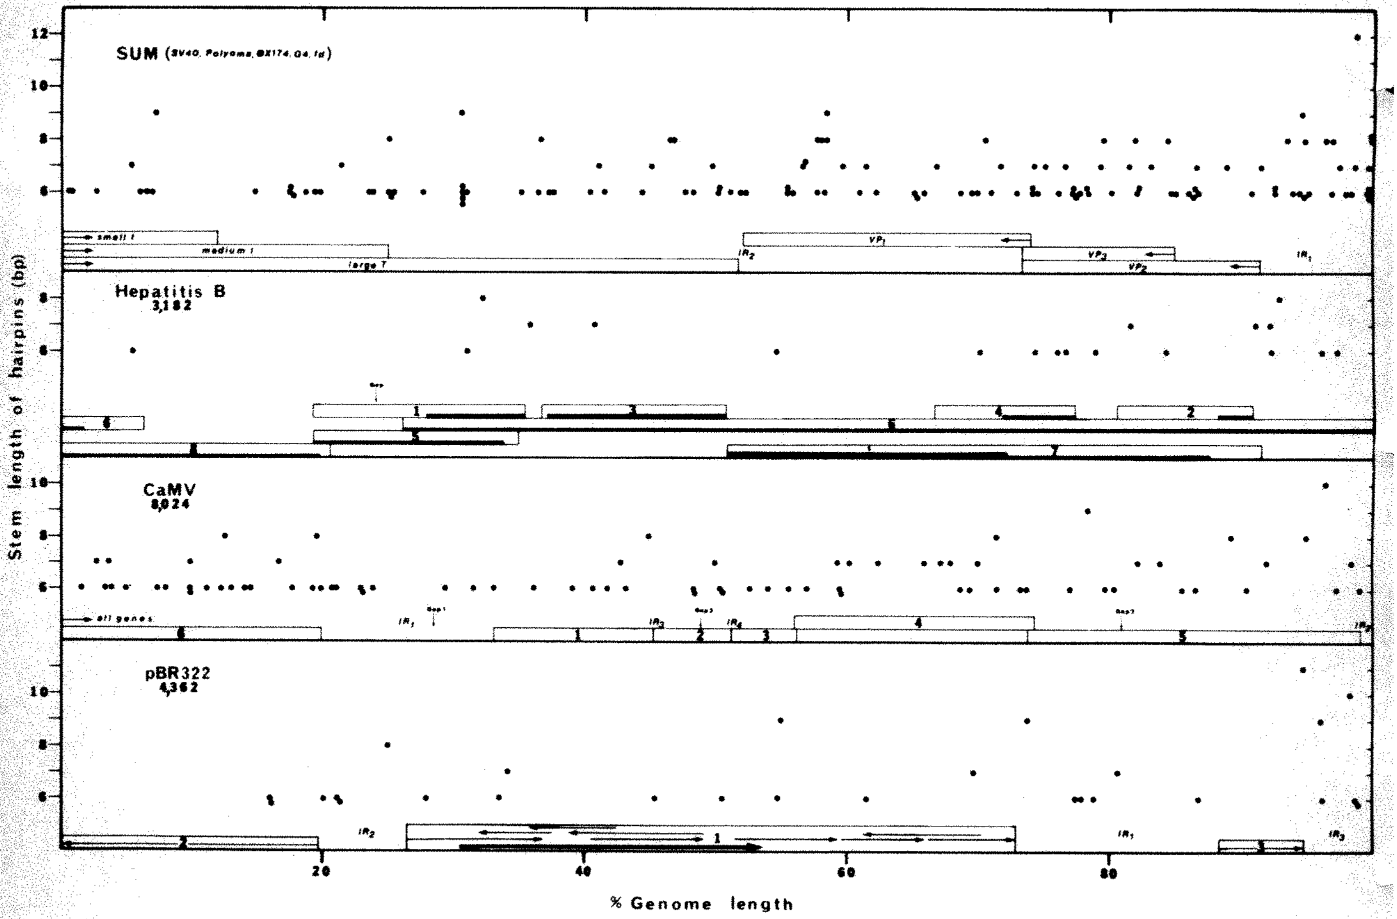

Fig. 2 Distribution of hairpins in the genomes of hepatitis B, CaMV and the plasmid pBR322. The position of hairpins was plotted against % genome length as described in Fig. 1 legend. The top panel represents a summary of Fig. 1 with respect to type and position of hairpins; the genetic map of polyoma virus has been included for comparison. The open reading frames of hepatitis B are indicated by boxes and labelled as in ref. 20. The heavier line at the base of each box has been drawn from the first start codon to the first stop codon within that reading frame and therefore indicates the direction of their transcription and the potentially translated segment. The identified gene product (S) is identified by an additional heavier line in reading frame 7. For pBR322, the boxes indicate possible genes or gene blocks. The arrows indicate the direction of transcription and the length of the putative genes[26].

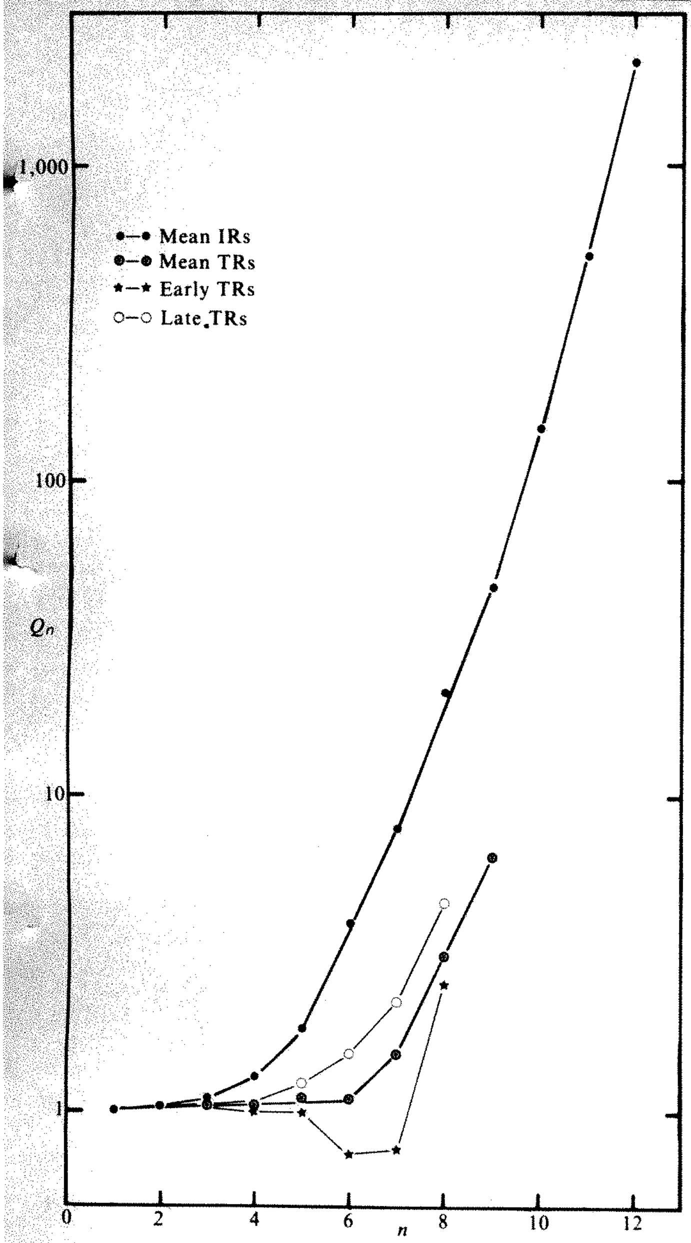

Fig. 3 The distribution of hairpins in intercistronic and translated regions. The intercistronic regions (IRs) and the genes or gene blocks (TRs) between them of the SV40, polyoma, ΦX174, G4, fd and pBR322 genomes were analysed individually and the Q_n values determined as described in the text. After weighting these values according to the length of each region, they were arranged and plotted on a log scale versus the stem length, n. The translated regions of SV40, polyoma, ΦX174 and G4 were separated into early (non-structural) and late (structural) genes and the weighted Q_n values were averaged.

Evolution of early mechanisms of translation of genetic information into polypeptides

Hans Kuhn* & Jürg Waser†

* Max-Planck Institut für biophysikalische Chemie,

† Terryhill Drive, San Diego, La Jolla, California 92093, USA

In devising models of the origin of life it is necessary to tackle the problems that the processes of genetic information transfer that are central to life depend on molecules that are themselves the products of such processes—enzymes. A proposed model must eventually yield a detailed chain of processes that can be checked experimentally. We have developed a model in which interactions between the helices of hairpin-loop 'adaptor' RNA molecules (amino acid carrying), lined up side-by-side by sequence complementarity to another 'messenger' RNA, promotes polypeptide synthesis.

Our model involves a picket-fence like linear array of hairpin molecules $B_1, B_2, \ldots, B_i, \ldots$ (Fig. 1), each of which consists of an RNA strand of some 40 monomers. The three nucleotides in the middle of such a strand form the loop of the hairpin, while its ends, twisted into a base-paired double helix, form the hairpin legs. The nucleotides in the hairpin loop hydrogen bond to complementary nucleotides contained in an extended RNA filament C, which is attached to another hairpin that forms the endpost of the picket-fence and is rotated 180° relative to the units B_i. The open ends of hairpin B_i possess affinity towards activated amino acids, and facilitate the formation of polypeptide bonds between amino acids attached to them. The hairpin RNAs are envisaged as the precursors of tRNAs, the nucleotides in the hairpin loop serving as anticodons to the codons along filament C, the precursor of mRNA. The endpost hairpin A would evolve into the messenger end used in the recognition of the start of the genetic message.

In many details, including the hairpin conformation of adapter molecules, this model is similar to one described several years ago[1]. Hairpin conformation of ancestral adapters is supported by tRNA sequence analysis[2,3]. We also suggest that another double-helical RNA-strand facilitates polypeptide synthesis, moving along the ribbon-like aggregate of hairpins, functioning as an early ribosome[4]. In the present model DNA became involved much later[1,3,4].

The assumptions underlying our approach are: (1) the presence of activated nucleotides and amino acids; (2) the existence of periodic temperature changes, as caused by sunlight and shadow-casting objects; and (3) a structurally diversified environment, such as pores of different sizes in rocks. Conditions (1) and (2) favour the creation, and later drive the replication and evolution of short nucleotide strands, with (+) strands acting as templates for (−) strands and vice versa; (3) provides confinement as well as all-important evolutionary pressure, because of the existence of a large variety of 'niches' available for 'colonization' by emerging life forms of increasing sophistication. For example, pores above a certain size cannot be colonized by strands that are too short, because they diffuse too quickly from the favorable sites. Calculations[3-5] show that

0028-0836/82/310585—02$01.00

strands of about 10 monomers may form directly. Longer strands may arise by fusion of shorter strands, but there is a limit to the length of a replicable strand of some 40 nucleotides, because of copying errors.

This impasse is broken by convolution of the strands into a conformation allowing aggregate formation. This permits the invasion of larger pores and, of the utmost importance, it eliminates erroneous copies because aggregate formation is crucially governed by RNA conformation and thus nucleotide sequence. The simplest conformation that permits such interlocking is that of the twisted hairpin B_i described earlier. A huge selective premium is associated with machinery that facilitates such aggregation, and the units described earlier provide such machinery (Fig. 2). C acts as collector strand, guiding the hairpins B_1, B_2, ... to the growth region of the aggregate, while A (to which C has become fused accidentally) acts as nucleation site that facilitates the onset of aggregation.

Our molecular model exhibits an astonishingly good fit between neighbouring hairpins, and between codons and anticodons, permitting stacking of bases. The model is based on left-handed GC RNA helices analogous to the Rich–Arnott–Dickerson Z conformation of DNA,[6-8], which has recently been shown to be possible for RNA as well (J. H. Van DeSande and T. M. Jovin, personal communication). All these steric fits require that the 3′5′ direction of strands connected by codon-anticodon interactions be opposite. In a model in which the hairpins have the conformation of a right-handed A helix the fits are not as good, but probably still adequate. The aggregates might be stabilized by polyvalent cations (Mg^{2+}, Ca^{2+}) that form links between negatively charged phosphatidyl groups on the outside of neighbouring hairpin strands. C would remain unconvoluted because convolution into a hairpin requires specific nucleotide sequences.

The presence of pores too large to curb strand diffusion favors the evolution of polypeptide-producing devices because polypeptides would block pore channels and at a later stage would coalesce into confining 'cellular' envelopes. The aggregates described develop catalytic properties toward polypeptide formation as follows.

Complementary (+) and (−) base-paired hairpins are identical (Fig. 2) except for the nucleotides in the mid-position and at the open ends. Ancestral tRNA contained largely, and perhaps exclusively, G and C[2], with C in the first and G in the third anti-codon position, and we assume the same for our (+) and (−) hairpins, leaving the midposition for purposes of an ancestral code, while the open ends possess or develop affinity towards activated amino acids. This view is also supported by a DNA sequence analysis[9] that suggests an ancestral reading frame PuNPy (Pu purine, Py pyrimidine, N either). If the midpositions and ends of (+) strands are occupied by C residues and those of (−) strands by G residues, and amino acids a_1 and a_2 activated by linkage with C and G respectively existed prebiotically[3,5] the two types of hairpins would serve as adapters.

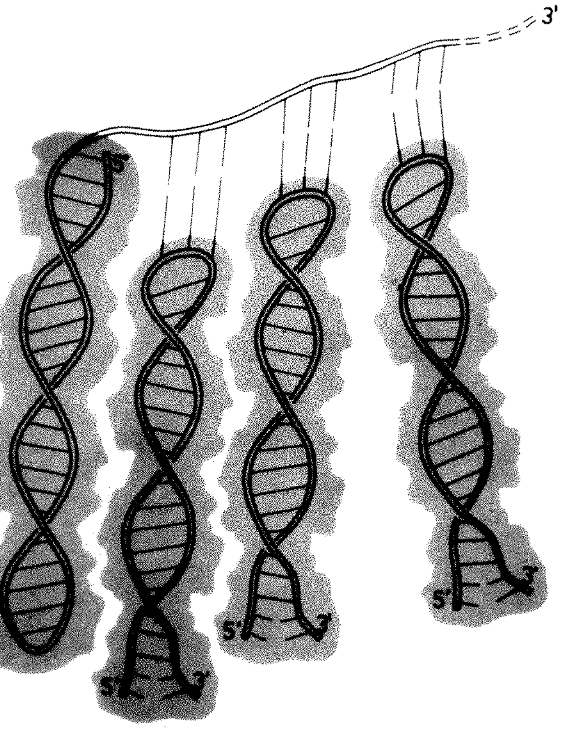

Fig. 1 Hairpin strands forming the beginnings of an aggregate. Legs of hairpins are twisted into double helices and outlines are as expected for van der Waals contacts.

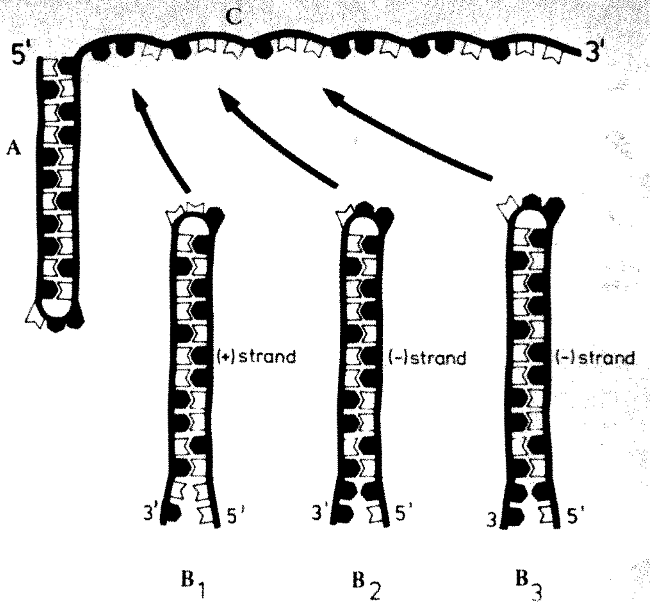

Fig. 2 Schematic view of strand C attached to hairpin A and hairpins B_1, B_2, B_3 in the act of forming a picket-fence like aggregate.

Eventually a sequence along C arises encoding a polypeptide acting as a primitive RNA replicase that decreases replication errors sufficiently so the information coding for it is not lost. (An increase of the survival rate by 10% by a replicase of 10 amino acids would only require a reduction of the error rate by a factor 3 for it to be fixed by selection. Such a 'replicase' might be a short polypeptide that fits into a notch of the double helix that exists during strand replication, slipping along in the notch as the new strand is lengthened (see ref. 10 for a discussion of the plausibility of this assumption).

The rate of evolution can be increased enormously once a 'replicase' has been produced. More diversified 'enzymes' evolve, the base pairs A and U become part of the code, the first and third anticodon positions gradually become used for coding purposes, and the number of amino acids being integrated into polypeptides increases during each of these steps[11]. Details of the proposed molecular model do not affect the potency of our methodology and we encourage others to think of improved scenarios.

We thank Drs Dietmar Möbius, Mary Price and Nickolas Waser for valuable discussions.

Koestler glimpsed

Nicholas Wade

Koestler: A Biography. By Iain Hamilton. Pp.398. UK ISBN 0-436-19101-6; US ISBN 0-02-547660-2. (Secker & Warburg, London/Macmillan, New York:1982.) £10, $19.95.

ARTHUR Koestler must have led one of the most varied and interesting lives of the twentieth century. For a life so filled with thought and action, and which reflects so accurately the major political and intellectual preoccupations of the time, parallels are hard to find. André Malraux and George Orwell are perhaps the closest, yet even they didn't venture into science, the realm of the century's most distinctive achievements.

The range of Koestler's interests is as formidable as his skill in pursuing them. Most of us find it difficult enough to write well in one language: Koestler, whose native tongue is Hungarian, wrote his famous novel *Darkness at Noon* in German, and his later work in English. As a novelist, political activist and historian of science, he has fitted at least three careers, each performed with unusual distinction, into one lifetime. There could be few greater challenges to a biographer.

Iain Hamilton, the poet and former editor of *The Spectator,* has made a creditable attempt to capture the protean nature of his subject. He dexterously follows Koestler through the changing milieus of his life, from student president of a Zionist duelling fraternity at the University of Vienna, to correspondent and science adviser for the Ullstein chain of newspapers, to his establishment in the English-speaking literary world. Yet the biography has several serious faults which spring, I think, from a severe lack of empathy that has somehow developed between the writer and his subject.

Mr Hamilton is too good a reporter to be anyone's Boswell. He has read everything and interviewed everyone relevant to his subject. He has unearthed many details of Koestler's private life, some of which Koestler might prefer not to have seen in print. Yet despite the close-up view, the nature of the subject remains blurred. Hamilton had access to Koestler's papers and diaries, yet does not quote from his interviews with Koestler himself. His desire to be totally independent seems to have led in places beyond detachment, to the point of rivalry with his subject. Too many of his own views obtrude into the portrait, while at the same time he frankly refuses to discuss Koestler's interests from 1970 onward, which have been focused on extrasensory perception. It may well be, as Hamilton implies, that Koestler's writings in this intractable field are worthless: all the more reason for a biographer to try to explain what led him into it.

Admirers of Koestler will be disappointed at the way Hamilton all but ignores the substance of his *oeuvre.* Since Koestler has written four volumes of autobiography covering his early life, perhaps there is little point in going over the same ground. But Hamilton does not have much to say about the subject matter even of *Darkness at Noon,* which along with *Animal Farm* surely ranks as one of the most important and influential political novels of the century. The French edition of *Darkness at Noon* sold by the thousands of copies just before the first post-War election in France, which the Communist Party was expected to win, and the book's impact has been held responsible for the party's narrow defeat. But Hamilton does not evaluate this claim, or discuss the book's influence on the many Western intellectuals who even in the late 1940s could not believe the Soviet experiment had so grossly betrayed its ideals.

Koestler's writings on the nature of scientific discovery are also given rather short shrift. *The Sleepwalkers,* a brilliantly fresh and stimulating account of the early history of astronomy, receives eleven pages of discussion in this 364-page book; *The Act of Creation,* an inquiry into the modes of scientific creativity, is dismissed in eight, and the treatment is thin. Yet these are two of Koestler's major post-War works.

A minor book produced during this period was *The Case of the Midwife Toad,* a passionate defence of the Austrian biologist Paul Kammerer who, like Koestler, was interested in psychic phenomena. Kammerer committed suicide in 1926 after the discovery by the American biologist G. K. Noble that nuptial pads on Kammerer's specimens of midwife toads, interpreted as evidence for Lamarckian inheritance, had been faked. Koestler argued that Kammerer was innocent, and that the pads, which really existed at one time, were perhaps touched up by an overzealous lab assistant. But a brilliant review by Lester Aronson (*Behavior Genetics* **5**, 115–125; 1975), a former assistant to Noble, persuades me that Koestler, in this instance, carried defence to the point of whitewash.

The Case of the Midwife Toad, like most of Koestler's other works, receives little substantive attention in Hamilton's biography, presumably on the assumption that they speak for themselves. The trouble with this approach is that the matters which Hamilton discusses at length, such as Koestler's relationships with his wives, or his problems in getting an American visa, are of little interest except in as far as they throw light on Koestler's public achievements. Hamilton does not use them to this end. Indeed the reader is occasionally led to wonder whether the purpose of some of the more trivial episodes isn't to belittle Koestler.

This cannot be the main purpose because, as Hamilton explains in the preface, he for many years "had admired Koestler's work (the greater part of it, at any rate)". Yet the reasons for that admiration are not clearly explained. There are few sustained themes or insights to unify the mass of chronological material presented here. Hamilton also remarks in the preface that:

> My reading of Koestler's works has convinced me that he is *au fond* a deeply religious man. He has never admitted this, confessing only to several experiences of the quasi-mystical Freudian 'oceanic' feeling . . . .

This is an interesting observation, yet one that is not further explored in the text.

Koestler's life can perhaps be seen as a search for faith. As a young man he embraced Zionism but quickly grew disenchanted. The next faith was Communism, but that was the god that failed. Pursuit of the divine spark led Koestler into the study of Kepler and scientific creativity. More recently came the interest in the paranormal. Like Sisyphus with his stone, Koestler has laboured mightily to ascend the peak, and when the effort fails, he has picked up the pieces and started again. It is this relentless search that has created work after work of intellectual inquiry, each exploring a new area with Koestler's own combination of intensity and clarity. Hamilton's biography portrays the private man behind these public explorations. It is well written and thoroughly researched, yet despite these substantial merits the portrait does not fully capture the essence of its subject.

Stars, listed and mapped for a new epoch

David W. Hughes

Sky Atlas 2000.0. By Wil Tirion. ISBN 0-521-24467-6. (Cambridge University Press/Sky Publishing: 1982.) £15, $29.95.
Sky Catalogue 2000.0. Volume 1, *Stars to Magnitude 8.0.* Edited by Alan Hirshfeld and Roger W. Sinnott. Pp.604. Hbk ISBN 0-521-24710-1; pbk ISBN 0-521-28913-0. (Cambridge University Press/Sky Publishing: 1982.) Hbk £32.50, $45; pbk £14.95, $29.95.

ATLASES and catalogues of the sky have one important characteristic for the publisher, and that is they get out of date quickly. The poles of the sky move, thus slowly changing the stellar co-ordinates. This is indicated by the epoch figure 2000.0 in the titles of the two books under review. The star positions given in the atlas and catalogue are only correct for that date. The last epoch was 1950.0 and these two books are the first comprehensive works for the new co-ordinate epoch. The pole does not move very quickly, the precession about the vertical to the Earth's orbital plane taking about 25,750 years, but still astonomers like being up to date and like to have the latest atlas and catalogue to hand.

The second thing to say about Tirion's atlas is that it is a joy to the eye. The sky is divided into 26 areas each represented by a chart measuring 12¼ by 17¾ inches. Stars are represented by black dots which decrease in size as the stars get fainter. Galaxies are red, nebulae green, clusters yellow and the Milky Way is represented by two shades of blue, following Pannekoek's isophotes. Secant conic and secant cylindrical projections are used which reproduce the constellation figures with minimum distortion. The labelling is clear. Simply to see this book is to want it.

The charts contain some 43,000 stars down to visual magnitude 8 and about 2,500 deep-sky objects. Brighter stars are labelled with both their name and their Bayer letter and Flamsteed number. Deep sky objects have their NGC or IC number as well as their Messier number. The Andromeda galaxy is, for example, shown as 224.M31.

Volume 1 of the *Sky Catalogue 2000.0* starts with an extremely useful ten-page introduction which is followed by 600 pages of tables. Each line in the table refers to one star, and 45,269 are tabulated. The brightest, Canopus, is 40 million times more luminous than the faintest, HD 153336. Thirty-seven thousand of them are visible with the naked eye from Earth. Following normal practice the stars are listed in order of increasing right ascension. Henry Draper and Smithsonian Astrophysical Observatory numbers are given, as are the name (where applicable), right ascension, declination, proper motion, visual magnitude, colour index, absolute visual magnitude, spectral type, MK type, radial velocity and distance. An example of the care taken by the authors is indicated by the way in which the distances are labelled according to whether they originate from trigonometric or spectroscopic parallax techniques or are just maximum or minimum values. Ninety-one per cent of the stars in the catalogue have their distances given.

Still to come, to complete the set, is Vol.2 of the *Sky Catalogue* which will describe in full the multiple and variable stars as well as the clusters, nebulae and galaxies. This is due to appear early next year.

Both the *Sky Atlas* and the *Sky Catalogue* are beautifully produced, good value for money and in my opinion essential acquisitions for all active astronomical observers.

David W. Hughes is a Lecturer in Astronomy and Physics at the University of Sheffield.

The great chain of non-being

A. Rupert Hall

Plurality of Worlds: The Origins of the Extraterrestrial Life Debate from Democritus to Kant. By Steven J. Dick. Pp.246. ISBN 0-521-24308-4. (Cambridge University Press: 1982.) £19, $34.50.

WHY should fairies be intrinsically any more absurd than Astrans? Partly, it is obvious, because the bottom of the garden is easier to inspect than even the planets of our own Solar System, and partly because the non-human qualities of pixy or fairy make this kind of being fantastic while we may imagine Astrans to be just as human-like as we wish. Indeed, the very principle of universal similitude which encourages us to contemplate the existence of Astrans — or in earlier days Lunatics and Martians — requires us, in starting from the assumption that these creatures are living, sentient and intelligent beings, to suppose them in some recognizable measure of behaviour to be like ourselves, however morphologically unfamiliar. The same argument applies to the imagination of extra-terrestrial animals and plants: a Venusian tree that runs, or an Astran flying elephant, are just as absurd as if we placed the same creatures in some unexplored Amazonian backwoods.

Nonetheless, for living things of all kinds the principle of universal similitude remains to this day an unsupported speculation. It is a principle, common to Epicuros and Hoyle, resting on a metaphysical belief that nothing in the cosmos can be unique, which many (including presumably most if not all religious believers) regard as unacceptable. In its original form, as adopted by the Greek atomists, it embraced the idea that no substance and no type of being can be unique, since everything is subject to probability and the occurrence of an event in one place does not reduce the likelihood of its repetition there or elsewhere. Hence time's arrow pointed in all directions at once as on a three-dimensional compass-card or, more exactly, must be interpreted as having but a local and reversible effect. Accordingly, the metaphysical rejection of singularity — and indeed the principle of universal similitude itself — are inconsistent with such an attribution of time-direction to the cosmos as the prevailing scientific view of its evolution seems to require; but as Dr Dick's consideration stops with Kant in the late eighteenth century, the relation of the Perfect Cosmological Principle and of the Primordial Bang to universal similitude falls outside his scope.

Throughout late antiquity and the Middle Ages Aristotle's rational arguments for a finite universe and a unique Earth held sway, though latterly mitigated by the contention, founded on God's omnipotence, that the creation of more universes than one was within his power. However, since it seems that mediaeval philosophers regarded such alien universes as in principle unobservable — surely a logical position to adopt — the assertion or denial of their existence was meaningless except perhaps in a theological sense. Then, as Dr Dick emphasizes, the Copernican revolution opened the door to a more effective version of universal similitude in that the Earth was now seen as a member of a class of bodies, planets, and later the Sun was placed in another class, stars. Since then, and with renewed emphasis from Newton, universal similitude has become a firm principle in thought about the physical structure of the cosmos though, paradoxically enough, the progress of scientific investigation has always increased rather than diminished our sense of the diversity within the classes of stars and satellites. Whereas the seventeenth century could (with some little violence to observation and plausibility) imagine the Moon as not at all unsuited to the existence of intelligent living beings, and the nineteenth century could similarly view Mars, we now recognize that the chances of finding another Earth-like planet, if finite, are quite small. The fact is that our search for analogues in the cosmos has had to be pushed ever further and further from home as our knowledge of the cosmos has become more positive. Even the bottom of the galaxy is now perhaps too close.

Dr Dick's interest is very much more in the philosophical rather than in the scientific stage of the debate about the plurality of worlds. Newton, to whom worlds of anti-matter — or at any rate "Worlds of several sorts in several parts of the Universe" — were by no means inconceivable, appears only 50 pages before the end of the 190-page text. I think this is a pity. The principle of universal similitude is much less interesting in the period where it was justified only by the experientially dubious argument that things are more probably like than unlike, than in the age of modern science when it has been justified by observational and theoretical successes. We have built up a fair body of knowledge of how this principle can be applied, and where it fails to work. Moreover, since Kant's time we have learnt a great deal about similitude in living things on Earth and have related this knowledge to a theory of their evolution in such a way as to transform the discussion of the possibility of living phenomena elsewhere. True, none of this has come near answering the question: "Are there other inhabited worlds?" but it has taught us at least where such worlds are not, and hardened the distinction between scientific imagination and scientific romance. The question: "Was Jesus Christ to be seen as the planet-hopping Savior in the new cosmology?" (Dr Dick's phrase), once so poignant to theologians, would not disturb a modern astrophysicist but scientist and theologian might agree that the most profitable working hypothesis for the present is to assume the Earth's singularity. Earths outside our galaxy seem likely to remain as unknowable to us as God's alternative universes in mediaeval thought.

Dr Dick's painstaking account contains few surprises. No one has made assertion or denial of the plurality of worlds the pole of a philosophical or scientific system; rather, the idea has been exploited or refuted as an exemplary consequence of more fundamental ideas about space, time and being. Very often, as in that most famous book of all on the subject, Fontenelle's *Entretiens* (1686), plurality has been defended in a fanciful or fictional manner. Belief in the plurality of worlds has also long been an intellectual symbol, like the expropriation of the expropriators or free love, a sign that he who holds this belief is fettered by no conventional dogmas of religion or science. It never seems to have done anyone much harm to assert this belief, not even Giordano Bruno (and Galileo rejected it). Whether it has ever done anyone any good I shall not attempt to say. ☐

There is a tide in the affairs of men . . .

Arthur T. Winfree

The Clocks That Time Us: Physiology of the Circadian Timing System. By Martin C. Moore-Ede, Frank M. Sulzman and Charles A. Fuller. Pp.448. ISBN 0-674-13580-6. (Harvard University Press: 1982.) $25, £17.50.

If you have cancer, don't accept another dose of cytotoxins or X-rays at a time scheduled for clinical convenience: the damage to your healthy tissue can be devastating at one time of day, yet go relatively unnoticed at another. If you read this en route across time zones, don't sleep off your jet-lag behind drawn curtains: exposure to people and sunlight will markedly shorten the time of discomfort. If you want a stimulating book to read, try this one.

Why this one? Wide-ranging books on circadian rhythms have appeared before: Bunning's classic *The Physiological Clock*, updated in 1973; Luce's popular *Biological Rhythms in Psychiatry and Medicine* in 1970; Ward's still-more-popular *Living Clocks* in 1971; Wever's 1979 classic-to-be *The Circadian System of Man*; my own *Geometry of Biological Time* in 1980; plus abundant, more specialized monographs and symposium proceedings. So who needs another?

You do if you found Winfree too mathematical, Wever too preoccupied with data and statistics, the journalists too excited for scientific reliability, and Bunning too preoccupied with invertebrates and plants. We mammals have clocks too, and clock physiology has immediate medical pertinence. A lot has been discovered by mammalian physiologists and medical doctors in the past decade, especially about sleep timing in human beings and the origin of sleep rhythms in the lower brain. *The Clocks That Time Us* is absolutely up-to-date in these respects, and does a superb job of presenting the major results in jargon-free English.

As with most scientists cum writers, the authors are liveliest on topics more distant from their scholarly speciality. The chapters on neuroanatomy and monkey physiology may become tiresome unless you are professionally involved. But if you are, you will appreciate the 150 or so figures, mostly depicting data, and some 900 reference citations, most of them less than a decade old. Regardless, you cannot help but appreciate the rich variety of illustrations drawn from *human* physiology, psychology and medicine.

Every author must compromise accuracy somewhat for a lively presentation and I might have chosen a different balance in some of the more theoretical sections. For example, the 30-page section about phase-resetting and entrainment, though well done, is drawn from outdated theory of the 1950s, and in any case is never referred to again. And a "mathematical model", vintage 1981, for the human temperature rhythm and sleep/wake alternations occupies most of a short chapter, but to my mind gives the misleading impression that we know a lot more than we do.

Though sceptically alert, even to the point of peppering pages with "howevers" in the physiology chapters, Moore-Ede *et al.* seem to me to accept many other, oftimes rather sensational, data too nearly at face value. For example, were I assigned to edit the next edition, I would urge less emphasis on the likelihood that we harbour two or more separate sources of circadian timekeeping in our various organs, unless more persuasive experiments appear. Nonetheless, every suggestive observation in this book deserves the emphasis given if it provokes immediate testing: for example, that the only four successful "test-tube baby" implantations carried out at the time of writing were performed between 10pm and midnight, and the 75 failures were attempted at other times.

The long last chapter was the most exciting to me: "Medical Implications of Circadian Rhythmicity". The effectiveness (and toxicity) of drugs and anaesthetics show marked rhythms which should be charted to improve the safety of medical procedures; this has already been done and reduced to clinical practice in the case of cortisone therapy. We also learn about jet lag and the inconveniences of disparity between external time and internal body time. Unfortunately, no evidence is presented that internal desynchronization is, in itself, part of the problem. The prospect of a "jet-lag pill" is discussed, but no drug more reliable than caffeine is suggested. Whoever invents this one seems sure to get rich. Note is made that shift-workers suffer from desynchronization while responsible for critical decisions in hospitals, nuclear power plants and submarines; the Three Mile Island incident occurred at 4am. Psychiatric disorders, too, may sometimes stem from derangement of circadian coordination: success has been reported in some attempts to cure insomnia and recurrent depression by phase-resetting.

So do not buy this book lightly — you may end by habitually charting your body temperature and hours of sleep. ☐

Arthur T. Winfree is a Professor of Biological Science at Purdue University, Indiana.

Richard D. Alexander's *Darwinism and Human Affairs*, first published in 1980 and reviewed in *Nature* **287**, 173 (1980), has now appeared in paperback. The book is published by the University of Washington Press and costs $9.95.

Bewitched by a computer

Simon Lavington

The Soul of a New Machine. By Tracy Kidder. Pp.254. US ISBN 0-316-49170-5; UK ISBN 0-7139-1482-3. (Little, Brown/Allen Lane: 1982.) $12.95, £7.50.

COMPUTERS are created by teams — for the simple reason that even the smallest of them is too complicated to be designed in a reasonable time by one person alone. This team approach is common to many other complex engineering projects, and yet a hint of sorcery does surround the birth of a new computer. In *The Soul of a New Machine*, Tracy Kidder examines this mystique through the eyes of a computer design team operating in the United States in the late 1970s.

The book is somewhat retrospective, for few computers are today things of mystery. Market forces and the increased use of design automation are producing a convergence of approaches amongst manufacturers. Standard computers are off-the-shelf items and it is only in the areas of very high performance or special-purpose computers that there is much scope for engineering innovation. It has not always been thus. Not too many years ago every computer was special. They were special not only in the engineering sense but also because of the unexpected avenues they opened up for human endeavour. Man could comprehend machines which enhanced his physical strength, mobility or range of communication, but here was a new type of machine which cooperated with and enhanced his very thoughts.

Of course the difficulty was — and is — that computers do not speak the same language or share the same preconceptions as human beings. The computer is simpler, faster, more rigorous, less forgiving than its designer and nowhere is this mis-match felt so keenly as during the testing of new hardware or software. Getting a computer to work properly — especially under commercial pressures — demands a particular kind of mental and physical stamina for which there are few parallels. There is all the difference in the world between thinking about a new computer and actually building one, though a result of modern design methodology has been to reduce the areas of uncertainty. A computer design team has thus to operate in an unusual environment and, until quite recently, the team morale was strengthened by the unspoken feeling that the members were in some way pioneers of a new age.

The Soul of a New Machine is something of a misnomer, for the book is really about the soul of the design team. Brought together and sustained by the god-like personality of their leader, the team is given the challenge of designing a relatively high performance machine within severe political constraints imposed by the company's top management. In describing this political background, Mr Kidder provides an interesting analysis of the minicomputer market at a time which saw the progression from 16-bit to 32-bit machines. In particular, the development of the Data General Company is charted with the financial precision of a business journal, and students of modern industrial development will find this very revealing. The machine itself remains in the wings for most of the story. It is in any case somewhat of a hybrid — an attempt to achieve large computer performance whilst maintaining compatibility with a small computer marketing base. Although by no means a technical landmark, the project does involve the solution of some unusual design problems and the emphasis on processing speed makes fault-finding the more difficult. Few hints are given about the precise tricks played by the engineers to obtain the performance they required, but this omission is perhaps just as well. Mr Kidder is not at home with computer terminology; his attempts to interpret the jargon for a lay readership are at times ungainly, and *cognoscente* will recognize instances where his simplifications are based on misconceptions.

Luckily, however, a precise technical understanding is not necessary for an appreciation of the book's underlying theme: the response of young engineers to stress. Mr Kidder's unease in some ways emphasizes the gulf between computer terminology and everyday language, a gulf which tends to place computer engineers apart from other mortals. The jargon, the project deadlines, the group pressure to work long and unsociable hours, the mental effort of pinning down faults from the most sketchy of clues — it is no wonder the engineers become totally absorbed by their machine.

There is also a subtle yet pervasive managerial influence applied to the team. To most of the engineers this is their first chance to make a personal contribution to the design of a new computer and the team leader appears to exploit this. The ephemeral glory of "having your name on the machine" is offered only to those who are willing to devote their total waking hours to the project. As the project progresses, any lesser commitment becomes unthinkable by the young engineers themselves; peer pressure ensures finally that they are not so much enslaved as bewitched. Wives and families receive scant mention in the book, but they probably felt that the machine was being weaned on men's souls.

The story will ring true for anyone who has been involved in the design of a new computer, and yet these same readers will find Mr Kidder at times frustrating. This is because the tantalizing glimpses of engineering problems leave unassuaged a thirst for more detail. But if the book is — thankfully — not a technical report, it is also not a novel. It fails to do justice to the dramatis personae; the character sketches dwell excessively on the scientific career of the team members and few of them emerge from the pages as flesh and blood. In a sense this criticism is unfair, since the book should be judged as a documentary which makes a successful attempt to bridge the gap between high technology and everyday experience. With computers, for better or worse, pervading every corner of society, such bridge-building books are badly needed. ☐

Simon Lavington is a Senior Lecturer in Computer Science at the University of Manchester, and author of Early British Computers *(Manchester University Press, 1980).*

Harvested thoughts

Wolfgang Pauli: I don't mind your thinking slowly: I mind your publishing faster than you think.

[Sir] Francis Galton: [Statistics are] the only tools by which an opening can be cut through the formidable thicket of difficulties that bars the path of those who pursue the Science of Man.

[Lord] Ernest Rutherford: If your experiment needs statistics, you ought to have done a better experiment.

Michael Flanders: One of the great problems of the world today is undoubtedly this problem of not being able to talk to scientists, because we don't understand science; they can't talk to us because they don't understand anything else, poor dears.

Francis [Lord] Jeffery: 'Damn the Solar System. Bad light; planets too distant; pestered with comets; feeble contrivance; could make a better myself.'

Samuel Butler: We shall never get people whose time is money to take much interest in atoms.

[Lord] John [of Selmeston] Wilmot [Minister of Supply 1945–1947]: What I like about scientists is that they are a team, so that one need not know their names.

Victor Frederick Weisskopf: Science has become adult: I am not sure whether scientists have.

Leo Szilard: Don't lie if you don't have to.

Eric Temple Bell: The cowboys have a way of trussing up a steer or a pugnacious bronco which fixes the brute so that it can neither move nor think. This is the hog-tie, and it is what Euclid did to geometry.

These quotations are taken from Alan L. Mackay's delightful collection, *Harvest of a Quiet Eye*, first published in 1977 by The Institute of Physics. The book contains well over a thousand such aphorisms and quotations, and has just appeared in paperback, price £3.95, $9.95. Hardback is £8.50, $22.50.

Disunited nations in outer space

The UN conference on space technology opened in Vienna earlier this week is certain not to ask the questions that need answering. So should conferences like these take place at all?

The United Nations conference on the peaceful uses of outer space, which opened this week in Vienna, seems to have set off on a familiar track (see page 595). It is right and proper, but also predictable, that the Austrian Foreign Minister, Dr Willibald Pahr, should have opened the proceedings with a declaration that the most urgent need is somehow to rid what the United Nations calls outer space of all military connotations. Better this, it may be thought, than that the keynote address should be yet another plea that the benefits of remote sensing satellites (whatever they may be) should be made freely accessible to all sovereign states that think they have a need of them, or which are just curious to know what they look like from aloft. Certainly it is far better than that the members of the group of seventy-seven, the developing countries whose interests in development are a part but only a small part (witness present anxieties about the Lebanon) of the proper objectives of the United Nations, should set up a howl that they do not have the direct-broadcasting satellites to put into the geosynchronous orbits with which the United Nations (through the International Telecommunications Union) endowed them in 1979. Even so, it is a serious question for the United Nations to consider whether conferences like these should continue to be held.

None of this is to suggest that the military use of space technology is not a serious problem. The past few years have shown all too well that the contrary is the truth. The major powers, principally the United States and the Soviet Union, are already dependent on satellites for much of their military intelligence. Quite soon there may be systems for putting other systems out of action (see *Nature* 15 July, p.211). And the process seems destined to catch on. Other states (France, for example) will soon be up there too. Other systems, perhaps laser weapons, will be added to the orbital ironmongery. Moreover, there seems no doubt that once these systems have multiplied the danger that they will be used provocatively if not in anger will be substantial. The trouble, unfortunately, is that no amount of speech-making at United Nations conferences will bring the perpetrators of these new devices to an agreement on restraint. Only hard-headed negotiations between parties willing that negotiations should take place could arrive at such a conclusion. Some international organization could, it is true, help to bring those who now use orbits for military (but not destructive) purposes to heel by keeping a close watch on what they are about, and then publishing the results. This is what governments such as that of Sweden have been urging. Unfortunately, for the United Nations to act in such a sense, either the political backing of the major powers or the financial backing of the others would be necessary. Neither is likely to be forthcoming.

So what, in these circumstances, can the latest conference hope to accomplish? By the end of next week, the delegations will no doubt be hard at work on the draft of a declaration so stuffed with anodyne pieties that even hard-headed governments will be shamed into endorsement. One certain ingredient in the communique — would that this prediction were proved wrong — will be that the benefits of telecommunications by satellite, the only commercially proven benefit of these devices, should be more freely available and more widely shared. Ever since the disastrous United Nations Conference on Science, Technology and Development (also at Vienna) in 1979, the notion has become entrenched that it is somehow inequitable that high technology should be exploited first by highly developed industrialized states. But this clamour is entirely mistaken. If industrialized states are to be persuaded not to win some commercial benefit from their high technology, how can they be asked (as they should be asked) to throw open their domestic markets more freely to imports from the developing countries?

This contradiction lies at the heart of much of what the United Nations seeks to accomplish in these periodic and increasingly gigantic conferences. Their form ensures that all parties go away frustrated — the high-technology states because they have been shamed into promises whose only saving grace is that they are empty, the others because they believe (or pretend) that the promises mean what the words say. The outcome, mutual despair, may be as dangerous as the militarization of space over which Dr Pahr wrung his hands this week. Has the time come when somebody should say no to the next conference (on nuclear energy next year) or at least to the one after that?

Gamekeeper turned poacher

The British need a new university boss; herewith some nominations and a job description.

Dr Edward Parkes seems a glutton for punishment. Most of his spell as chairman of the University Grants Committee has been spent in forcing arbitrary government economies on British universities. His decision now to quit is understandable, and would have been forgiven at any time in the past few years. His decision to be instead the next vice-chancellor of the University of Leeds is more surprising. Is it self-sacrificing heroism, a wish to be seen lying on the bed of nails that universities accuse him of having fashioned for them? Or bravado, an ambition to show that the economies are not so bad after all? Either way, the University of Leeds, already distinguished among British universities not merely for its academic strength but, these days even more important, for the strong regional loyalty that sustains it, must count itself lucky. For a university to have as its chief officer someone who knows how the grants committee functions must be an advantage of some kind. Parkes is unlikely to use his position to win extra leverage for Leeds with the grants committee, although many of his new colleagues are hoping that he is not that straight. But at the worst, he will be able to help his new university to understand more readily than others what may lie behind the inscrutable instructions that issue from time to time from the committee he is now leaving.

For the British government, Parkes's departure now is probably more of an embarrassment than an opportunity to fill the empty office with a kind of stool-pigeon or Uncle Tom. Not that there is a shortage of potential successors to Parkes. Sir Alec Merrison, vice-chancellor at Bristol, would suit quite well, even if Sir Peter Swinnerton-Dyer from Cambridge would be more interesting. Lord Flowers, rector of Imperial College London, would be a strong appointment, but would the government welcome a grants committee chairman free to speak his mind in the House of Lords? Lord Swann, under-employed since quitting as head of Oriel College, Oxford, a year ago, is similarly

0028-0836/82/320593 02$01.00

encumbered by a peerage. But then Sir Ronald Mason will be leaving his post as scientific adviser to the Ministry of Defence later in the year, while Mr Geoffrey Caston, who has administered the vice-chancellors' own lobby (the Committee of Vice-Chancellors and Principals) for the past five years, probably knows as intimately as anybody how the British university system functions. Any one of these, and no doubt a host of others, could embark on a stint as chairman of the grants committee without having first to win the confidence of British universities. The government would even find that most of them accept its own view that even when direct support for the universities has levelled off in 1984-85, continuing reorganization will be necessary within the British system. But none of them would take Parkes's job without certain assurances, the most important of which is that there should be an understanding between the government and the universities on what the grants committee is for.

What should they ask for? The natural temptation is to ask for more independence, but that will not be as simple as it seems. Although the grants committee was established to be an independent buffer between the universities and the government, it has never been autonomous. In principle, in the old days, the government would say what subsidy it could afford, the committee would recommend how that should be divided and the government would send out cheques to individual universities accordingly. In practice, of course, the grants committee was very much a spokesman for the university system, arguing the case for new developments in some field or other (more medicine, more science perhaps), whose credibility with the government stemmed from its periodic invigilation of how universities individually conducted their affairs. So even in the halcyon days when the committee dealt with the Treasury rather than with the Department of Education and Science, and when the scale of spending on the universities was settled five years ahead, the government was inevitably drawn into decisions about the character as well as the scale of British higher education. Most of the changes that have come about in the past few years are changes only of degree. After the government decreed at the end of 1980 that its subsidies for the universities should be reduced by 8.5 per cent in real terms, it seems genuinely to have been left to the grants committee to decide how the misery should be distributed. The declaration a few weeks ago by the Secretary of State for Education and Science that ministers might in future shoulder more responsibility for issues of university policy is therefore not an innovation of principle. The danger is merely that they will choose to intervene too often and too trivially.

Candidates for Parkes's job will therefore ask for an assurance that they will have a job to do, and not be mere office-boys (or girls?) for ministers. More important, they should also ask for a restoration of the old civilities by which the grants committee was consulted in advance on important issues of public policy on higher education. Parkes appears to have been told in advance of the two decisions that have most affected British universities in the past few years, the increase of fees for students from overseas and the reduction of the general subsidy (coupled with limits on student numbers). The government may now regret that on enither occasion was the grants committee given a chance to suggest how its objectives might be more sensibly, and more equitably, attained. Yet even these examples of the present government's disrespect for the grants committee (to some extent made good by Sir Keith Joseph's offer of a "dialogue") are not unprecedented. The creation in the 1960s of what is called the "binary" system of higher education, with parallel systems of universities and polytechnics, was presented to the universities by the late Mr Anthony Crosland as a bolt from the blue. Yet that has become the most serious unsolved problem in British higher education. In the government's interest as well as his own, Parkes's successor should make it clear in advance that if he first learns of radical changes in his working environment from the morning newspapers, he will be up and off before the day is out.

Given suitable assurances, Parkes's successor could have a rewarding job. In the promised period of stability after the present contraction is over, it should be possible to make a start on the restoration of the spirits of academics and of their universities. The new grants committee chairman will have the advantage of dealing with universities that, by definition, will have survived, sometimes to their own surprise. Many of them will by then be enlivened by innovations forced out of them in these hard times, from science parks and essays in continuing education to the discovery that research of high quality does not necessarily require an entail on the output of a gold mine. Administratively, so far as the universities are concerned, the trick must be to find a way of giving all universities a sense that they are more fully than at present in control of their own destinies, from which would follow the beneficent consequence that they have an incentive to be different from each other, not an incentive to ape each other — or Oxbridge. (The criteria of academic standards and the conventions of "peer review" might have to be subordinated to others, the interests of students perhaps.) Politically, the objective would be to provide the government with a solution to the problem of the binary system, showing how it might be made unitary. Philosophically the need is for a chairman who could help to redefine the functions of higher education in countries such as Britain now that the participation rate is high enough to falsify the traditional academic assumption that the purpose of being a student is to become an academic. Such a chairman might even be able to find a way of creating some tangible linkage between higher education and national prosperity — everybody's ambition and nobody's boast. Then, so the daydream goes, British universities might have friends again in the House of Commons . . . Is that too much to hope for?

Jumpiness of bankers

Science and technology, usually respectful of banking, will suffer if bankers lose their nerve.

Why are the world's bankers so much on edge? In the past few weeks, these ordinarily imperturbable figures have taken to whispering behind their hands as if they were selling not credit (a respected commodity) but something disreputable. The change of demeanour is in the short term easily explicable. The bankers worry that they may not be permitted by their governments to roll over their credits to Poland when that question has to be decided next month, or that some unsophisticated member of their community may not agree to forgo payment on its Polish loan even if the governments concerned suggest that bankers should be compliant. But that is very much a short-term calculation. The sum of what the Polish government owes the Western banks, estimated at $15,000 million or thereabouts, is perhaps only 5 per cent of what the commercial banks of the industrialized West have lent overseas in the past few years. Obviously, a default by Poland would be an inconvenience, but arithmetically it should not spell the end of the Western way of life. Western bankers will not be readily forgiven if they let the Polish credits jeopardize their survival — and that of their depositors.

So what really makes them jumpy? A sense of guilt, the certain knowledge that they are no longer as much in charge of their own affairs as they pretend they are. Once upon a time, when bankers earned their reputation for probity, banks undertook to look after the money entrusted to them by depositors, lent that to borrowers who had a need of it, and made their living on the turn. For at least half a century, however, the banks have been partly the prisoners of their governments — or suckers for their governments' propaganda. In the 1960s, the banks helped pay for the Vietnam war by exporting the US government's excess expenditure through the Eurodollar market, exporting inflation at the same time. More recently, in countries such as Britain and the United States, the banks have helped their governments both fiscally (with high interest rates that cause deflation) and politically (by lending to unknown clients overseas). Their profit margins have been assured, but their assets have been just as much at risk as are other people's. Discrimination, the banker's stock in trade, has gone by the board. Who, except the rest of us, will cry if they go bust?

More trouble for Stanford's patent

US patent office gives reasons for refusal

Washington

Further doubt has been cast on the validity of the key Cohen–Boyer patent covering basic processes in genetic manipulation by a decision on a second patent application taken last week by the US Patent and Trademark Office. On 30 June, the office announced that the granting of the second patent, originally planned for 13 July, would be postponed (see *Nature* 29 July, p.409). Last week, the office took a further step in the minuet-like US patent process and notified Stanford University (acting on its own behalf and that of the University of California, San Francisco) that the second patent application was to be rejected.

The decision of the patent office seems to turn on the status and origin of the plasmid called pSC101, that first used by Cohen and Boyer as a means of cloning foreign genes in *Escherichia coli* plasmids. Originally, Cohen and Boyer considered that this plasmid had been derived from a naturally occurring plasmid called R6-5 by recircularization of some fragment itself produced by hydrodynamic shear.

Last week, the US patent office cited an article published by co-inventor Stanley Cohen and a collaborator in 1977 (Cohen, S.N. and Chang, A.C.Y. *J. Bact.* **132,** 734; 1977) in which other possible origins of pSC101 were canvassed. The possibility of a relationship with the *Salmonella* plasmid SP219 was mentioned.

The patent office now says that the 1977 article "sets forth a revised view of the origin of the pSC101 plasmid. That view conflicts with the origin of pSC101 as set forth in this application".

The first patent, which was issued to Stanford and the University of California at San Francisco in December 1980, presumably suffers from the same potential defect. The patent office has the authority to reexamine an already-issued patent, but has only exercised this option once since it was given the authority in 1980. Alternatively, a third party could file a challenge to the first patent.

A possible counter to the patent office's objection would be to show that the plasmid was publicly available at the time of application, and thus the claims in the patent for how the plasmid is used as a starting point in the creation of recombinant plasmids does not depend on the accuracy of the recipe for making pSC101. This matter is open to question; Cohen and his co-worker Herbert Boyer did make the plasmid available to qualified scientists who requested it, but with some restrictions. The patent office asked Stanford to provide data on how many scientists were supplied the plasmid and whether any were refused.

Cohen said last week that the 1977 *Journal of Bacteriology* article "did not admit an error in the original procedure" but rather only in the "interpretation" of where the pSC101 plasmid came from. He said that procedure was totally reproducible.

Stanford has already sold one-year licences to the first patent to 73 companies. Stanford has three months to respond to the patent office's action; a Stanford official said he did not see any "insurmountable obstacles" in successfully asserting its claim.

Stephen Budiansky

Space wars at UN conference

Vienna

Austrian Foreign Minister Willibald Pahr has called on the world scientific community to "oppose vigorously" the increased militarization of space. He was addressing the opening session of Unispace 82, the second United Nations conference on the exploitation and peaceful uses of outer space, now meeting here. Dr Pahr had just been elected president of the conference, an honour shared with Dr Kurt Waldheim, who, in 1968, had been Austrian Foreign Secretary when the first Unispace conference was held in Vienna.

Unispace-1 had been mainly concerned with the potential of the new space technologies. Unispace-2, fifteen years later, is interested primarily in what can be done with those technologies to improve the quality of life of mankind. An exhibition, staged parallel to the conference, shows an impressive range of space technologies.

In one respect, Unispace-2 might be considered as a showcase for the space techniques of the more developed nations, in their hopes that these benefits could be extended to the less fortunate.

UK Minister of State Kenneth Baker observed that, "Unispace is particularly significant for those countries which do not have their own space industry, but who seek quite rightly the assurance that the way that space applications are developing is of value to all".

The prestige element was, of course, present. The Soviet exhibit was under the direction of Dr A. P. Kapitsa, son of the Nobel prizewinner. The Americans brought to their stand not only their shuttle astronaut Henry Hartsfield but also a female trainee astronaut. The American impact, however, was somewhat lessened by the recent Soviet media campaign which stressed the military aspects of the shuttle and by fears of what President Reagan's 4 July speech about a "more permanent" US presence in space might mean — a subject on which US delegates to Unispace 82 were remarkably non-communicative.

The idea that the "demilitarization" of space was a prime prerequisite for its peaceful exploitation was taken up by many of the delegates, including the representatives of non-governmental organizations, who have a special session on this theme scheduled for Saturday. If, unlike its predecessor, Unispace-2 produces some concrete recommendations, the peace issue is almost certain to be among them. So far, however, no concrete proposals for the "demilitarization" of space have emerged.

Vera Rich

India's space hopes

Bangalore

India's ambitions in space remain high despite a number of setbacks. Next month, the indigenous rocket, SLV-3, will carry a 42-kg satellite during its first operational flight and next year the first Indian astronaut will fly aboard the Soviet spacecraft Salyut-7. But the country's most ambitious space project yet, the multi-purpose operational domestic satellite INSAT-1A, has been crippled by the failure of its solar sail to deploy.

INSAT-1A, the world's first civilian telecommunications, weather and direct broadcasting satellite rolled into one, was built by the Ford Aerospace Corporation under contract from the Indian Space Department and launched by the US National Aeronautics and Space Administration aboard a Thor Delta rocket. The Indian government had planned to use the satellite for meteorology, long distance communications and for broadcasting direct to remote villages, but the failure of the solar sail will reduce the satellite's lifespan to two and a half years and limit its usefulness. The Indian Space Department is hoping for better luck with INSAT-2, due for launch aboard the space shuttle in July 1983.

High hopes are also pinned on the operational launch of SLV-3, India's own solid-fuelled, four-stage rocket. After a disastrous first test flight in 1979, SLV-3 had a successful test flight in July 1980 and was partially successful in May 1981 when it placed a small satellite into an unexpectedly low orbit, thereby condemning the satellite to 9 rather than 90 days of life.

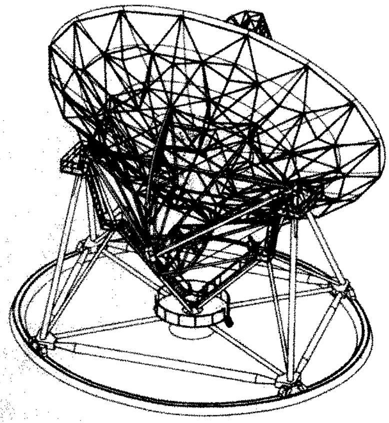
US astronomy

Arrays in, dishes out

Washington

The US radioastronomy community, after much agonizing, has decided to give first priority to the construction of the Very Long Baseline Array (VLBA) radio telescope — a decision that effectively means that the 25 metre telescope — which it has sought for several years without obtaining funds — will not now be built.

Associated Universities Inc., the management group that runs most major US radioastronomy facilities, recently submitted a formal proposal to the government asking for $51 million in 1982 dollars to build the network, which would extend from Alaska to Hawaii and across the continental United States to New England.



The 25-m millimetre wavelength telescope

Using interferometric techniques, VLBA will have a baseline on the order of the radius of the Earth, and so will be able to achieve extraordinary resolutions of 0.3 milliarcsecond. Thus it will be able to study many aspects of the so-called "violent universe", such as explosive events in quasars and in the nucleii of galaxies. It may also permit precise distance determinations to maser sources in our own galactic system."

The 25-metre telescope, on the other hand, would have used very short, millimetre wavelengths to investigate interstellar molecular chemistry. It was first recommended in 1972 by a committee of the National Academy of Sciences (NAS) headed by Jesse L. Greenstein of the California Institute of Technology. The National Radio Astronomy Observatory in Charlottesville, Virginia, has sought funds for the 25-metre telescope since 1977; in some of those years, the National Science Foundation forwarded the request to the White House, where, for unrelated budgetary reasons, it stopped. Meanwhile, related work has continued at smaller dishes at Caltech, the University of California at Berkeley, Bell Laboratories and the University of Massachusetts.

Other countries, too, entered the promising field: the United Kingdom has a 15-metre dish at Mauna Kea, in Hawaii, while the Franco-German telescope institute IRAM (Institut de la Radioastronomie Millimetique), based at Grenoble in France, plan two telescopes — one almost ready at Pico Veleta in the Sierra Nevada near Granada in Spain, the other under construction at the Plateau de Bure in the southern French Alps (near Grenoble). The Japanese, too, plan to build one, and a copy of the dish destined for Granada has even been ordered by the government of Iraq.

But in spite of its once-widespread support in the United States, "time has passed the 25-meter by", as one astronomer said last week. The most recent review of astronomical priorities, a report by another NAS committee headed by Harvard astronomer George Field (see *Nature* 8 April, p.482), included a subcommittee to set priorities in radio astronomy hardware, headed by Pat Thaddeus of Columbia University's Institute for Space Studies. At that time, the 25-metre telescope seemed likely to be funded, so the final Field report gave top priority to the need for VLBA. Only afterwards, was it clear that even in fiscal year 1983, the 25-metre telescope would not be funded. So its virtual omission from the Field report meant it was doomed.

US radioastronomers hold mixed views about this gap in the field, in which the United States was a pioneer.

On the other hand, nobody disputes that VLBA, if it is built, will be a major advance, as nothing like it is planned elsewhere in the world.

Deborah Shapley

Fields Medal awards

Two Americans and a Frenchman are the 1982 winners of the Fields Medal, the "Nobel Prize" of mathematics, it was announced in Warsaw on Sunday.

The International Congress of Mathematicians (ICM), meeting this year in Poland, awarded the medal to William Thurston of Princeton University, S. T. Yau of the Princeton Institute of Advanced Studies, and Alain Connes, who is at present a director of research at the headquarters of the Centre National de la Recherche Scientifique in Paris. As a mathematician, Connes is attached to the Ecole Normale Superieure and the University of Paris VI.

The Fields Medal, an inspiration of an early president of ICM, is awarded every four years. These are the ninth and tenth awards for Americans, and the sixth for a Frenchman — a remarkable record for France, bearing in mind that the United States has four times the population of France.

Robert Walgate

British academic pay

Five per cent

Last Wednesday a council meeting of the Association of University Teachers (AUT) approved a 5 per cent pay increase for university lecturers. It had little choice. When talks between AUT and the Universities Authorities Panel (the body nominated by the Committee of Vice-Chancellors and Principals to negotiate salaries) reached an impasse, the matter went to arbitration and 5 per cent was recommended. The award, which has been approved by Sir Keith Joseph, Secretary of State for Education, means that the universities will be faced with yet another book-balancing feat. The outcome may be further job losses.

Negotiations between AUT and the vice-chancellors were mainly over how much the universities could afford to set aside for salaries. Initially the vice-chancellors said they could afford nothing. The body both sides most wanted to negotiate with was the government. Each made representations to the government for more money to meet a pay increase. But the government remained adamant that any award must be met from the grants given to the universities by the University Grants Committee. The government did decide, however, to provide £770,000 to meet two-thirds of the cost of the 6 per cent award made to clinical academics to maintain their parity with National Health Service workers. "That is in some way understandable", commented Mr Laurie Sapper, general secretary of AUT, "After all, most government ministers are over 50 and don't want to upset the medics".

AUT was hoping for a much higher award to keep in line with other public sector settlements and to compensate for inflation. The vice-chancellors were in agreement with AUT that it was unfair for members of university staff to have their pay further depressed in relation to other employees in public institutions. But they insisted that an award over 4 per cent, the amount allowed for in the government-set cash limits, could not be met without outside help.

Dr Albert Sloman, chairman of the Committee of Vice-Chancellors, pressed the case for more money in a meeting with Sir Keith Joseph on 25 June. In a further letter on 23 July, after the settlement of the award, Dr Sloman pointed out that the rising salary costs would mean a further running down of the university system. In his written reply Sir Keith Joseph made it clear that additional money would not be forthcoming.

Given the universities' stringent cash limits, the negotiations between AUT and the vice-chancellors left little room for manoeuvre. In giving a 5 per cent award the government's attitude seems to be, if the unions want more money, they know it may mean fewer staff.

US drug regulation

Congress finds FDA wanting

Washington

Eli Lilly and Company has repeatedly failed to report adverse findings about drugs it was testing or marketing, according to Food and Drug Administration (FDA) documents made public last week. Sales of one of the drugs mentioned in the documents, Oraflex (benoxaprofen), were suspended last week in both Britain and the United States after a review of British data revealed 61 deaths associated with its use (see box).

The allegations against Lilly are spelled out in a series of internal FDA memoranda released by the House intergovernmental relations subcommittee, which was holding hearings on FDA's proposed streamlining of the new drug evaluation process.

One of the most serious charges is that "data for benoxaprofen appear to have been deliberately withheld, thus biasing the NDA (new drug application) in favour of approval". The investigator who reached that conclusion, Dr Michael Hensley, recommended last September that FDA "consider prosecution of appropriate Lilly employees".

Dr Hensley's investigation revealed in particular that 65 adverse effects that occurred during the clinical trials of Oraflex were not reported to FDA, even though they were apparently related to the drug, and were in Lilly's files when the application was made in December 1979. These effects were principally photosensitivity and onycholysis (loosening of the fingernails), and all occurred after the "cut-off date" of November 1978 that Lilly had set on data that were to go into their application. The cut-off is apparently a usual procedure.

But the Lilly employee in charge of the application, Dr H.A. Bartlett, did review the adverse effect reports from trials that continued after the "cut-off date", and included "serious" reactions in the application, according to a memorandum written by Dr Hensley on 16 September 1981. This memorandum then states that Dr Bartlett instructed an employee "not to report others (such as onycholysis and photosensitivity) which he allegedly felt were, because of their frequent occurrence, no longer alarming" (*sic*). In fact, the new data showed a sharp increase in the incidence of these side effects. A letter from Dr Marion Finkel, then associate director for new drug evaluation, to R.D. Wood, chairman of the board of Lilly, on 12 March this year charges that "the consequence was a biased presentation clearly more favourable to the drug than was warranted by the data".

Lilly's answer is that FDA regulations simply do not require applications to include data on all adverse reactions observed after the cut-off date. At the subcommittee hearings, Dr Robert Temple, acting director of the office of new drug evaluation, agreed. He called it a "defect in the regulations".

A similar mix-up occurred over the reporting of four deaths from jaundice associated with the drug. Attention was focused on this matter by reports (Goudie, E.M. *et al. Lancet* **i**, 959; 1982/Halsey, J.P. & Cardoe, N. *Br. med. J.* **284**, 1365; 1982.) of several jaundice deaths in Britain associated with Oraflex. On 23 June, FDA officials met Lilly officials to discuss the matter, and "expressed surprise that (American) cases of jaundice had not been submitted prominently to the NDA (new drug application) prior to its approval".

"I'M AFRAID YOU HAVE DOW JONES SYNDROME!"
LILLY
CLINICAL TRIALS
BIRCH

Lilly officials claimed that they had in fact submitted two reports to the IND file before approval. At the subcommittee hearings, FDA officials said they had had no way of checking that, since there was a six-month backlog in processing the IND files. They said they have since found that all four cases were reported to FDA by Lilly — but that FDA reviewers apparently approved the application without seeing the reports. FDA Commissioner Arthur Hayes Jr says that it "wouldn't have made any difference" in the approval, since the reviewers knew about the problem.

Dr Hensley's memorandum of 29 September 1981, in which he recommended possible prosecution of Lilly employees, referred to three other drugs about which he said "allegations . . . . that Lilly has repeatedly failed to make required reports of important adverse findings" had been "confirmed" by FDA investigators. About aprindine, an anti-arrhythmia drug, Dr Hensley found that "Lilly employees may have engaged in highly objectionable, perhaps ethically questionable practices in their handling of the aprindine clinical programme". Furthermore, Lilly apparently ignored findings from its own experiments with dogs of a possibly lethal side effect of the drug, fibrillation. It was not until January 1974, after four patients in the aprindine clinical trials had died, that the dog studies were reviewed and finally reported to FDA on 4 February 1974. An FDA memorandum dated 4 February 1982 recommends that Lilly be issued a "Notification of Adverse Findings" for failing to incorporate the data from the

Arthritis drug proscribed in Britain

A voluntary decision by Eli Lilly to withdraw the anti-arthritis drug benoxaprofen from sale in all countries came soon after the imposition of a 90-day ban on UK sale by the Committee on Safety of Medicines (CMS). The Department of Health withdrew the product licence for the drug (sold under the trade name Opren in the United Kingdom) to allow time to assess the alarming total of 3,500 reports of serious side effects, especially in the elderly.

Benoxaprofen had rapidly become one of the most prescribed of anti-rheumatic drugs since the UK product licence was issued in 1980, and the CMS review cites 61 deaths associated with its use. In the United States the drug (sold as Oraflex) was given FDA approval only in April of this year, but already at least 11 deaths have been linked with benoxaprofen, again mostly in elderly patients and mostly involving liver or kidney damage.

In withdrawing the drug, Eli Lilly was at pains to explain that it still believed benoxaprofen to be safe and effective if used as directed. But after seven years of development before being allowed on the market, the question of why possible contraindications seem to be emerging only at this stage will be taxing regulatory authorities and Lilly's medical teams on both sides of the Atlantic.

Benoxaprofen is undoubtedly effective in many cases of rheumatoid arthritis and osteoarthritis but it is probably not irreplaceable — other non-steroid anti-inflammatory agents with similar activity include aspirin, naproxen, ibuprofen and fenoprofen. For Eli Lilly, though, the whole episode is a major setback. Even if benoxaprofen is allowed back onto the market, the damage will have been done and doctors will be reluctant to prescribe it and patients to take it.

The latest events surrounding benoxaprofen provide another reminder of the high risks involved for companies attempting to reap the high rewards that accompany a successful new drug launch. Only two weeks ago the London Stock Market witnessed extraordinary fluctuations in the price of shares in the pharmaceuticals company Glaxo. High hopes of massive profits from sales of the new anti-ulcer drug Zantac (ranitidine) were dampened when a few reports of possible side effects were publicized with little analysis in the financial press. Share prices recovered when Glaxo and others pointed out the relatively minor nature of the reported effects, but predictably the price has not matched the high levels seen before the fracas.

animal studies into the clinical protocols and failing to report properly to FDA.

Dr Hensley's memorandum of 29 September 1981 concludes that for a third drug, drobuline, proper case report records were not maintained, and protocols were not followed. In the case of the fourth drug, monensin, the FDA documents charge that Lilly failed to report adverse effects in animals and humans exposed to the drug, or delayed reporting these effects by as much as 23 months. Lilly was issued a notice of adverse findings on monensin on 6 July 1981.

At the subcommittee hearings, Lilly issued a statement to reporters denying the charges. "Eli Lilly and Company takes vigorous exception to any implication that it withheld data, maintained inadequate records, or failed to comply with the requirements of the FDA".

Stephen Budiansky

FDA regulations

Saving time, but carefully

Washington

The Food and Drug Administration (FDA)'s plans to relax some of its requirements for new drug applications came under congressional scrutiny last week during two days of hearings that also raised serious questions about Eli Lilly and Company's reporting of adverse effects of its drugs (see p.597).

FDA Commissioner Arthur Hull Hayes Jr, testified that the proposed changes in FDA procedures should shorten the approval process for the average application by six months. It now takes nearly two years. An FDA spokesman said, however, that the new procedures would probably have little effect on applications for drugs deemed important, since they are already given expedited treatment.

Representative L. H. Fountain (Democrat, North Carolina), chairman of the House subcommittee that conducted the hearings, focused strongly on two of FDA's proposed changes. One would drop the requirement that drug companies submit the detailed "case report forms" from clinical trials of the drug; the other would allow FDA to approve a new drug application on the basis of foreign studies.

At present, applicants are required to turn over to FDA all case report forms. These are the reports made by the clinical investigators on each patient; according to FDA, they make up 70 per cent of the applications now, often running into hundreds of volumes. FDA is proposing that, instead, the drug companies should be allowed to submit tabulations of the raw data, and only submit the case reports for cases that raise significant safety questions, such as patients who died, or dropped out of the study because of an adverse effect. The companies would still have to supply the case reports if requested by FDA.

Dr Robert Temple, acting director of the office of new drug evaluation, assured the subcommittee that FDA would not lose anything in the change. But detailed reports "will still be asked for as they're needed", he said; and Commissioner Hayes argued that tabulation of the raw data is "more consistent with current scientific practices".

Subcommittee staff members, however, noted that two in-house reviews at FDA found tabulations which did not agree with the case reports they were supposedly drawn for. They were also concerned that FDA reviewers might be intimidated by the prospect of having to make a special request for the case reports, if for no other reason than the time it would take.

On the issue of foreign data, FDA officials similarly tried to be reassuring that the proposed changes would not undermine FDA's ability to make a thorough evaluation. FDA rules now allow foreign studies to be accepted if the investigators are "well-qualified" and if they make background data available to FDA. But in almost all cases, at least one domestic study is also required.

That would change under the new rules. A drug could be approved solely on the basis of foreign data; Hayes suggested that this would be especially important when requiring domestic trials would "cause an unjustifiable delay in the drug's availability to the public", would result in "unnecessary or duplicative testing", or would present an "unnecessary burden on the drug sponsor".

Foreign data would still have to meet US standards and be the product of "investigators of recognized competence". Critics worry that standards will nonetheless be lowered. Dr Sidney Wolfe of Ralph Nader's Health Research Group, said, "The main problem with the use of foreign data is that the drug laws and the protection of human subjects are weaker everywhere in the world" than they are in the United States. And according to Dr John Nestor, a retired FDA employee who worked for many years reviewing drug applications in the agency's cardio-renal drug division, the main effect of the change will be that "the drug companies will be getting their studies done in Mexico and Canada and everywhere else because it's easier to escape surveillance by FDA". At the subcommittee hearing, Representative Fountain released evidence that FDA had encountered just such problems when it attempted to investigate studies done in Mexico and Canada.

The changes FDA is planning appear to enjoy support in Congress. But there are some reservations. Representative Elliot Levitas (Democrat, Georgia) enthused about the benefits of deregulation, and then implied that the only weapon against the drug companies is vigilance.

Venture capital investment

Now Monsanto

Britain now has one of the best environments in Europe for innovation, a director of the US chemicals company Monsanto said last week. And Mr Richard A. Onians has put Monsanto's money where its mouth is, investing £4.75 million in a new £9.7 million venture capital fund launched last week in London (see *Nature* 5 August, p.505).

Onians describes Monsanto's investment as a window on European technology, but what the company will see through it is mostly British work. The fund is to be managed by Advent Management, which already controls another £10 million fund, Advent Technology, now 15 months old and with ten British investments already under its belt. Monsanto will have no control over the new fund, but Advent Management will use Monsanto for technology assessment.

Monsanto itself seems to have been tempted to Britain for its "window" because of government willingness to allow foreign investment (France would not let Monsanto invest there, in spite of a desperate need to rebuild the French chemical industry), low capital gains taxes and because of what Onians called British inventiveness. There are probably plenty of potential British entrepreneurs as well, he thinks, if only the money is made available.

Sir Kenneth Cork, the accountant and ex-Lord Mayor of London who is chairman of the new fund, believes Britain could make good use of £500 million of venture capital, ten times the total probably now on offer. "But the Trades Union Council plan of £1,000 million from government and £1,000 million from industry just wouldn't work", he said; venture money needs to be hard to get.

Advent Management has certainly found it harder to raise the money for Advent Eurofund than it was two years ago to raise it for Advent Technology, an essentially similar fund. The fashion among finance houses and insurance companies for investing in such funds seems to have been short-lived, says Advent director David Cooksey.

University investment in high technology venture funds seems, however, to be new — new certainly for Cambridge (£500,000) and Oxford (£100,000). St Andrews, Imperial College London, the Nuffield Foundation and Boston University (Massachusetts) have also invested, reaching a total academic interest of £1.5 million. Some 20 other British universities were interested, said Cooksey, but they had not got the cash.

From the universities' point of view, these investments are dealt with like any other but offer a chance of protecting assets against inflation. Cooksey, however, clearly sees them as a window on potential invention, and this is bound to be

0028-0836/82/320598-02$01.00

the case even though no formal arrangements have been made. There is no need for formal committees, Mr W. Hyde, Secretary of the Chest (finance officer) at the University of Oxford, says the "old boy network" will suffice. **Robert Walgate**

Polish students abroad

A helping hand

Polish University students stranded in Britain by the declaration of martial law last December should be able to continue their education in Britain under a scheme launched by a group of academics at the London School of Economics (LSE). Following a personal appeal to university principals by Lord James of Rusholme, thirty universities and colleges have offered free places to Polish students unable to continue their studies in Poland.

A preliminary count of students last spring suggested that between forty and fifty places would be needed. Since 22 July, however, when General Jaruzelski made it clear that there would be no early end to martial law, some fifty more students have applied for assistance.

Most of the students had come to Britain on temporary leave of absence from their universities in order to learn English. Many of them, at the same time, had been appointed as roving delegates of the Independent Students' Association (NZS), which hoped to build up strong ties with students unions abroad. NZS was outlawed last January (unlike Solidarity, which technically is only "suspended"), a factor which has undoubtedly influenced the students' decision to remain abroad.

Incorporating the Polish students into the British university structure involves a number of difficulties, even with science students where the curriculum differences are least. Poland has no bachelor's degree; university courses normally last five years, ending with a master's degree.

A compromise has been worked out, whereby students who should be beginning fourth or fifth year work in Poland will enter the second year in British universities, while their juniors will begin again from the beginning. The students themselves seem fairly happy with this plan, since a few terms of what is essentially revision will offset the difficulties of studying in English.

The LSE team, which is acting as an unofficial placement board, feels confident that places will be found for all Polish students who genuinely wish to continue their studies in Britain. The main problem is now that of maintenance; the team estimates that, to take advantage of the places so far offered, it will have to raise some £200,000 for the students' maintenance over three years. A charitable trust — the Polish Students' Appeal Fund — has been launched, and possibilities such as local authority rent rebates are being explored. **Vera Rich**

Nature guide to bio-riches

As a service to readers working in biotechnology, to those who may have invested in this new technology or who may regard its commercial fortunes as an indicator of the success with which bright ideas can be turned into commercial reality, *Nature* will in future publish a monthly listing of the stock performance of 15 representative biotechnology companies in the United States.

This scoreboard of performance will appear in the second issue each month, and will record the price of each of the stocks as traded on the last Friday of the month immediately preceding, the traded price at the end of the preceding month, and the high and low prices during the calendar year.

Where the stocks concerned are traded on the New York Stock Exchange or the American Exchange, the prices listed are those traded. For stocks traded over-the-counter, the prices listed are the bid prices.

***Nature* will also publish once a month a weighted index of the listed stocks, taking an initial value of 100 as of 25 June 1982. In the calculation of this index, the contributions of the 15 listed stocks to the index are weighted according to the total value of the issued stock.**

Between the Fridays of 25 June and 30 July, the *Nature* Biotechnology Index increased from 100 to 102.7.

The data (as of 25 June 1982) on which these calculations will be based are shown in the following table.

Market value of biotechnology stocks, 25 June 1982

	Outstanding shares (millions)	Closing price 25/6/82 ($)	Total market value ($ million)	% of all total market values
A.B. Fortia	19	23.375	444.1	21
Bio-Response	5.5	4.25	23.4	01
Cetus	22	8.0	176.0	08
Collaborative Research	8	8.0	64.0	03
Collagen	5.1	17.875	91.2	04
Damon	6.6	6.5	42.9	02
Enzo-Biochem	5.0	14.75	73.8	04
Flow General	8.0	8.5	68.0	03
Genentech	8.1	32.75	265.3	13
Hybritech	8.8	12.5	110.0	05
Molecular Genetics	4.0	8.5	34.0	02
Novo Industri A/S	16.6	38.25	635	30
Monoclonal Antibodies	2.0	9.5	19	01
Genetic Systems	13.7	2.75	37.7	02
Bio Logicals	5.9	2.75	16.2	01
Total			2,100.6	100

From time to time, *Nature* will also publish graphical analyses of the performance of stocks of particular interest, perhaps because the corporation is going through an eventful period or because the industry as a whole is at some turning point.

The stocks listed have been selected from among the much larger number for which data are available on somewhat arbitrary criteria — because of the volume of transactions, for example. It is intended to review the listing from time to time.

***Nature* is grateful to E.F. Hutton and Co., Inc., for advice on the design of this service and for assistance with the compilation of the data. Suggestions from readers will be welcome.**

Performance of biotechnology stocks, 30 July 1982

1982 high	1982 low		Close previous month	Close July 30	Change
28	16$^1/_8$	**A. B. Fortia**	23$^3/_8$	25¾	+2$^3/_8$

CORRESPONDENCE

Celltech and MRC

Sir — The House of Commons Select Committee's remarks (*Nature* 5 August, p.505) on Celltech's links with the Medical Research Council (MRC) raise some important issues:

(i) The cost of developing a discovery and bringing it to the market often makes a degree of monopoly essential if it is to be worthwhile for anyone to take on the development risk. On the other hand, giving one body monopoly rights for all inventions for all time may lead to stultification. So a good balance between exclusivity and competition needs to be struck.

(ii) Industry and academia quite rightly differ in their aims and ways of doing things, so collaboration between them will not be productive unless mutual understanding about aims and methods reaches a high enough level. This probably requires individuals and organizations to work together quite closely over a period of time.

The agreement between Celltech and MRC gives Celltech only a first option — MRC must always be satisfied with the commercial plans. It has other features novel in the United Kingdom which bring MRC and Celltech scientists closer together. Experimentation with a variety of frameworks for industrial/academic collaboration is highly desirable and that between MRC and Celltech may turn out to be worth copying. It has been operating for less than two years but has already led to commercial success, for example, in anti-interferon. The time is perhaps too short to have tested the ideas fully but if a review at this stage could be helpful to others, I would be happy to see it.

G.H. Fairtlough

Chief Executive,
Celltech Limited,
Slough, Bucks, UK

The numbers game

Sir — Dr H. H. Rossi (*Nature* 22 July, p.320) makes a plea for a modification of our way of writing quantities in the SI system.

This raises various issues. The numbers we write in English speaking countries as 1.234 and 1,234 tend to be written the other way round in continental Europe (with a "decimal comma" instead of a decimal point, and a dot for thousands). This is a dangerous confusion, and one has to be thankful that so far it hasn't resulted in catastrophe. What makes it worse is that especially in handwriting (and sometimes also in print) not only may dots and commas be difficult to distinguish reliably, but also they may be so faint as to escape notice altogether.

What is wanted is a good clear symbol for the decimal point, which ideally should be already present on all ordinary typewriters, and not already used as a symbol for a unit of measurement or easily confused in handwriting with such a symbol.

About the only symbols satisfying all these conditions are "&" and the letter "u". If we wrote "2&34" or "2u34" for "2.34" there would be little danger of confusion. There is also a lot to be said for the admirable brevity of the occasional continental habit of writing, say, 2.34 m as "2m34". It is quicker to write and to say, and is unambiguous. Brevity is a great help to clarity. Although "0.700" means exactly the same as ".7", it is ".7" which makes the quickest and strongest impression on the mind.

For representing numbers in so-called scientific notation, I would suggest that we write, for example, 2(6)34 for 2.34×10^6. This notation is brief and more flexible than the traditional one. There is no objection to writing 1(3)234(0)567(-3)g if one wishes, showing simultaneously that this is 1.234567 kg, or 1234.567 g, or 1234567 mg, according to which units are most convenient. In addition, 2(3), meaning 2000, could be written unambiguously as 2(3 with the second bracket understood, again encouraging brevity, and similarly (6)14 (= .14 million) could be written 6)14.

Of course some problems remain; for example most computers already use brackets in at least two other senses already. Perhaps a convention should be made of using square brackets in computer programs, writing 2[68]34 for what is now more clumsily written 2.34E06 or 2.34×10^6. But these problems should resolve themselves in due course.

Department of Genetics and Biometry,
University College London, UK

Drugs as carcinogens

Sir — The main impression given by Dr M. Weatherall (*Nature* 1 April, p.387) is that the maintenance and improvement of the health of humans should be based principally on the development of new drugs, and that any delay, such as compliance with government regulations, in the introduction of a new drug would result in an increased loss of human health.

Fortunately the approach of regulatory agencies differs from that of the pharmaceutical industries. The agencies attempt to reduce the occurrence in the population of side effects of drugs and to assess the benefits of drug therapy. The causes of the major diseases are only partly known, and an incomplete rationale behind the therapy for such diseases results in what L. Thomas has called "halfway technology"[1], involving very high costs and relatively unsatisfactory results. An additional problem is that the effectiveness of medicines is oversold[2].

Improvement of human health in the future will depend on greater knowledge of the aetiopathogenesis of diseases, on improvements in social conditions and on more specific treatments[1-7]. Priority should be given to maintaining a proper balance among these different approaches.

There are certainly limitations in the capacity of *in vitro* assays and *in vivo* carcinogenicity tests for the detection of possible carcinogenicity in humans. However, the intelligent use of such tools has proven valid in predicting carcinogenic effects in man[8]. Of the drugs mentioned by Dr Weatherall, phenacetin induces tumours of the urinary system of rats, and epidemiological studies[9] show the same organ system to be the target for its carcinogenic effect in humans; there is also evidence that phenacetin is a mutagen in bacteria and mammalian cells[9]. Azathioprine, chlorambucil and cyclophosphamide, known to be responsible for an increased risk of developing tumours among patients undergoing kidney transplantation, are carcinogenic in experimental animals and mutagenic in various systems[9]. Metronidazole is carcinogenic in mice and rats and mutagenic in bacteria and fungi, while the available epidemiological data are inadequate for a proper assessment of its carcinogenicity in humans. The following drugs or treatments, proven to be carcinogenic in humans, were also found to be carcinogenic in experimental animals: chlornaphazine, myleran, melphalan, methoxsalen (in combination with ultraviolet A irradiation, PUVA), and diethylstilboestrol. Chlornaphazine, myleran, melphalan and PUVA are also mutagens[9].

Thus evidence of an adverse effect observed in experimental systems should not be underestimated, and in some cases, it can have value as a predictor for a similar effect in humans. This value should increase as more is known of the mechanisms of carcinogenesis.

A summary by Dollery[10] of a recent meeting concludes that there is still a tendency to underestimate risks and to overestimate benefits when evaluating drugs. It seems reasonable that the experimental tests to detect possible side effects of drugs should remain a part of the process of the development of a drug, one of the main aims being the provision of reliable information on which a risk-benefit evaluation can be made. The argument that this process is expensive is tenuous, when one considers that approximately 10 per cent of the budget of the pharmaceutical industry is devoted to research and development and 20 per cent to the marketing of drugs. It is worth mentioning that recently, WHO has listed a total of approximately 200 essential drugs to help in the maintenance of health[11], a very small number compared with the number of drugs now on the market.

What are quarks made of?

from Louis Lyons

In 1964, the properties of the hundreds of 'elementary' particles then known were explained in terms of just three quarks. But, since then, the number of quark types has grown. Added to the original up, down and strange quarks are the charmed and bottom quarks and a sixth, the top quark, is presumed to exist. Furthermore, each quark is now known to exist in three different 'colours' and a further eight particles, the gluons, are required to mediate the binding forces between them.

History thus seems to be repeating itself for in each past attempt to explain the ultimate structure of matter, an initial reduction in the number of entities required — be they atoms, nuclei or elementary particles — has been followed by further discoveries of similar objects until, finally, the cycle has repeated itself and another level of substructure has been proposed at which the number of basic particles has again become small. Are we to believe then that quarks are not, after all, elementary?

In addition to quarks, which are the constituents of the strongly interacting particles mentioned above, the world also contains leptons. The best known are the electron and its neutrino, but nature has twice replicated them with the muon and the tau leptons, which both appear to be simply heavier versions of the electron and both of which have their own neutrino. Some of the properties of leptons and quarks are listed in the table.

The repetitive similarities of both the quarks and leptons suggest that they be grouped in families or generations with increasing mass, in a manner somewhat reminiscent of the chemical periodic table. This in itself is suggestive of another level of substructure for quarks and leptons. Again, further generations may also exist, still waiting to be discovered.

A wide variety of suggestions concerning substructure has been made in the past couple of years[1]. Any prospective model must address a number of issues: (1) How many preons (the name given to the substructure elements) make a quark or lepton? (2) Should quarks and leptons be constructed entirely from the same preons or should at least one preon in a quark and in a lepton differ? (3) Are the preons bound together by gravity, electromagnetism or some new extra strong force? (4) What is the energy scale Λ or distance scale r on which quarks and leptons are composite? Popular values congregate around about 10^3 GeV or 10^{15}–10^{19} GeV (equivalent to $r \sim 10^{-17}$ cm or 10^{-39}–10^{-33} cm [the mass of the proton is ~ 1 GeV]). (5) What makes the different generations, and how many are there? Are the higher ones simply some form of excitation of the first, do they contain extra combinations of preons, does one preon exist in a few different forms, do they correspond to a fine structure type splitting, or something entirely different? (6) What is a plausible scenario for making the composite systems so light on the scale of Λ, and yet still have an interesting mass spectrum (see Table 1)? (7) What other dynamical predictions can be made?

Louis Lyons is in the Department of Nuclear Physics, University of Oxford, Keble Road, Oxford OX1 3RH.

One model[2] has preons T and V of charge 1/3 and zero respectively. The first generation quarks are TTV and $\bar{T}\bar{V}\bar{V}$ composites while the electron and its neutrino are $\bar{T}\bar{T}\bar{T}$ and VVV (the bar above a preon denotes its antiparticle). In another model[3] the preons are labelled h_i, w_j and c_k, where h_1, h_2 and h_3 determine the generation, w_1 and w_2 are two different charged preons, and c_1, c_2 and c_3 give the three colours to the quarks while c_0 is the charged colourless lepton's preon. Here the blue up and down quarks are $h_1 w_1 c_3$ and $h_1 w_2 c_3$, while the μ^- is $h_2 w_2 c_0$.

Most models nowadays try to do more than simply obtain the quantum numbers (that is spin, charge, colour, generation number, etc.) of the observed quarks and leptons. However, there are not many testable predictions and those that exist are often not very specific to substructure models. Thus many composite models suggest that neutrinos should not be exactly massless and that the proton should decay at a very slow rate; but other non-composite models make these predictions as well. A significant advance would be if a mass formula were deduced, which enables as yet undiscovered quarks and/or leptons to be predicted.

The obvious question is whether there is any experimental evidence in favour of quarks or leptons being composite. The answer to date is 'No'. The relevant experiments can then be used to set lower limits on Λ.

For example, the magnetic moments of truly elementary particles can be predicted from quantum electrodynamics. Substructure effects are likely to produce deviations; the composite nature of atoms, nuclei and even 'elementary' particles results in their magnetic moments differing from the predictions for point-like objects. The fact that the magnetic moment of the electron and muon agree with point-like values, to accuracies of 1 in 10^9 and 1 in 10^8 respectively, results in stringent constraints on their composite structure.

Other sources of information on Λ include reactions such as $e^+e^- \rightarrow \mu^+\mu^-$, e^+e^- annihilations producing strongly interacting particles, and the scattering of muons or neutrinos off nuclei. In all cases

Table 1 Properties of quarks and leptons

Generation 1	Up(u)	Down(d)	Electron(e^-)	Neutrino(ν_e)
Mass (GeV c^{-2})	0.3	0.3	5×10^{-4}	$<5 \times 10^{-8}$
Generation 2	Charm(c)	Strange(s)	Muon(μ^-)	Neutrino(ν_μ)
Mass (GeV c^{-2})	1.5	0.5	0.1	$<6 \times 10^{-4}$
Generation 3	[Top(t)]	Bottom(b)	Tau(τ^-)	Neutrino(ν_τ)
Mass (GeV c^{-2})	?	5	1.8	<0.3
Quark or lepton	Quark	Quark	Lepton	Lepton
Electric charge	+2/3	−1/3	−1	0
Colour	Red, green, blue		Colourless	Colourless
Directly observed?	No		Yes	Yes
Forces	Strong Electromagnetic Weak		Electromagnetic Weak	Weak

0028-0836/82/320601-02$01.00

to date, the predictions based on a point-like nature of quarks and leptons agree with experiment.

The above data can be used to deduce that Λ is greater than 600 GeV. Thus quarks and leptons, if they are composite, must be very tightly bound systems, since their masses are so much smaller than Λ.

There are other reactions and decays which are expected in some models of substructure. Thus if the muon is an excited state of an electron, the decay $\mu \rightarrow e\gamma$ should occur. Similarly, if the quarks in a proton share a common substructure with leptons, proton decay becomes possible. Again none of these types of processes has been seen, but because of the model dependence of the predictions, no firm limit on Λ can be deduced.

Theoretical speculation to date has thus been unhampered by any positive experimental evidence. Models have thus become exercises in self-consistency with the main constraints coming from the need to produce almost massless composite states and the necessity of not violating any experimental bounds which have been set in attempts to observe substructure effects.

The main hope for the future is that experiments at the new accelerators becoming available during this decade may reveal direct evidence for quarks and/or leptons possessing substructure. This would then change the motivation for the subject from the realms of aesthetics, history, psychology and sociology to that of physics. □

Proteins containing nickel

from Andrew J. Thomson

NICKEL long stood out among the six metallic elements of the latter half of the first transition series, namely, Mn, Fe, Co, Ni, Cu and Zn, as being apparently without biological function apart from its toxicity. The situation has changed rapidly in the last few years[1]. Nickel is now known to be a nutritional requirement for many eukaryotic and prokaryotic organisms.

The element has been shown to be a component of urease in plant cells growing on urea as sole nitrogen source[2], to be present in the hydrogenases from several types of bacteria including those which can perform the Knallgas reaction ($2H_2 + O_2 \rightarrow 2H_2O$)[3] and the sulphate-reducing bacterium *Desulphovibrio gigas* [4,5], to be in the enzyme carbon monoxide dehydrogenase in acetogenic bacteria[6] and, lastly so far, in a low molecular weight tetrapyrrole present in methanogenic bacteria[7,8]. Other roles for nickel are also apparent in, for example, a plant such as *Alyssum* which accumulates large amounts of nickel[9] and in a strain of *Bacillus cereus* which forms a nickel-containing intracellular pigment that is probably a protein[1]. It has also been suggested that nickel is involved in endosphere formation of these bacteria[1].

Urease catalyses the hydrolysis of urea in the reaction

$$(NH_2)_2CO + H_2O \rightarrow CO_2 + 2NH_3$$

The enzyme from jack bean contains about 6–8 mol of nickel per mol of protein (molecular weight 480,000). The metal appears to be in the oxidation state +II (ref. 2). This contrasts with the nickel centres recently discovered in some hydrogenases from *Methanobacterium thermoautotrophicum*[3] and from *D. gigas* which have been ascribed to nickel in the trivalent or +III state since electron paramagnetic resonance (EPR) signals are readily detectable[4,5]. These discoveries stemmed from earlier observations that nickel is required for the biosynthesis of hydrogenase in 'Knallgas' bacteria[10] and that there is an EPR signal in both soluble and membrane-bound fractions from the methanogen *M. bryantii* [11]. The assignment of the EPR signals in this latter case to Ni III, by Lancaster [11], was a bold one. The Ni III/Ni II potential of inorganic complexes of peptides was known to be above 0.7V, making Ni III an unlikely species in a hydrogenase[12].

However, Lancaster was persuaded of this assignment for the following reasons[11]. The signals occurred at $g_1 = 2.30$, 2.23 and 2.02, all above the free-electron value and therefore unlikely to arise from haem. They were observable up to 80K and were quite unlike those of any known iron-sulphur centres. The *g*-factors pointed to a metal ion with the electronic structure low-spin d^7. The lack of nuclear hyperfine structure eliminated cobalt(II). This left Ni III as the only candidate, however unlikely on chemical grounds.

It has since been shown that the hydrogenase from *M. thermoautotrophicum*[3] also gives the characteristic nickel EPR signals at *g*-factors of 2.3, 2.2 and 2.0. Studies of the hydrogenase purified from cells grown on a medium enriched in ^{61}Ni, an isotope with a nuclear spin of 3/2, showed nuclear hyperfine structure on the lines at 2.23 and 2.01, which proved beyond doubt that these signals arise from nickel. A spin quantification of the nickel EPR signals gives a value in close correspondence with the chemically determined nickel content, being about 0.6 mol Ni per mol enzyme.

The assignment of the nickel ion to the trivalent state has now been confirmed by a study of the EPR spectrum of the periplasmic hydrogenase from *D. gigas* [4,5]. A redox titration of the $g = 2.24$ signal from nickel in this enzyme shows that it is lost on reduction with a mid-point potential (E_m) of −145 mV at *p*H 7.2 (ref. 5). Moreover the E_m value is *p*H dependent, showing that one proton is picked up during reduction[5]. These potentials are higher than those of the $2H^+/H_2$ couple by about 280 mV, raising obvious mechanistic difficulties for the involvement of the nickel centre directly.

The low redox potential for the Ni III/Ni II couple also raises interesting questions about the likely coordination site of the metal ion in the protein. Several nickel–peptide complexes have been prepared which involve a rather narrow range of amino acids, including leucine, phenylalanine, histidine and aspartic acid[12]. The complexes can be electrochemically oxidized to the trivalent state at E_m values of between +0.79 and +0.96 V. The oxidized state appears to involve the deprotonated peptide linkage. The EPR properties of the Ni III peptides are not dissimilar from those of the protein-bound Ni III ion. However, the remarkably different redox properties argue for a very different site of ligation in the protein possibly involving sulphur ligands.

The periplasmic hydrogenase from *D. gigas* also contains about 12 Fe atoms per mol, undoubtedly arranged into several separate iron-sulphur centres[4]. EPR signals are also observed from these centres both in the oxidized and reduced states of the enzyme. Curiously, however, Albracht *et al.* could detect no iron-sulphur EPR signals in the hydrogenase purified from *M. thermoautotrophicum*[3]. All hydrogenases purified before this report contain iron-sulphur centres. The authors do not yet discount the possibility that the iron-sulphur centres could have been lost during aerobic purification of the enzyme. If not, this will be an intriguing case of a hydrogenase containing only nickel as its metal component.

Pre-dating much of this work on the EPR detection of Ni III in hydrogenases were the observations that nickel is necessary for the biosynthesis of carbon monoxide dehydrogenase in acetogenic bacteria such as *Clostridium thermoaceticum*, *C. aceticum* and *Acetobacter Woodii*[13] and also for the growth of methanogenic bacteria with H_2 plus CO_2 as sole energy source[10]. The two classes of reaction being catalysed are respectively

$$8[H] + 2O_2 \rightarrow CH_3COOH + 2H_2O$$
$$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$$

Andrew J. Thomson is in the School of Chemical Sciences, University of East Anglia, Norwich NR4 7TJ.

0028-0836/82/320602-02$01.00

From the methanogenic bacterium *M. thermoautotrophicum* it is possible to isolate a yellow, low molecular weight nickel-containing compound with an absorption maximum at 430 nm, hence named factor F$_{430}$ (ref. 7). This factor has been found in every methanogenic bacterium so far examined[8]. The extinction coefficient at 430 nm is high, $\sim 23 \times 10^3$ per cm per mol Ni. The exact structure of this pigment has not yet been elucidated but there is evidence from the biosynthetic incorporation of δ-amino laevulinic acid that F$_{430}$ is a nickel tetrapyrrole[14]. Chemical degradation products of F$_{430}$ have appreciable absorption in the region 500–600 nm and react with cyanide. It has been suggested that the spectrum resembles that of vitamin B$_{12}$ with, presumably, the implication that the nickel species is related to nirrin, the nickel analogue of corrin[1]. There is evidence of a mechanistic kind that the carbon monoxide oxidation in acetogenic bacteria may also involve a prosthetic group similar in structure in vitamin B$_{12}$ but with nickel in place of cobalt[15]. There is a very recent report that the co-enzyme of the purified methyl reductase of *M. thermoautotrophicum* is F$_{430}$, with a stochiometry of 1 mol of nickel per mol of F$_{430}$ and 2 mol of F$_{430}$ per mol of methyl reductase[16].

Thus it is now clear that there are at least two new classes of nickel-containing enzymes: the nickel-containing hydrogenases and those with a nickel tetrapyrrole-related co-factor. Much work on their structural elucidation needs to be carried through. □

Remote operation of telescopes

from Michael Penston

BRITISH astronomers have recently moved to the fore in several branches of optical astronomy, thanks largely to the building of new telescopes in favourable sites abroad — in particular the Anglo-Australian Telescope at Coonabarabran, New South Wales, and the UK Infrared Telescope (UKIRT) on Mauna Kea in Hawaii. Access to the telescopes has, not surprisingly, so far depended on the opportunities provided by air travel. Now, astronomers have begun discussing whether modern communications technology offers an alternative way of working. Early in June experts in communcations and computer technology came together with astronomers and builders of astronomical instruments at the Royal Greenwich Observatory (RGO) to discuss the feasibility of remote operation of telescopes*.

Remote operations of telescopes is possible and, indeed, has already been carried out in an experimental way by Kitt Peak National Observatory and UKIRT. The Kitt Peak 4 m and 2.1 m telescopes have been used by observers at the end of telephone lines both from nearby downtown Tucson and at distant sites in Michigan and the East Coast of the United States. Three lines were used — one for voice, one for TV pictures needed by the astronomer to identify his target star and one to run a remote terminal linked to the computer in the telescope dome. UKIRT is running a similar system which offers the major advantage of being able to diagnose and solve instrumental problems from sea level without suffering the problems of lack of oxygen at the Mauna Kea telescope site 14,000 feet higher up.

There is little difficulty in sending the acquisition images of star fields. Images with 10,000–20,000 pixels with 3–4 grey levels transmitted each 10–20 seconds are perfectly adequate as this update rate is used by current integrating TV systems on telescopes. These could pass down a standard 9.6 kbit line even without data compression. In fact, the Kitt Peak experiment had found a 30 second update rate to be satisfactory. On the other hand, present astronomical practises regarding weather monitoring and protection of the instruments from damage were not so easily compatible with remote operation. A better ways of determining whether the humidity is high enough to hazard the telescope mirror than the traditional test of 'whether the dome rail is wet' needs to be developed. A more professional approach would even benefit conventional observing with the observer present.

The financial benefits of remote observing are obvious, given rising air fares and falling communications costs. Advantages in flexibility might also be provided — the difficulties of scheduling simultaneous observations on different telescope and/or satellites might, for example, be eased. When some particularly demanding meteorological requirement is expected to be met for only a short time (for example, conditions dry enough to use an IR telescope in the 350 μm 'window') it would be easier to put a different observer on the telescope if he did not have to travel so far to exploit this short period. Efficiency would also be improved as astronomers would spend less time travelling and recovering from jet-lag.

There are individual problems in communicating from different sites as reports by Paul Bryant (Rutherford and Appleton Laboratories) and Peter Kirstein (University College London) showed a somewhat anarchic situation in the communications field. There are differences in computer-to-computer communication protocols, in line tariffs and in regulations from country to country so that the best solution at one observatory might not apply at another. Obviously, however, common requirements exist and common solutions and standards are highly desirable as participants, looking ahead, foresaw a network for remote operation of telescopes linking Australia, Hawaii, Chile, continental United States, the Canary Islands and Europe. One solution to the present problem was to separate the difficulties of communication and control, defining interfaces between these segments only. Thus cheap entry to the field could be obtained with use of dial-up telephone lines, as at present, and when wide band lines or public packet switching networks become cheaper it would be possible to change to them with minimum distruption. The eventual use of wide-band 50 kbit lines was foreseen since that would allow near-real-time transmission of astronomical data from the telescope to the site of remote operations. In the meantime it seems most practical to progress using two to three dedicated telephone lines.

At the end of the meeting Alec Boksenberg, Director of the RGO, undertook to have remote operation from Herstmonceux of the 2.5 m Isaac Newton and 1.0 m telescopes on La Palma working by the end of next year. Obviously at this pace, the sky is the limit in the remote operations field. □

Michael Penston is at the Royal Greenwich Observatory, Herstmonceux Castle, Hailsham, East Sussex BN27 1RP.

---

*The two-day workshop on 'Remote operation of telescopes' was held at Herstmonceux Castle, home of the Royal Greenwich Observatory. Participants included representatives from UKIRT, Kitt Peak National Observatory, the European Southern Observatory and the European Space Agency as well as British astronomers and experts in computer networking.

The biogeography of the Pacific Basin

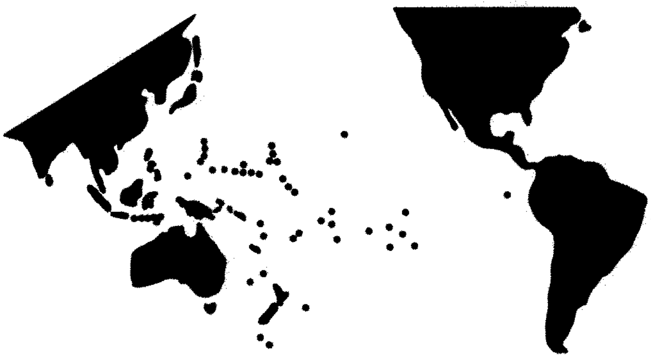
from Jared M. Diamond

THE Pacific Basin includes the world's largest and deepest ocean as well as most of the world's islands. It constitutes the eastern half of the richest province of marine biogeography, and is bordered by five of the six provinces of terrestrial biogeography. Its biota includes textbook examples of adaptive radiation, such as the Galapagos finches, the honey-creepers and *Drosophila* of Hawaii, and the marsupials of Australia and New Guinea. Little wonder then, that it has long held a fascination for biogeographers.

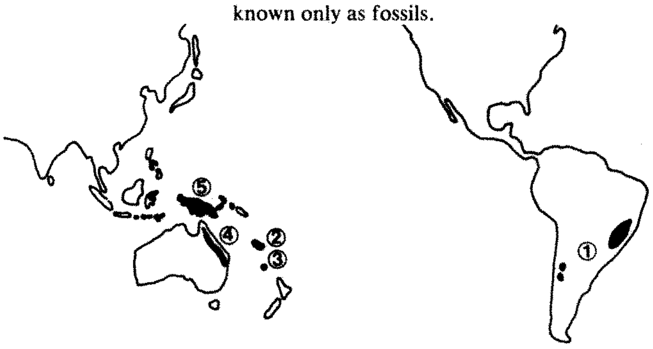
The last major symposium on Pacific Basin biogeography was convened 21 years ago in Honolulu at the 10th Pacific Science Congress, by J.L. Gressitt[1]. For the recent 10th annual meeting of the Association of Systematics Collections* Gressitt again organized a symposium on Pacific Basin biogeography at Honolulu's Bishop Museum. Sadly, the symposium took place without him — a month before the conference he died in an aeroplane crash in China.

The 1961 symposium was marked by polemical discussions about the relative contributions of long-distance overwater dispersal, former land bridges and continental drift to the founding of Pacific biotas. Proponents of one factor often dismissed the possibility of any significant role of the other factors in scathing terms. In retrospect, we can now see that the polemics arose because convincing evidence to settle the dispute was unavailable in 1961. At that time it equally strained one's credulity to accept that continental drift had occurred, or to accept that long-distance dispersal could explain everything in the absence of drift. In the following 21 years new types of evidence have made continental drift an accepted fact. Participants at the 1982 symposium took it for granted that drift and dispersal were both significant, and they proceeded without polemics to seek explanations for distributional patterns in terms of both.

Carson's studies on Hawaiian *Drosophila* provide a good example. In Hawaii, this genus is represented by hundreds of endemic species, whose interrelationships can be determined from the banding patterns of giant chromosomes[2]. For all of the 26 large picture-winged species of Big Island, the nearest relative among the species on the older islands of Maui, Oahu and Kauai (respectively 1.8, 3.3 and 5.6 Myr old) has been identified. As Big Island is only 700,000 years old, these 26 populations (25 of them endemic to Big Island at the species level) must have arisen within that time by overwater colonizations from known sources, followed by reorganization of the gene pool (see J.S. Jones *News & Views* **289** 743; 1981). One infers similarly rapid speciation in the Hawaiian honey-creepers (Drepanididae) and other Hawaiian taxa, and in the tree sunflowers of the Juan Fernandez islands (about 1–4 Myr old).



Above, Pacific distribution of herons of genus *Egretta,* resulting from overwater dispersal that continues today. These birds are strong fliers and reach almost every scrap of land in the Pacific, no matter how remote. Herons have landed on ships in mid-ocean thousands of miles from land. Below, Pacific distribution of araucarias, resulting from continental drift. The huge cones and large seeds of these trees are unsuitable for overwater dispersal. Today, native araucarias are confined to South America (1), New Caledonia (2), Norfolk Island (3), Queensland (4) and New Guinea (5). After the breakup of the supercontinent Gondwanaland 50–100 Myr ago, araucarias survived on some of its fragments and were rafted by continental drift to their present locations. On other fragments, such as Antarctica, New Zealand, India and South Africa, araucarias became extinct and are known only as fossils.



Yet biochemical dating indicates that the Hawaiian *Drosophila*[3] and honey-creepers[4] diverged from their mainland relatives at a date estimated at 15–42 Myr ago, considerably before the oldest of the existing Hawaiian high islands rose above the sea! The explanation is that the existing Hawaiian high islands are merely the youngest in a chain of volcanoes formed by relative motion of the Pacific Plate and a volcanic hot spot, and subject to gradual erosion and submergence after formation. The Hawaiian low islands (11–27 Myr old) and the submerged Emperor Seamounts (37–70 Myr old) are the modern remains of older high islands on which the ancestors of the Hawaiian *Drosophila* and honey-creepers presumably made their initial colonization and then diverged.

In contrast to this explosive radiation of *Drosophila*, some other taxa, such as ferns, bats, inshore marine fishes and molluscs, and plants of coral atolls, exhibit little or no local adaptive radiation and little local endemism beyond the species level on Pacific islands east of New Guinea. At the opposite extreme, achatinellid land snails have evolved numerous endemic genera on Hawaii, Juan Fernandez and the Australs, including nine endemic genera and one nearly endemic subfamily on the small (16 mi²) island of Rapa alone[5]! Numerous groups of insects and flowering plants are also prone to local endemism and adaptive radiation, while Pacific land birds have radiated only on Hawaii, the Galapagos and New Zealand and belong elsewhere mainly to New Guinea genera or closely related genera. Why such differences among taxa? A large part of the explanation is intertaxon differences in dispersal ability. Differentiation and radiation proceed rapidly when a rare colonist of a sedentary group, such as land snails, reaches an island. However, differentiation and radiation are inhibited by the rain of colonists in mobile species such as ferns, with their wind-borne spores, or marine fish and molluscs, with their planktonic larvae. Another relevant factor is inter-taxon differences in propensity for evolutionary losses of dispersal ability[6,7]: colonizing birds and insects often evolve to become literally flightless, and plants figuratively so, but there is no case of a flightless bat (how could one forage?).

A major contribution of continental drift has been to clarify how certain taxa of poor overwater crossing ability came to

0028-0836/82/320604-02$01.00

have far-flung representatives on New Caledonia, New Zealand, Australia, New Guinea and South America. The numerous examples include southern beech (*Nothofagus*), hoop pines (*Araucaria*), marsupials, leptodactylid frogs, migadopine carabid beetles and peloridiid bugs. It was tacitly assumed without argument at the 1982 symposium, and hotly debated at the 1961 symposium, that these land masses were formerly joined in Gondwanaland and that these taxa were rafted to their present locations by the motion of Gondwanaland's fragments. Yet a mystery remains why the rafted survivors constitute such a selective fraction of Gondwanaland's former biota. With the doubtful exception of a flightless bird (the Kagu), New Caledonia has no Gondwanan relict vertebrates: in fact its only other flightless vertebrates are some lizards and one other flightless bird, endemic but recently derived. The sole candidates for Gondwanan relict vertebrates on New Zealand are its flightless birds, its two frogs and a primitive reptile (the Tuatara). How did New Caledonia and New Zealand come to lack marsupials and other Gondwanan vertebrates that survived in Australia and South America? Could New Caledonia and New Zealand somehow have acquired Gondwanan trees without the vertebrates living in them, and Gondwanan insects without the vertebrates eating them[8]? Or, did most of the old vertebrates become extinct in the confined areas of New Caledonia and New Zealand, because vertebrates require larger areas for long-term survival than do many insects and plants? Could some of the flying birds of Australia be Gondwanan relicts, like the marsupials[9,10]? □

Warts and all

from M. Saveria Campo

THE last few years have seen a remarkable progress in our knowledge of papillomaviruses, as was very evident at a recent workshop* involving clinicians, pathologists and virologists and held in Freiburg. Papillomaviruses are the aetiological agents of papillomas or warts in their natural hosts, and are widespread and heterogeneous: so far twelve different types of human papillomavirus (HPV1-12) and six types of bovine papillomavirus (BPV1-6) have been characterized (Orth, Institut Pasteur; Jarrett, University of Glasgow).

Although originally benign, some papillomas can become malignant under the influence of environmental and genetic factors, as in the case of epidermodysplasia verruciformis lesions in humans[1], papillomas of the upper alimentary tract in cattle[2] and papillomas of the cottontail rabbit[3].

In addition to these well documented cases, ample evidence was presented at the workshop of the possible pathogenic role of papillomaviruses in some anogenital malignancies in humans. Thus, HPV6 DNA has been found in several types of genital warts (Gissmann, University of Freiburg; Mounts, Johns Hopkins Medical School; Grussendorf, University of Aachen; De Villiers, Onderstepoort, Pretoria) and HPV particles and antigens have been detected in anal warts (Oriel, University College London) and in several lesions of the uterine cervix (Pixley, University of Western Australia; Rilke, Istituto dei Tumori, Milan; Meisel; Morin, University of Quebec; Braun, Johns Hopkins Medical School). Both anal and genital warts have occasionally been found associated with malignant tumours.

In a particularly extensive survey of 250,000 unselected individuals, Meisel found that about two-thirds of the cases of mild and moderate atypia of the cervix are in fact papillomavirus-induced flat warts. In a more selected sample of cone biopsies, flat warts were frequently found associated with cervical displasia, *in situ* carcinoma and microinvasive carcinoma. These findings confirmed the view held by the clinicians and the pathologists present at the workshop that, although it is commonly accepted that severe atypia of the cervix is the result of direct progression from mild and moderate atypia, most cases of the latter are in fact papillomavirus lesions, and thus different entities from severe atypia. However, the question of whether or not there is a direct transformation from flat warts to frankly malignant structures is still open.

Perhaps the most striking and best known example of the malignant conversion of virus-induced tumours is provided by epidermodysplasia verruciformis (Orth; Jablonska, Warsaw Medical School). Several types of HPVs with different degrees of oncogenicity have been found in EV lesions, but despite this multiplicity, only HPV5 DNA is found in the squamous carcinomas, as multiple non-integrated episomes (Orth; Jablonska; Pfister, University of Freiburg; Faras, University of Minnesota).

Malignant transformation of papillomas is observed also in animals, where the synergism between the virus and other co-carcinogens can be studied experimentally.

Injection of bovine papillomavirus in the urinary bladder of cattle causes lesions which usually regress with time, but can occasionally progress to malignancy, particularly in animals eating bracken fern (Olson, University of Wisconsin), which contains both immunosuppressant and co-carcinogenic substances[4].

Papillomatosis of the upper alimentary canal, adenocarcinomas of the large intestine, and transitional carcinomas and haemangiosarcomas of the urinary bladder have been experimentally reproduced in cattle injected with virus and either fed with bracken or immunosuppressed with azothioprene. Non-integrated multiple copies of viral DNA have been found in both the experimentally induced bladder cancers and in naturally occurring ones (Jarrett).

Multiple copies of non-integrated non-methylated BPV DNA have been found also in *in vitro* transformed cells (Moar, University of Edinburgh; Pfister). Non-integration and non-methylation of papillomavirus genomes in tumours and transformed cells seems to be the general rule. One exception, however, is provided by papillomas and carcinomas induced by the cottontail rabbit papillomavirus in the domestic rabbit, where the viral DNA is partially methylated and some of it is integrated as long tandem repeats (Wettstein, University of California, Los Angeles).

The complete DNA sequences of BPV1 (7,945 base pairs; obtained by Chen, Levison and Seeburg of Genentech, and presented by Howley, National Cancer Institute, Bethesda) and of HPV1 (7,811 base pairs; Danos, Institut Pasteur) and the almost complete sequence of HPV6 (6,860 base pairs; Schwarz, University of Freiburg) were presented. In all cases, the viral genetic information is probably contained in only one strand, where four overlapping coding regions have been identified, as the other strand is blocked by stop codons in all three frames. The presumptive genes for both structural and non-structural proteins have been identified, and several putative splicing signals have been found in the non-structural region, strongly suggesting that appropriate splicing may generate a variety of transcripts.

The interpretation of the sequence data is coroborated by the mapping of the BPV1 transcripts. In productive warts (Howley; Amtmann, Cancer Research Center, Heidelberg), RNA species are found which

M. Saveria Campo is at The Beatson Institute for Cancer Research, Garscube Estate, Switchback Road, Glasgow G61 1BD.

---

*The workshop on 'Papillomaviruses and Cancer' was held in Freiburg, 7-8 April 1982, and was sponsored by the Deutsche Forschungsgemeinshaft.

0028-0836/82/320605-02$01.00

are absent in non-productive transformed cells and which only hybridize to the 30 per cent DNA fragment that is not necessary for cell transformation and contains the putative structural genes. These RNAs can be translated *in vitro*, and their polypeptide products appear to be genuine capsid proteins (Howley).

Four viral RNA species have been identified in BPV1-transformed cells, which, not surprisingly, hybridize to the 70 per cent DNA fragment capable of cellular transformation and thought to encode the non-structural viral antigens (Amtmann; Freese, University of Freiburg). More surprisingly, they are all co-terminal at their 3′ end, but extend for different lengths to the 5′ end where a 5′-leader sequence has been found (Amtmann). Thus, during the genesis of the non-structural BPV RNAs, the same 5′-leader sequence would be spliced onto different bodies, to give rise to a family of several distinct transcripts, as predicted from the sequence data.

By the end of the workshop it had become clear that, if the progress of our knowledge of papillomaviruses continues at the same break-neck speed of the past few years, we can soon expect to learn about their mechanisms for interaction with, and transformation of, the host cell. □

Antigenic variation in the trypanosome

from Mervyn Turner

PARASITES have evolved many methods of evading the immune system of their host[1], but perhaps none is so spectacular as the mechanism of antigenic variation adopted by the salivarian trypanosomes. These tsetse fly-transmitted parasites inhabit the bloodstream and tissue spaces of their mammalian hosts, where they rapidly stimulate the production of trypanocidal antibody. Before all the trypanosomes can be eliminated, however, antigenically distinct variants appear in the bloodstream which perpetuate the infection until they in turn are removed by antibody. Usually, the trypanosome can outstrip the immune system in this cycle, which leads eventually to the death of the host. How can such a simple eukaryotic organism produce sufficient antigenically distinct forms to subvert the sophisticated mechanisms possessed by the host for the generation of antibody diversity?

The antigenic profile of the trypanosome is governed by the structure of its surface coat, which in turn is made up of a densely packed layer of glycoprotein molecules, the variant surface glycoproteins (VSGs), whose composition is unique for each variant antigen type. The trypanosome genome contains in excess of 100 variant antigen genes probably generated by gene duplication and mutation[2], and by controlling the expression of these genes, the trypanosome is able to parade a sequence of different variants past the immune system of the host. Naturally, the mechanism by which expression is controlled has attracted much attention and a recent edition of *Nature* contains a contribution (Majiwa *et al.* **297**, 514; 1982) which is sure to add fuel to the controversy surrounding the subject. Furthermore, a second contribution this week (Rice-Ficht *et al.*, p. 676) shows how the trypanosome may have developed a mechanism to extend its repertoire of antigens, perhaps indefinitely.

It has been clear for some time that VSG genes are capable of undergoing rearrangements. These rearrangements do not generate new variants in a fashion analogous to that used by immunoglobulins, but they are detected as alterations in the sequences flanking the VSG gene. Thus, Hoeijmakers *et al.*[3] showed that expression of some VSG genes is accompanied by the generation of an additional copy of that gene, the expression-linked copy (ELC), in a different chromosomal location. Similar findings have been reported from other laboratories[4], and Pays *et al.*[5], by comparing the sensitivity to DNase I of both the basic copy and ELC of a VSG gene, concluded that the ELC was in transcriptionally active chromatin. To date, it has not proved possible to clone the ELC, but on the basis of R-looping, S_1 nuclease protection experiments and comparison of restriction enzyme sites in cDNA and in the ELC it has become apparent that VSG gene activation involves a duplication–transposition mechanism in which the 3′ end of the gene is replaced in the formation of the ELC[6].

Sequencing of cDNA clones has revealed that the 3′ region of VSG mRNA encodes a 17–23 amino acid C-terminal extension[7,8]. It is presumed that this largely hydrophobic sequence serves to anchor the VSG to the membrane at some stage during its biosynthesis, although it is certainly absent from mature VSGs. One possibility is that VSG gene activation involves the generation of a functional end, but DNA sequencing has shown that the codons specifying the hydrophobic tail are present in the basic copy genes[9]. The recombination event at the 3′ end of the gene that leads to the generation of an ELC probably takes place just outside the coding region. In contrast, comparison of restriction enzyme sites around basic copy and ELC genes shows that a 1–2 kilobase (kb) 5′ sequence is transposed with the gene in the generation of the ELC[10]. It is not known whether this sequence contains the promoter sequences allowing VSG expression when placed in transcriptionally active chromatin, or whether such promoters are present only at the expression locus. Nor is it known at what stage in the cell cycle of the bloodstream trypomastigote this duplication/transposition occurs.

So much is clear. What is in dispute is whether activation of VSG genes can occur only by the generation of an ELC. In particular, a group working at the International Laboratory for Research on Animal Diseases (ILRAD), Kenya, has consistently claimed that expression need not be linked to a specific duplication–transposition event. Thus an early analysis of one VSG gene was consistent with the presence of two gene copies, irrespective of whether that gene was being expressed or not[11,12]. Sequence rearrangements around the two copies were observed in all trypanosome clones, even in different clones expressing the same antigen, and restriction enzyme mapping was compatible with the insertion and deletion of lengths of DNA between the 3′ end of the cloned cDNA sequence and a group of restriction enzyme sites some 5–15 kb downstream from the end of the gene. No alterations in sequence were observed within at least 1–5 kb upstream from the 5′ end of the cDNA sequence used as a probe. These results have now been extended to an analysis of VSG gene rearrangements in three different variants, A, B and C, all related by descent from a common, single trypanosome (see Majiwa *et al. Nature* **297**, 514; 1982), and surprisingly, each of the three variant antigen genes behaves differently. Probes specific for variant A recognize the same single fragment in Southern blots of total genome digests from variants A, B and C when using restriction enzymes which do not cut the cDNA, but also recognize an additional, larger fragment in DNA from the clone expressing VSG A. Such results are fully consistent with the ELC model. In contrast, as in the earlier studies, probes specific for VSG B recognize two fragments in the DNA from cells expressing VSGs A, B or C, but the size of

both fragments differs in each variant. Has B lost its basic copy gene? This seems unlikely, because B was generated from A, which should therefore contain the basic copy of gene B. Is one of the B genes in an environment such that it is susceptible to the action of DNase I? Are both copies truly in chromosomal DNA? Answers to both questions are unknown. There appear to be four copies of gene C, in clones A, B and C. Two copies are invariant, whereas the sizes of the fragments carrying the other two genes alters in a way similar to that observed for variant antigen B.

Such results imply that different mechanisms may exist to control expression of VSG genes. The ELC model is attractive because it offers a ready explanation for control of antigenic variation, but as the principal proponents of the model themselves admit[2,3], not all the data are consistent with generation of an ELC. Another problem relates to the ploidy of trypanosomes. It has been estimated that ELC genes and basic copy genes exist in a ratio of 1:1 (ref. 4). If this estimate is correct, and if trypanosomes are diploid as generally assumed[13], this implies coordinate expression of the products of two alleles. If the estimate is incorrect, some mechanism of allelic exclusion must operate. Such problems are not resolved by incorporating the results of the ILRAD group for their findings suggest no obvious mechanism for the control of antigenic variation. The two B-specific genes identified could, for example, be allelic forms of the same antigen, but it is not apparent how expression of each is controlled. Is one copy silent, and can the other be activated? Hence the importance of the DNase I protection experiment. Perhaps a very large fragment of DNA (>50 kb) is transposed into a site allowing expression. Such a phenomenon could be identified only by using restriction enzymes which cut outside the transposed unit and a detection system which allowed resolution of very large fragments. All groups agree that the sequence on the 3′ side of the active gene is unusual[2,12] in that it is apparently devoid of restriction enzyme sites for up to 15 kb, and is therefore presumably a simple repetitive sequence. The apparent clustering of many restriction enzyme sites at the end of this sequence could represent the end of the DNA molecule. Resolution of these paradoxes is awaited with interest.

As a further sophistication, VSG genes appear to be capable of localized 'somatic' hypermutation which may extend the antigenic diversity yet further. Sequence analyses of VSGs have shown that the N-terminal 350–400 amino acids are highly variable. The next 100 or so amino acids form a homology region which can be used to divide VSGs into two subsets, followed by the hydrophobic tail of about 20 amino acids which is absent from mature VSGs[7,8,14-16]. Rice-Ficht *et al.* (see p.676) have now compared the DNA sequence of the basic copy gene with cDNA sequences corresponding to the mRNA transcribed from the ELC of variant antigen gene A described by Majiwa *et al.* Surprisingly, considerable differences were observed in the variable region and in the C-terminal hydrophobic tail, amounting to nucleotide changes at four per cent of all codon positions. The homology region is identical in the two sequences. As previously recorded, the 3′-non-translated sequences are quite different in the two clones, consistent with generation of the ELC through recombination in this region. What could be the significance of such findings?

One possibility, which cannot be rigorously excluded, is that the 'wrong' basic copy gene has been cloned and sequenced. A second is that cDNA cloning artefacts are responsible. However, sequences from different cDNA clones were compared and found to be identical, and cloning artefacts are unlikely to respect homology regions. The assumption must therefore be that such sequence alterations are generated in the formation of the ELC, with the possibilities for 'somatic' diversity that that implies. Changes at nine per cent of codon positions in the influenza haemagglutinin are sufficient to produce new variants, corresponding to alterations at four antigenic determinants[17], hence the trypanosome may be using this mechanism to extend enormously its repertoire of VSGs.

Two difficulties remain. First, only half the VSG variable region has so far been analysed in this way. Does the N-terminal region show similar hypermutation? Second, how much of this variable region is exposed on the trypanosome? It has been known for some time that immunizations with either living trypanosomes, or pure VSG can lead to the production of a high proportion of variant-specific monoclonal antibodies which will react with soluble VSG, but not with the surface of the trypanosome[18,19].

Trypanosomes readily shed their VSG during infection, so much of the immune response must be against soluble VSG, but why have variant-specific determinants on soluble VSGs which are not exposed on the surface of the trypanosome, and which are therefore not under selective pressure? Of the several potential antigenic determinants on the VSG molecule only a small number may be exposed on the closely packed surface coat, and such sites may be 'hot spots' for the 'somatic' hypermutation described by Rice-Ficht *et al.* For the trypanosome to then induce the host to make variant-specific antibody which cannot recognize the trypanosome surface could be a diversionary form of antigenic competition which surely would be the ultimate caprice of this virtuoso parasite? ☐

100 years ago

We observe that a correspondent of a daily paper proposes that men addicted to the pursuits of science should be called *scientiates*, after the Italian *scienziati;* and in like manner the studies of science, *sciential* studies (*studj scienziali*). The substitution of the American *scientist* for our unsatisfactory phrase *men of science* is of course much to be deprecated; perhaps we shall come to accept Sir William Thomson's proposed use of *naturalist* for the designation in question, if its sense may be extended. *Scientific studies* is a phrase which cannot be commended for accuracy.

A curious and little-known experiment, showing the resistance of the air in guns, is described by Prof. Daniel Colladon, of Geneva. It resembles a feat that was sometimes performed by soldiers with the old Swiss carbines. M. Colladon fully charged with compressed air the hollow iron breech of an air-gun, serving as reservoir. Having screwed up the gun, he introduced a round lead ball, running freely, but nearly filling the bore; then, placing the gun vertical, he seized the upper end and pressed his thumb vigorously on the mouth. The gun was then "fired" by an assistant; the thumb remained in position, and the ball was heard to fall back in the bore. Thereupon, after recharging the breech and with the same ball, he shot the latter at a pine board about 4in. thick and it passed through. The experiment, M. Colladon says, is without danger, if the operator is sure of the strength of his thumb, if the gun is more than 32in. long, and if the ball is spherical and nearly fills the gun (in which it must act like a piston). While M. Colladon has repeated the experiment twenty or thirty times, without the least inconvenience a trial of it is perhaps hardly to be recommended.

Anilides and the Spanish toxic oil syndrome

from A. Pestaña and E. Muñoz

During May and June, 1981, an epidemic outbreak of interstitial pneumonitis occurred in Spain. Over 20,000 people were affected, and nearly five per cent subsequently developed persistent neurodistrophic- and schlerodermia-like conditions. More than 300 people have died. The disease, at first attributed to a never isolated mycoplasm, is now thought to be due to the consumption of adulterated cooking oil containing the processed products of crude rapeseed oil denatured with 2 per cent aniline. The oil was enriched in fatty acid anilides (up to 2,000 p.p.m.) and almost freed from aniline (less than 30 p.p.m.), as a result of thermal processing (220°C) under vacuum.

Comprehensive research into the causes of the toxic oil syndrome was slow to start but tremendous efforts are now being made by many clinical and research institutes — although lack of effective coordination still remains a problem. Progress made so far was reviewed at a National Symposium[1] organized by the Ministry of Health and held in Madrid on 11–12 June.

Initial doubts about the toxicity of anilides and uncertainties in the cause–effect relationships between the disease and the available samples of suspicious oils led the Consejo Superior Investigaciones Cientificas (CSIC) to a research programme based on two priorities. First, a series of screening tests of a wide sample of oils was to be carried out in HeLa cells to uncover toxic factors. Second, a comparative study of synthetic anilides and suspicious oils would be made in several animal models, such as chick embryo, mouse, rat and rabbits. After 9 months of intensive research, a working hypothesis of the toxic oil syndrome can be put forward in light of the clinical findings reported at the meeting.

Toxicological screening of more than 100 samples of oil led the CSIC researchers to conclude that the *in vitro* test is probably not directly relevant to human and animal pathology. No correlation was found between cell toxicity and anilide content of the oils, and the synthetic anilides were found to be almost devoid of *in vitro* toxicity. The direct toxicity of the oils seems to depend on their content of free linoleic acid and/or its oxidation products, such as hydroxy and epoxy derivatives.

Most of the suspicious oils were found to be a mixture of vegetable oils (rapeseed, olive seeds and grapeseeds) and liquid fats, extracted from lard. Their average linoleic acid content was high (42 per cent of the total fatty acid) and their content of lipid peroxides was also very high (four times higher than the legal limits, on average). Furthermore, all the oil samples were very susceptible to oxidative damage, indicating a low content of natural antioxidants, the tocopherols.

As it is generally thought that the tocopherols (vitamin E compounds) mainly function as antioxidants for unsaturated lipids and so protect lipid membranes from attack by free radicals, it is possible that consumers of the oil mixtures may have developed vitamin E deficiency. They would have been subjected both to a higher requirement for vitamin E (because of the oil's high linoleic and peroxide contents) and to a decreased dietary supply (because of the oil's lack of tocopherols).

We do not, however,believe that this would suffice to explain the epidemic outbreak of the toxic oil syndrome as suggested by McMurray[2], since it is generally accepted that similar mixtures (devoid of anilides) have been fraudulently marketed for years. But we think that it must be considered an important pathogenic factor, in association with fatty acid anilides or their presumed imino-quinone derivatives, as has been shown with *p*-hydroxy acetanilides[3].

There are no clinical data in support of free radical pathology. A systematic study of the vitamin E content in humans affected by the toxic oil syndrome is also lacking. However, an increase in the product of peroxidative damage of membrane lipids (assayable with thiobarbituric acid) has been reported in human necropsies and experimental animals after anilide treatment. A marked decrease in T-cell immunosupressive functions in toxic oil syndrome patients, which is an expected result of free-radical pathology[4] and vitamin E deficiency[5], was also reported.

Working with chicken embryo, Garcia-Gancedo *et al.* have shown that the toxic effects of synthetic anilides can be prevented by the simultaneous administration of tocopherol. The result indicates that the anilides are acting, at least in this experimental model, through a toxic route susceptible to free radical scavengers. Clinical trials with vitamin E were ineffective, but it should be remembered that the disease was at an advanced stage when the treatment was applied.

The experiments employing chicken embryo, carried out by the CSIC, deserve a few comments. First, the toxicity of anilides is dose related. Second, toxicity appears only 2–3 days after hatching and does not affect embryonic development, suggesting the involvement of inhaled oxygen on the toxicity of anilides. Last, but not least, the toxic syndrome in chicken evolves rapidly towards respiratory distress and paralysis. Histopathological study of the affected animals reveals a perivascular infiltrate with eosinophils, interstitial pneumonitis with abundant eosinophils in the alveolar lumen and widespread lesions in the cerebellum, with pycnotic degeneration of the Purkinje cells and vacuolar degeneration of the white matter. These same pathological signs were found in rabbits treated with low doses of synthetic anilides.

Work with rabbits was aimed at elucidating the involvement of immunological mechanism in the toxicity of anilides — a possibility that arises from the clinical signs (fever, rash with marked eosinophilia and large titres of IgE) and the structural relationships between anilides and pentadecil cathecol, the agent of the delayed hypersensitivity to poison ivy[6]. Rabbits treated for 15 days with oral anilides (10 μg per kg) showed a typical delayed response in a skin test with anilides and titratable antibodies against the same synthetic anilides. Moreover, anilide-treated animals developed a syndrome of progressive paralysis and the cerebellar lesions (Purkinje cells and white matter) described above, in close resemblance to the Gordon phenomenon[7]. In addition, eosinophilic infiltrates were seen in the skin lesions after challenge with anilides and in the pia madre around the cerebellar cortex.

Some results from human necropsies indicate the occurrence of similar lesions in human brains. There is also histochemical and electron microscopic evidence (Rycoll, personal communication) of peroxidase-positive granula in the vicinity of the neural lesions observed in muscle biopsies from toxic oil patients.

On the basis of these clinical and experimental observations, we think that the pathogenesis of the toxic oil syndrome could be explained by an eosinophil-mediated cytotoxicity, probably directed by specific antibodies towards anilides, that could be incorporated in the cellular plasma membranes[8]. These inmunopathological causative effects (relatively well documented in toxic oil syndrome humans with depression in T-cell supressor functions, eosinophilia, high IgE levels and autoantibodies) could have arisen through the synergistic effects of anilides and the peroxidative status, resulting from the poor nutritional quality of the oil mixtures. Although we do not exclude other pathogenic possibilities, we think that these ideas may provide a conceptual framework and working hypothesis by which the Spanish toxic oil syndrome could be experimentally approached. □

A. Pestaña, Instituto de Enzimologia, CSIC, is responsible for the coordination of the CSIC programme on toxic oil syndrome and E. Muñoz, Unidad de Biomembranas, Centro de Investigaciones Biológicas, is Vicepresident for Scientific Affairs at the CSIC.

Aspherical Earth structure from fundamental spheroidal-mode data

Guy Masters, Thomas H. Jordan, Paul G. Silver & Freeman Gilbert

Institute of Geophysics and Planetary Physics, University of California, San Diego, La Jolla, California 92093, USA

Free-oscillation data reveal heterogeneity in the Earth's mantle whose geographical pattern is dominated by spherical harmonics of angular degree two and correlates well with the hydrostatically referenced geoid. The heterogeneity can be modelled as localized in the transition zone (420–670 km depth) and may be related to a large-scale component of mantle convection.

THE study of the Earth's lateral, or aspherical, heterogeneity using long-period seismic observations has since 1966[1] been based on the 'pure-path' approximation; variations in the phase velocities of travelling waves are represented as a sum of their fractional dispersion across several types of tectonic structures. Recently, this sort of analysis has been extended to normal-mode frequency shifts[2]. We investigate here a new data set of nearly 4,000 fundamental-mode frequencies measured from over 500 records of the International Deployment of Accelerometers (IDA) network. The extensive coverage provided by these measurements shows that the present schemes of tectonic regionalization are inappropriate at periods longer than ~200 s; the lateral heterogeneity revealed by the low-order fundamental modes is more suitably represented by a spherical-harmonic expansion with the dominant power in the degree-two terms. A drawback of this representation is that the data do not constrain the odd-order harmonics[3,4], a fact which must be kept in mind when interpreting the observed patterns. The source of the observed signal cannot be determined unambiguously, but our analysis suggests that the transition zone of the Earth's mantle (between about 400 and 700 km depth) is the most plausible location of the dominant heterogeneity.

Observations of fundamental-mode frequencies

In a recent study of fundamental-mode attenuation the complex frequencies of the modes ${}_0S_8$ to ${}_0S_{46}$ from 557 IDA recordings were measured[5]. Because the primary goal was to obtain reliable Q determinations, only large-amplitude peaks showing little signs of overtone interference or beating due to splitting were retained. A by-product of this analysis was 3,934 reliable measurements of fundamental-mode frequencies, forming the data base for the present study. Below $l = 39$ each mode has an average of 118 independent observations, but the number of measurements decreases rapidly at higher angular orders. The modes above $l = 43$ had <20 observations and were dropped from the data set. A complete account of the data analysis techniques can be found in ref. 5.

A convenient way of displaying the data is to plot the observed frequency shifts at the location of the pole of the great circle joining the source and receiver. In the geometrical optics limit, when the horizontal wavelength of the heterogeneity is much greater than that of the mode, the frequency shift is solely a function of the pole position[6]. If this condition is not met in the Earth, then effects not described by this asymptotic theory become important, and a more complete interpretation may be required[6,7]. In particular, the exact first-order expressions for the frequency shifts depend on the details of the source mechanisms, so that if non-asymptotic effects were to dominate the signal, the apparent frequencies would not be a smooth function of pole position. Figure 1 shows the frequency shifts for several sets of angular orders. The patterns revealed by these diagrams have a large-scale simplicity and are consistent from angular order to angular order; this suggests that the geometrical optics limit is a valid approximation and that the asymptotic theory can provide an adequate framework for the interpretation of the data.

Theoretical developments[6,8] define the peak location in terms of the ratio of the first polynomial moment of the multiplet spectrum to its zeroth moment, an estimator employed in the first systematic observational study[2]. The values used here were derived by least-squares fitting of a singlet shape to the observed spectrum[5]. However, for the large-amplitude, singlet-like peaks considered in the present study, these different estimators give almost identical results, a behaviour consistent with the asymptotic theory[8]. The least-squares estimation technique is less sensitive to contamination by nearby higher modes and has the additional benefit of a comprehensive error analysis[9]. The errors in the frequency estimates are typically 0.05%, roughly a factor of 10 less than the frequency variations ascribed to aspherical heterogeneity.

One well determined feature of the Earth's asphericity is its ellipticity of figure, which causes a positive frequency shift for poles at low latitudes and a negative shift at high latitudes. The expected variation with latitude—amounting to 2.2 μHz for ${}_0S_8$ and 9.3 μHz for ${}_0S_{43}$—is evident at low angular orders, but above $l = 16$ or so it disappears almost completely. This behaviour has been attributed by Silver and Jordan[2] to the existence of some sort of lateral heterogeneity which, in terms of its effects on the fundamental spheroidal modes, is anti-correlated with the ellipticity of figure. The present study confirms this conclusion. Because we believe the hydrostatic component of ellipticity is well modelled by the Clairaut theory, we have adopted an elliptical Earth as a reference model and have corrected the raw peak frequencies for this signal using the asymptotic formula derived by Dahlen[10].

Table 1 Localized models of degree-two aspherical heterogeneity

		Normalized coefficients					Total variance reduction
Zone	Amplitude*	δm_2^0	Re δm_2^1	Im δm_2^1	Re δm_2^2	Im δm_2^2	(%)
1	1.84	−0.70	0.27	−0.17	0.12	0.62	52
2	1.76	−0.72	0.26	−0.15	0.20	0.59	61
3	2.10	−0.69	0.25	−0.13	0.27	0.60	49
4	7.74	−0.67	0.26	−0.13	0.26	0.63	46
5	10.62	−0.70	0.26	−0.16	0.19	0.61	59

* Amplitude of the heterogeneity as a percentage of shear velocity; perturbations in density and compressional velocity are constrained to have relative amplitudes of 0.4 and 0.8 of the shear-velocity perturbation (see text).

0028–0836/82/320609—05$01.00

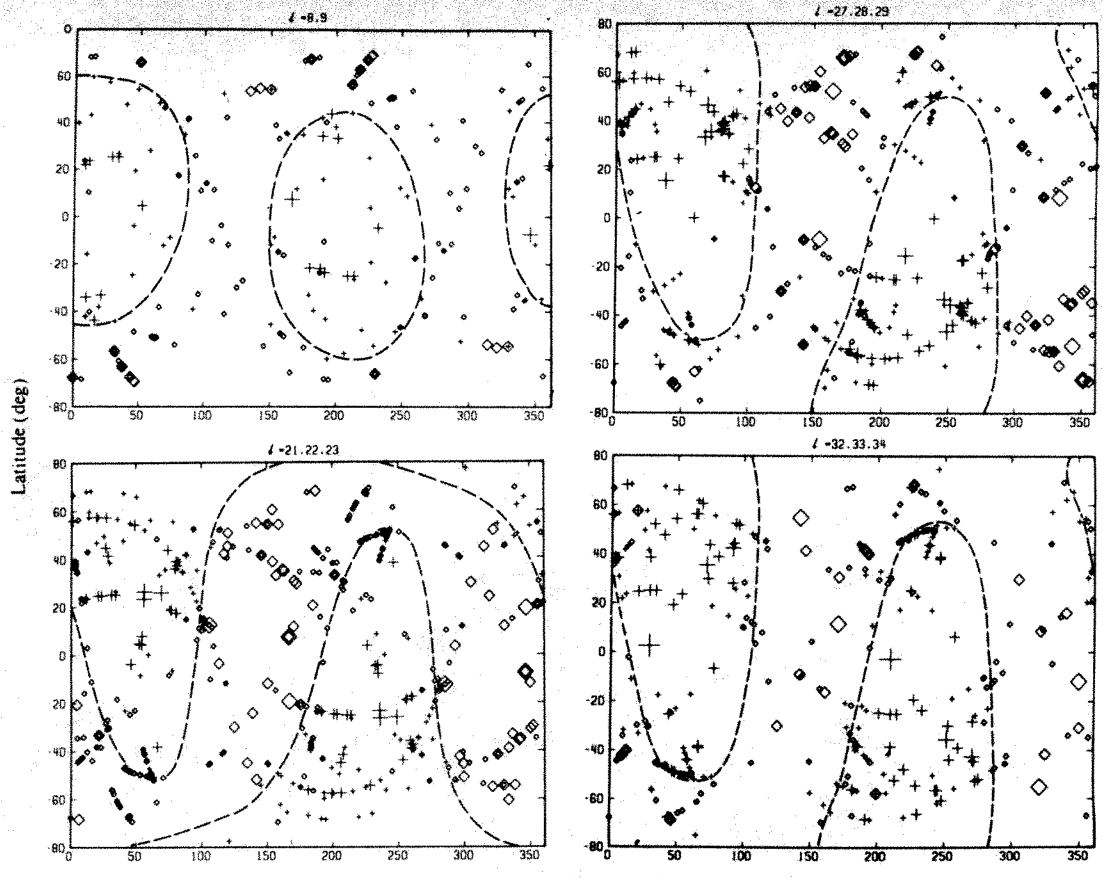

Fig. 1 Multiplet-location data from selected fundamental spheroidal modes plotted at the poles of the great circles connecting the sources and receivers. Frequency shifts are relative to the estimated degenerate eigenfrequencies of Fig. 2*c*. Symbol type indicates sign of the frequency shift (+, positive; ◇, negative); symbol size indicates its magnitude (smallest symbols correspond to shifts of 0.0–0.1%; the largest to 0.3–0.4%). Dashed lines are the nodes of the best-fitting degree-two patterns for $\delta\omega_{\text{local}}$ uncorrected for ellipticity of figure; the patterns are very similar except for the P_2^0 components, which are large for $l = 8, 9$ but small for the other modes shown.

Models of the heterogeneity

The elastic part of the terrestrial monopole is specified by $\bar{\mathbf{m}}(r)=[\bar\rho(r),\bar v_p(r),\bar v_s(r)]$, where r is radius ($0\leq r\leq a=6{,}371$ km) and $\bar\rho$, $\bar v_p$ and $\bar v_s$ are the spherically averaged mass density, compressional velocity and shear velocity, respectively. The degenerate eigenfrequency of the kth mode of this spherically symmetric model is denoted $\bar\omega_k$. Aspherical heterogeneity is represented by the perturbation

$$\delta\mathbf{m}(r,\theta,\phi)=\sum_{s=1}^{\infty}\sum_{t=-s}^{s}\delta\mathbf{m}_s^t(r)Y_s^t(\theta,\phi) \qquad (1)$$

where Y_s^t is the complex surface spherical harmonic of degree s and order t; the conventions of Edmonds[11] are adopted, so that $Y_s^{-t}=(-1)^tY_s^{t*}$. Because the perturbation is real, $\delta\mathbf{m}_s^{-t}=(-1)^t\delta\mathbf{m}_s^{t*}$.

The asymptotic first-order theory relating the multiplet locations to the aspherical model (1) is well developed[6,8]; for a source and receiver connected by a great circle with pole at colatitude Θ and longitude Φ, the peak frequency of a mode of radial order n and angular order $l\gg n$ is

$$\omega_k=\bar\omega_k+\sum_{\substack{s=2\\ s\ \text{even}}}^{\infty}P_s(0)\sum_{t=-s}^{s}(\delta\omega_{\text{local}}^{(k)})_s^tY_s^t(\Theta,\Phi) \qquad (2)$$

The coefficients in this expansion are given by

$$(\delta\omega_{\text{local}}^{(k)})_s^t=\int_0^a\mathbf{M}_0^{(k)}(r)\cdot\delta\mathbf{m}_s^t(r)r^2\,\mathrm{d}r \qquad (3)$$

where $\mathbf{M}_0^{(k)}$ is a triplet of functional derivatives computable from the eigenfunctions of the terrestrial monopole[12]. The apparent eigenfrequency (2) can be shown to equal the great-circular average of the 'local eigenfrequency' $\bar\omega_k+\delta\omega_{\text{local}}^{(k)}(\theta,\phi)$, whose harmonic coefficients are defined by equation (3). Such averages place no constraints whatsoever on the odd-parity (s-odd) part of the aspherical perturbation, a point first noted by Backus[3] in his analysis of great-circle dispersion. Equations (2) and (3) can be combined to give a linear inverse problem for the even part of $\delta\mathbf{m}$.

Alternatively, equation (2) can be solved directly for $\delta\omega_{\text{local}}^{(k)}$, permitting an investigation of the even part of the spherical harmonic patterns underlying individual modes without introducing the additional questions of nonuniqueness associated with the complete inverse problem. Figure 2 shows the results of this analysis assuming $\delta\omega_{\text{local}}^{(k)}$ is representable by harmonics of degree two. To reduce the variance and ensure a good sampling of the sphere, the data from three consecutive angular orders were combined in each calculation. The inversion determined estimates of the degenerate eigenfrequencies and the complex coefficients of $s=2$, for a total of eight independent parameters per mode triplet. The coefficients in Fig. 2*a* have been normalized to unit power to facilitate comparisons among the modes; their normalization scalars are shown in Fig. 2*b*.

The estimated degenerate eigenfrequencies are plotted relative to the PEM-A model[13] in Fig. 2*c*, together with the weighted means of the apparent frequencies and the estimates given in ref. 2. (Figure 2*c* was constructed using the PEM-A eigenfrequencies published by Dziewonski *et al.*[13]; these differ from the values calculated from the PEM-A model by up to 2 μHz.) The offset in the eigenfrequencies between ${}_0S_{11}$ and ${}_0S_{18}$, is prominent. Present Earth models predict significant quasi-degenerate Coriolis coupling between the ${}_0S_l$ and ${}_0T_{l+1}$ modes at the ends of this band[14], which could explain the shifts of ${}_0S_{11}$ and ${}_0S_{18}$, but the reason for a nearly constant offset of the

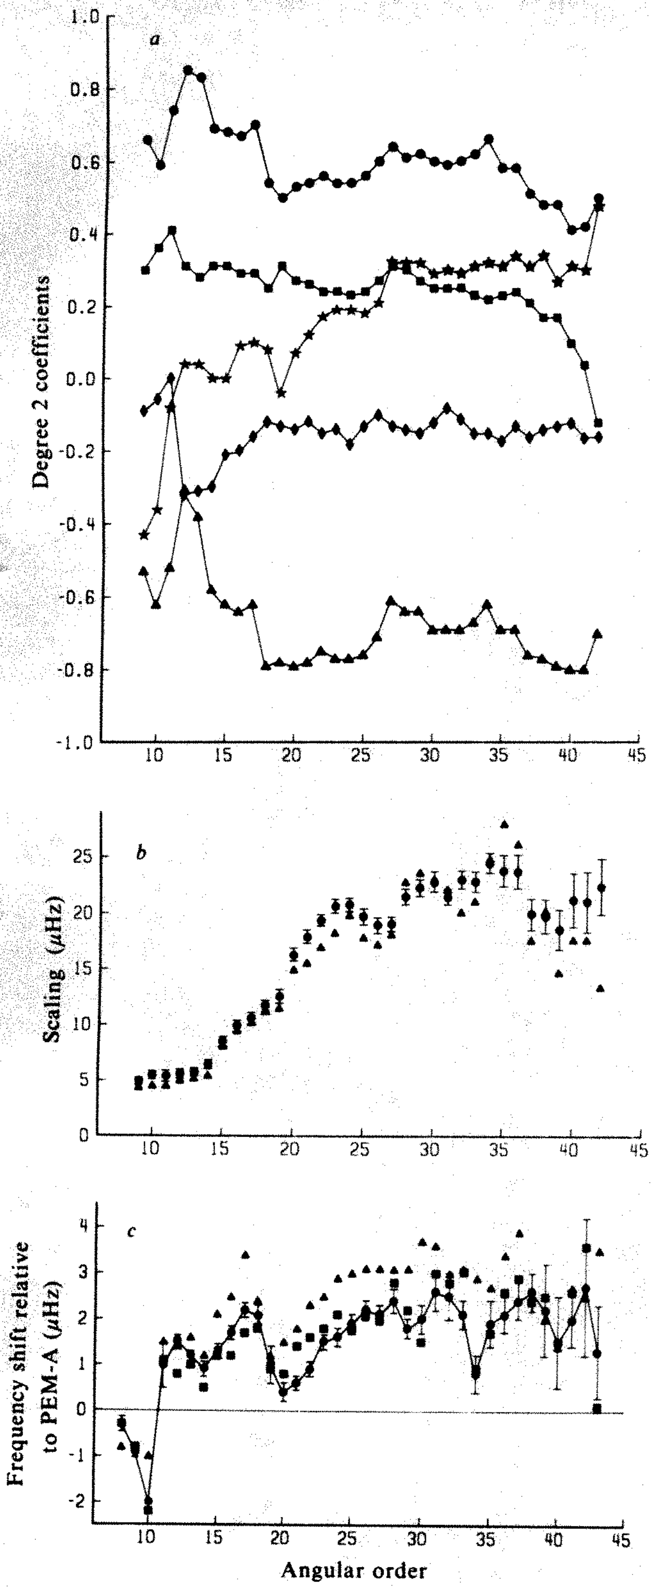

Fig. 2 *a*, Normalized degree-two coefficients of $\delta\omega_{\text{local}}$ from a least-squares fit to the ellipticity-corrected multiplet locations assuming $s_{\max}=2$(▲, P_2^0;■, Re P_2^1; ◆, Im P_2^1; ★, Re P_2^2; ●, Im P_2^2). Three consecutive angular orders were combined in each calculation (eight-parameter inversion). *b*, Scale factors for these coefficients, with 1σ error bars. ▲, Degree-two scale factors for 30-parameter ($s_{\max}=6$) inversions. *c*, Estimates of the degenerate eigenfrequencies $\bar{\omega}_k$ plotted as residuals with respect to published eigenfrequencies of the PEM-A model[13]. Values from eight-parameter inversions are connected by a solid line; error bars are 1σ. Simple weighted means of our data (■) and those from ref. 2 (▲) are shown. The latter two estimates are more sensitive to bias caused by incomplete sampling of the aspherical heterogeneity.

intermediate modes remains obscure. This important observation, previously noted in ref. 2, may provide strong constraints on the spherically averaged Earth structure.

Note that the average eigenfrequencies estimated by the degree-two inversion form a generally smoother function of angular order than the simple weighted means, particularly at the higher angular orders. This is because the pole positions for our data set are biased to temperate latitudes and there consequently exists a significant tradeoff between $\bar{\omega}_k$ and any P_2^0 component of $\delta\omega_{\text{local}}^{(k)}$. At the higher angular orders the acceptable data are fewer, the sampling is more variable, and the P_2^0 component is large; hence, a simple averaging of the data can introduce spurious variations in estimates of $\bar{\omega}_k$. The small positive shift of the Silver–Jordan means relative to our estimates appears to be ascribable to a bias in the way their pole positions sample the patterns shown in Fig. 1.

Several conclusions can be immediately drawn from Fig. 2*a*, *b*. The normalized spherical harmonic pattern of $\delta\omega_{\text{local}}^{(k)}$ is quite stable, especially for the modes ${}_0S_{20}$–${}_0S_{38}$, where only the real part of the P_2^2 term appears to exhibit a significant trend. The pattern consists of a large P_2^2 component and a large negative P_2^0 component. It is this latter term which at the higher angular orders almost cancels the signal due to the ellipticity of figure. The P_2^1 component is comparatively small, accounting for only ~10% of the total power. The scale factors multiplying this nearly constant pattern increase with angular order to $l\sim35$, but level off at higher angular orders.

The variance reduction provided by this simple model is remarkable (Fig. 3). Except for ${}_0S_{11}$ whose scatter is probably dominated by the vagaries of quasi-degenerate coupling, the median variance reduction is 60% and, in the centre of our mode band where the data are most numerous, it exceeds 70%.

This variance reduction is far superior to that achievable by tectonic regionalizations with comparable numbers of parameters. We have, for example, inverted these data using a six-parameter regionalization[2,15]. The median variance reduction is only 24% and for only nine of the 35 modes does it exceed 30% (Fig. 3). Furthermore, the patterns in $\delta\omega_{\text{local}}^{(k)}$ derived from the tectonic regionalization are much less stable with respect to variations in angular order number.

The possibility that power is aliased into the degree-two coefficients from higher-degree heterogeneity by inadequate sampling of the sphere can be checked by comparing these results with inversions allowing higher harmonics in $\delta\omega_{\text{local}}^{(k)}$. The scale factors for the degree-two coefficients from inversions with $s_{\max}=6$ (30 parameters per mode triplet) are plotted with those from the eight-parameter inversions in Fig. 2*b*. Throughout most of the band the agreement is quite good. In fact, below $l=36$ the power in the higher harmonics is down by a factor of four or more. Above $l=36$ the scale factors for the 30-parameter inversion are generally lower, the power in the higher harmonics increases, and the possibility of appreciable aliasing cannot be discounted. As shown in Fig. 2*b*, ignoring higher harmonics tends to increase the degree-two scale factors for $l>36$. Because this bias appears to be small and the variance reduction at the lower angular-order numbers is not significantly improved by the addition of the higher-degree terms, we shall restrict further attention to the degree-two components.

The uniformity of the $\delta\omega_{\text{local}}^{(k)}$ patterns suggests that the dominant signal arises from anomalies localized in radius. If this is true, the variation of the pattern's amplitude with angular order constrains the position of the heterogeneity inside the Earth. We consider five zones based on the major seismological divisions of the mantle as defined by the PEM-A model:

Zone 1:	5,350–5,701 km (top of the lower mantle)
Zone 2:	5,701–5,951 km(transition zone)
Zone 3:	5,951–6,151 km
Zone 4:	6,151–6,291 km (low-velocity zone)
Zone 5:	6,291–6,352 km (lid)

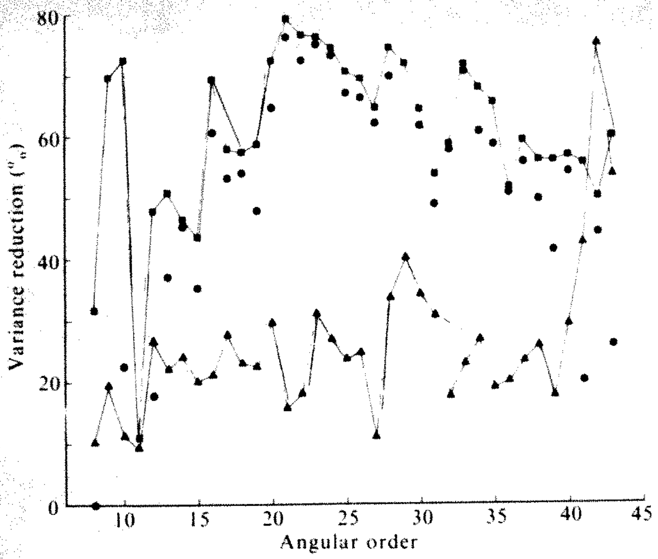

Fig. 3 Percentage variance reductions achieved by the degree-two representation of $\delta\omega_{\text{local}}$ given by Fig. 2 (–■–), the tectonic regionalization of Jordan[15] (–▲–), and the degree-two transition-zone (zone 2) model of Table 1 (●).

Five models of degree-two heterogeneity have been constructed by least-squares inversion of the entire data set (excluding ${}_0S_{11}$) assuming the perturbations to ρ, v_p and v_s are constant functions of radius localized in one of these zones. Of course, the radii of the discontinuities separating zones could be (and probably are) laterally variable, but their effects on the data have been shown by numerical experiments to be similar to constant perturbations in adjacent zones; for these preliminary experiments we have therefore fixed these radii.

If ρ, v_p and v_s are allowed to be independently variable in the inversion, then the results depend strongly on the integrals of the functional derivatives across each layer. In zones 4 and 5, for example, the differential kernels for ρ and v_p are of the same magnitude but opposite sign, and the inversion yields models with large positive ρ perturbations correlated with large negative v_p perturbations, and vice versa. From what we know about mantle properties this behaviour is unphysical. To eliminate such models we have scaled *a priori* the perturbations in density and compressional velocity to those in shear velocity by assuming $d\ln\rho/d\ln v_s = 0.4$ and $d\ln v_p/d\ln v_s = 0.8$. These scalings were derived from the temperature derivatives of possible mantle constituents given by Anderson *et al.*[16], but they are equally appropriate for the chemical variations observed in naturally occurring periodotites[17,18]. If the heterogeneity is confined to zones 1, 2 or 3, then the scaling is unimportant, as the modes are primarily sensitive to only the v_s perturbations in these regions. This is not true for zones 4 and 5, where the ρ and v_p perturbations predominate, although it is unlikely that any reasonable scaling will alter our conclusions.

The results of the inversions for the five zones are listed in Table 1. The spherical-harmonic pattern is essentially the same for each zone, but the magnitude of the requisite perturbation increases rapidly for the shallower zones. The localized perturbation giving the best overall fit to the data is the zone-2 (transition-zone) model with a total normalized variance reduction of 61%. Except at the very low and high ends of the mode band, the variance reduction provided by this simple model is almost as great as the optimal values for a degree-two parameterization attained by the $\delta\omega_{\text{local}}^{(k)}$ inversions (Fig. 3). Zones 1, 3 and 4 have much less satisfactory residuals. Although the zone-5 (lid) model is better, it systematically under-predicts the magnitude of the frequency shifts in the band ${}_0S_{20}$–${}_0S_{30}$ and overpredicts the shifts above ${}_0S_{35}$.

These aspects of the data fit are illustrated in Fig. 4, which compares the scaling of the degree-two pattern derived from the $\delta\omega_{\text{local}}^{(k)}$ inversions with the scalings predicted by the various models. The dependence of the scaling on angular-order number is clearly best matched by the transition-zone model. The zone-1 solution predicts too rapid a roll-off, whereas the models for zones above the 420-km discontinuity do not roll off fast enough.

Correlation with the geoid

The geographical pattern of aspherical heterogeneity synthesized from the transition-zone model of Table 1 is mapped in Fig. 5 (the contours for the other models are very similar). High-velocity anomalies are centred near the Equator in the western Pacific and central Atlantic, whereas lows occur at high latitudes in the southeastern Pacific and northern Eurasia. These features are remarkably similar to the dominant large-scale undulations of the geoid when the latter is referenced to the hydrostatic ellipsoid. The correlation coefficient between the degree-two harmonics of the transition-zone model and the GEM 9 geoid[19] corrected for Jeffreys' hydrostatic value of J_2 (ref. 20) is +0.79, which is significant at the 94% confidence level. We hypothesize, therefore, that the heterogeneity detected by the multiplet-location data is responsible, at least in part, for the degree-two geoid anomalies.

None of the localized perturbations in Table 1 can by itself adequately account for these anomalies, however; the predicted amplitudes are too large. For example, the root-mean-square (r.m.s.) geoid amplitude calculated for the transition-zone

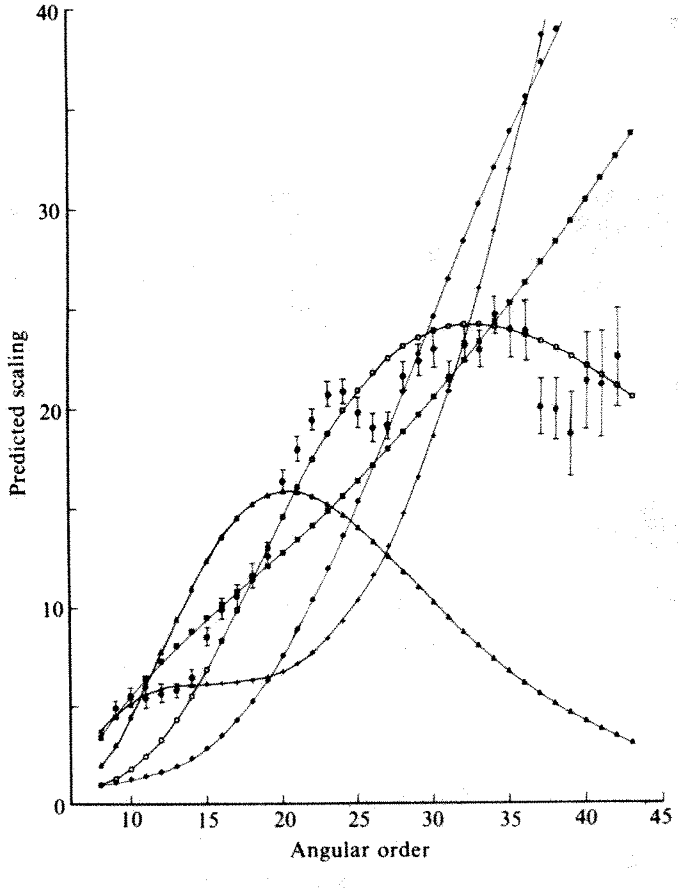

Fig. 4 Variation of degree-two scale factors with angular order predicted by localized models of aspherical heterogeneity (△, zone 1; □, zone 2; ◇, zone 3; +, zone 4; *, zone 5). Solid circles with 1σ error bars are the degree-two scalings from the eight-parameter inversions shown in Fig. 2*b*.

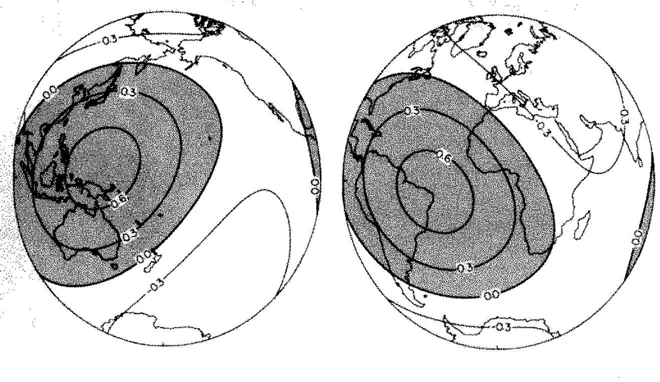

Fig. 5 Lambert equal-area projections of the Earth showing the degree-two heterogeneity of the transition-zone model, normalized such that its square integrates to unity on the unit sphere. Regions of positive anomaly are shaded; contour interval is 0.3 units.

models exceeds the observed degree-two value by about a factor of five. The discrepancy for the zone-5 model is even larger, nearly a factor of nine. Either the velocity-density scaling adopted in the inversions is grossly incorrect or the heterogeneity sensed by the multiplet-location data is compensated at other levels within the Earth. We prefer the latter hypothesis, as the former would imply substantial lateral variations in mean atomic weight[17] which would be difficult to maintain in a convecting mantle.

The compensation is not likely to be confined to the upper mantle. If our scaling parameters are roughly correct, then only models with large and nearly cancelling radial excursions in upper-mantle properties can satisfy both the multiplet-location data and the geoid. It seems improbable that any mechanism responsible for such excursions would yield multiplet-location patterns so similar at different angular orders. A lower-mantle compensation is more plausible. The changes in the $\delta\omega_{\rm local}^{(k)}$ patterns at low angular orders are suggestive of a deeper-seated heterogeneity, as are the observations of splitting of high-Q, low-angular-order modes[21]. In fact, heterogeneities anti-correlated with the geoid have already been proposed for depths greater than 1,100 km by Dziewonski *et al.*[22] to explain certain large-scale variations in P-wave travel times.

Discussion

Aspherical heterogeneity of the sort implied by the transition-zone model could be produced by lateral temperature differences of the order of 200–300 °C associated with a large-scale component of mantle convection. Such variations could occur in a thermal boundary layer between the upper and lower mantle, or alternatively, in a mantle-wide system of convective flow. To differentiate between these possibilities will require better resolution of the heterogeneity distribution as a function of depth. Although the simple scaling of the $\delta\omega_{\rm local}^{(k)}$ patterns with angular order suggests some localization in depth and motivates the modelling experiments of Table 1, the data now in hand certainly do not exclude models wherein the aspherical variations are distributed throughout the Earth. Indeed, we have argued that the geoid requires the heterogeneity constrained by the multiplet-location data to be largely compensated elsewhere in the mantle, most likely near its base.

There are at least four additional sources of seismic data which should help to increase our vertical resolution of structure. The first is the measurement of phase-velocity dispersion at periods shorter than 200s. We have attempted to extend our data set using published phase-velocity observations, but these have proved inadequate in both quantity and quality to improve our spherical-harmonic models of lateral heterogeneity. The second is the study of fundamental toroidal modes whose energy is more strongly concentrated near the surface than spheroidal modes, and the third is the measurement of resolvably split high-Q modes of low angular order. Finally, the inversion of large sets of teleseismic travel times[22] can be used to constrain the odd-order harmonics of deep-seated heterogeneity to which the free-oscillation data are insensitive. With the addition of these data detailed models of the Earth's large-scale lateral heterogeneity should be within our reach in the near future.

Conclusions

A data set comprising 3,886 apparent centre frequencies of the modes ${}_0S_8$–${}_0S_{43}$ measured from over 500 IDA records has been analysed for aspherical Earth structure. When plotted as a function of the pole position of the great circle connecting the source and receiver the frequency shifts show a remarkably coherent geographical pattern clearly dominated by surface spherical harmonics of degree two. Although the degree-two pattern is well constrained by the data, the depth distribution of the aspherical heterogeneity cannot be determined unambiguously. Models of degree-two heterogeneity localized in various mantle layers have been constructed using the asymptotic theory of multiplet locations by scaling the density and compressional-velocity perturbations to those in shear velocity. The best fit to the data is obtained by localizing the degree-two perturbations in the mantle transition zone (420–670 km depth). This transition-zone model is characterized by shear-velocity variations of 1.7% (r.m.s. amplitude). The overall variance reduction provided by the model is 61%, more than a factor of two better than that achievable by tectonic regionalization. The degree-two pattern has high-velocity anomalies centred near the Equator in the western Pacific and central Atlantic and lows at high latitudes in the southeastern Pacific and northern Eurasia; these features correlate well with the hydrostatically referenced geoid. The transition-zone model predicts geoidal undulations too large by about a factor of five, however, suggesting a compensation mechanism which we infer to be heterogeneity in the lower mantle. Aspherical heterogeneity of the sort implied by our data could be produced by lateral temperature differences of the order of 200–300 °C associated with a large-scale component of mantle convection.

We thank Jon Berger, Duncan Agnew and the other members of the Project IDA team for providing data which made this study possible, and Loren Shure for assistance in constructing Fig. 5. This research has been supported by NSF grants EAR-80-07823 and EAR-80-25261.

Sm–Nd, Rb–Sr and U–Th–Pb systematics of granulite facies rocks from Fyfe Hills, Enderby Land, Antarctica

D. J. DePaolo*, W. I. Manton†, E. S. Grew* & Martin Halpern†‡

* Department of Earth and Space Sciences, University of California, Los Angeles, California 90024, USA

‡ Present address: Enserch Exploration, Inc., Dallas, Texas 75221, USA

New Sm–Nd isotopic measurements made on granulite-facies metamorphic rocks from East Antarctica provide firm evidence that crust of ~3,500-Myr age exists in the Fyfe Hills. Zircon U–Pb data provide further documentation for a granulite-facies event 2,500 Myr ago, during which Rb, U, Sm and Nd were highly mobile. The U–Pb and Rb–Sr isotopic systems were seriously disrupted and in most samples give meaningless model ages. In contrast, Sm–Nd model ages were offset only slightly. A large time interval of 1,000 Myr between the times of crust formation and granulite-facies metamorphism has not previously been reported for Archaean rocks, and suggests that 2,500 Myr ago the Fyfe Hills may have been located in an Andean- or Himalayan-type continental margin where crust already 1,000-Myr old was involved in an orogenic event.

THE Napier complex of coastal Enderby Land, East Antarctica (46°–57°E) (Fig. 1) is an Archaean granulite-facies terrane[1–3] that was cut by pegmatites 2,500 Myr ago at about the time of metamorphism[3,4]. Sobotovich *et al.*[5,6] reported a 4,000-Myr Pb isochron age for six whole rock samples of enderbite and granulite of the Napier complex at Fyfe Hills (67°22′S, 49°12′E). This age was calculated assuming a two-stage development of the U–Pb system, an assumption that has been invalidated by the evidence for a 2,500 Myr metamorphism[4]. Nonetheless, recalculation of Sobotovich *et al.*'s data, assuming a three-stage development, yields a minimum age of 3,500 Myr (ref. 4).

If this age is correct, the Napier complex would represent the first documented example of an Archaean granulite-facies metamorphic event that significantly post-dated crust formation. This in turn places a new perspective on the mode of formation of the early crust and the causes of granulite-facies metamorphism. In view of these implications, we have reanalysed Sobotovich *et al.*'s Fyfe Hills samples for U–Pb isotopes, and also analysed them for Rb–Sr and Sm–Nd isotopes. U–Pb isotopic systematics are often ambiguous in granulite terranes[7]. However, Sm–Nd isotopes can place more stringent constraints on the age of the complex[8]. Furthermore, the concurrent study of the entire suite of chemically diverse elements provides a much better understanding of the geological processes which affected this part of the Antarctic crust during the Archaean. We have also analysed zircons in one of the Fyfe Hills granulites for U–Pb isotopes to document further the ~2,500-Myr age of metamorphism inferred from previous measurements on pegmatite minerals[4].

Samples

Grikurov provided seven samples (28-I to 28-VII) collected by Kamenev and co-workers in 1970–71, and Kamenev provided a sample 28-VIII, collected in 1978. The samples include garnet-two pyroxene granulite (28-I, IV), magnesian pyroxene granulite (28-II, III), quartzofeldspathic granulite (28-VI, VII and VIII) and magnetite–garnet–orthopyroxene ironstone (28-V) (Table 1). The granulites are medium grained (0.1–3.5 mm) and lack a marked foliation while the ironstone has a cataclastic fabric. The mineral identified as perrierite or chevkinite in 28-VII forms rare brown isotropic (metamict) grains containing major Si, Ti and Ce, and subordinate Ca, Al and Th (energy dispersive scan). Minor biotite, chlorite, hornblende, or a low Ca-amphibole appear to result from post-metamorphic alteration.

0028–0836/82/320614—05$01.00

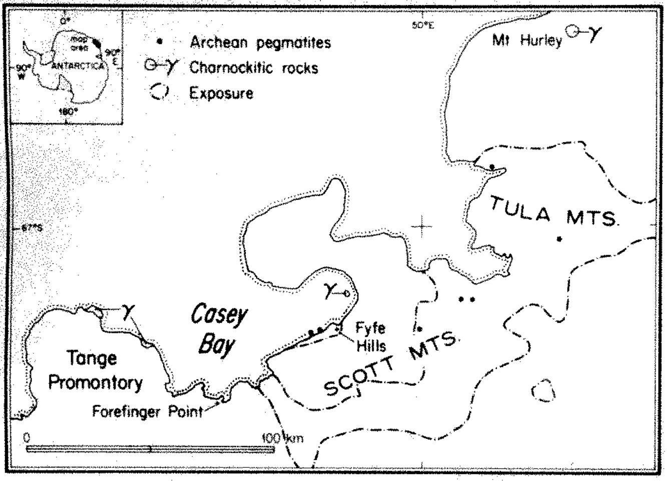

Fig. 1 Map of a portion of the Napier complex in Enderby Land showing Archaean pegmatites of possible plutonic origin[31] and intrusive charnockitic rocks (γ) on Tange Promontory (ref. 1, p. 494; ref. 3), east end of Casey Bay (J. W. Sheraton, personal communication), and Mt Hurley (ref. 1, p. 494). Specific localities of Soviet samples provided by Ye. N. Kamenev (personal communication).

The rocks vary considerably in major and trace element composition, especially in their SiO_2 content and in the relative proportions of Fe and Mg (Tables 1 and 2). Samples I and IV have igneous compositions corresponding to Fe-rich tholeiitic basalt. The other rocks, with the exception of the ironstone (sample V) have compositions that are broadly igneous except for a notable deficiency in Na_2O and K_2O. In general, the rocks are especially poor in K_2O, Rb and U, have low values of Rb/Sr and U/Pb, and high values of Th/U and K/Rb. All of these features are characteristic of granulite facies rocks[9,10]. An additional feature is the low Sr abundances of all the rocks, some three or more times lower than typical crustal abundances[11]. Sample VII, the only sample containing significant K-feldspar, is unique in that it contains much higher concentrations of K, Rb, Th and Nd than the other rocks, and has a high Rb/Sr ratio. Only sample VII has high U/Pb and low Th/U values. From the chemical compositions, we infer the protoliths for the samples to be volcanic rocks or immature detritus shed from an igneous terrane. The ironstone is clearly of sedimentary origin. The protolith for the magnesian pyroxene granulites is enigmatic. Their chemical compositions are not similar to igneous rock compositions, as both granulites have relatively high Mg/Fe ratios and Al_2O_3 contents, and low alkali contents.

Analytical techniques and data representation

The isotopic data were obtained using techniques described previously[12-14]. The U–Th–Pb and Rb–Sr data were obtained at the University of Texas; the X-ray fluorescence and Sm–Nd data were obtained at the University of California at Los Angeles. The Nd isotopic data were monitored for internal consistency by measuring all seven isotopes in all runs. Tracers for Sm and Nd concentration determinations were calibrated against gravimetric standard solutions using ultrapure metals from the Ames Laboratory[15,16]. All Sm–Nd analyses were by the total spike method. The measured $^{143}Nd/^{144}Nd$ ratios are expressed here in the ε-notation:

$$\varepsilon_{\mathrm{Nd}}(0) = 10^4\left[\frac{(^{143}\mathrm{Nd}/^{144}\mathrm{Nd})_{\mathrm{sample}}}{0.511836} - 1\right]$$

We also use the Sm–Nd enrichment factor, defined:

$$f_{\mathrm{Sm/Nd}} = \left[\frac{(^{147}\mathrm{Sm}/^{144}\mathrm{Nd})_{\mathrm{sample}}}{0.1967} - 1\right]$$

The values in the denominators are the isotopic ratios determined for average chondritic meteorites[17]. Our $\varepsilon_{\mathrm{Nd}}$ values as defined here are comparable with those of ref. 16 to within ±0.1 units.

Results

Sample 28-VIII contained abundant rounded, unzoned zircon for which U–Pb data have been obtained (Table 3). Two fractions were dated. The 100–200 mesh fraction is nearly concordant at 2,500 Myr (Fig. 2). The >100 mesh fraction is discordant and indicated an age of 2,550 Myr on the basis of a discordia line passing through 500 Myr (by analogy with the pegmatite minerals of Grew and Manton[4]). A 2,500-Myr age for the granulite-facies metamorphism, which Grew and Manton[4] inferred to be nearly coeval with the 2,500-Myr-old hypersthene-bearing pegmatites found throughout the Napier complex, is supported by the ages obtained from the zircons in this study. These zircons appear to have been reset at about the same time the pegmatites were emplaced. We have taken the 2,550-Myr value as the time of metamorphism for the purpose of discussion of the other isotopic data. It has been proposed that the Napier complex was also affected by a granulite-facies metamorphism about 3,000 Myr ago[18,32], but a second metamorphic event antedating 2,550 Myr would not affect the following arguments significantly.

Figure 3 shows the isotopic evolution of the samples as a function of time. We represented the data for each of the three isotopic systems in an analogous fashion. In all three plots, the trajectory labelled 'Mantle' represents an approximation to the isotopic evolution of the parental reservoir from which continental crust is derived by magmatic processes. It is assumed that any segment of continental crust must have had isotope ratios that lay on the mantle lines at the time it was originally derived from the mantle.

The Sm–Nd isotopic data (Fig. 3*a*) give the most direct indication of an ancient age of crust formation. The measured values of $\varepsilon_{\mathrm{Nd}}(0)$ (Table 2), shown at $T = 0$, are extrapolated back in time using the measured values of $^{147}Sm/^{144}Nd$. The points at which these lines intersect the mantle curve correspond to the Sm–Nd model crust-formation ages (T_{DM}) (ref. 8). We have used T_{DM}, rather than T_{CHUR} (ref. 19), because there is an increasing amount of evidence that continental crust is derived mainly from depleted mantle (DM), even as far back as the Archaean[8,17,20]. The model ages clearly show that crust formation predated 3,100-Myr ago. Probably much of the crust represented by these samples formed before 3,300 Myr. The spread of model ages does not allow precise definition of crust-formation ages for these rocks. Nonetheless, the data clearly confirm the existence of early Archaean crust at Fyfe Hills. The interpretation of the T_{DM} ages is discussed further below.

Sample numbers refer to the numbers as supplied to us. The Soviet field numbers were deduced from Table 5 of ref. 6 in which the same Rb–Sr data are presented.

All Fe as Fe_2O_3. ND, none detected. U, Th, Pb, Rb, Sr, Sm, Nd measured by isotope dilution; all other by X-ray fluorescence.

* Analytical precision is ±0.0003 for $^{87}Sr/^{86}Sr$, ±0.5 for $\varepsilon_{Nd}(0)$, and ±0.1% for Pb isotopic ratios.

† Uncertainty in model ages is typically 1–2%.

Our U–Pb and Rb–Sr data (Fig. 3*b, c*) also require that crust formation substantially predates the granulite-facies metamorphism. For U–Pb, the extremely low measured μ values ($\mu = {}^{238}U/{}^{204}Pb$) give calculated $^{206}Pb/^{204}Pb$ ratios that lie above the mantle evolution curve at 2,550 Myr ago[21]. Consequently, the rocks must have had much higher μ values during all or part of the time interval between crust formation and 2,550 Myr ago. The broken lines on Fig. 3*b* show the Pb isotopic evolution before 2,550 Myr for an arbitrarily assumed crust formation age of 3,600 Myr. The measured μ values, compared with those calculated for the time interval between crust formation and metamorphism, suggest that μ decreased by factors of 2–100 during the metamorphism as a result of severe U loss. This conclusion is independent of the value assumed for the crust-formation age. If instead of using the measured μ values, we use the measured $^{206}Pb/^{204}Pb$ and $^{207}Pb/^{204}Pb$ ratios to calculate a self-consistent set of values for μ_1 (3,600–2,550 Myr ago) and μ_2 (2,550 Myr ago to the present, see ref. 7), the calculated values of μ_2 agree with the measured values to within a factor of two. This agreement indicates that the low measured μs are a real feature that cannot be explained by loss of U in the outcrop by recent weathering. Sample 28-VIII differs in that it apparently has recently acquired a high μ value, possibly because of a gain in U, for Pb loss is ruled out by the Th–Pb data.

The Rb–Sr data (Fig. 3*c*) are analogous to the U–Pb data because the calculated $^{87}Sr/^{86}Sr$ ratios at the time of granulite metamorphism lie well above the mantle curve. This requires the rocks to have had high values of $^{87}Rb/^{86}Sr$ over an extended time interval before 2,550 Myr ago. $^{87}Rb/^{86}Sr$ apparently decreased during the granulite facies event by factors of 10–20 in most of the rocks. The marked loss of U and Rb observed in the Napier complex is characteristic of granulite grade terranes but is more extreme than examples from younger terranes. The resultant changes in μ and $^{87}Rb/^{86}Sr$ cause the model ages, as determined by the point of intersection of the sample evolution line with the mantle evolution line (Fig. 2), to be either unreasonably young (U–Pb) or undefined (Rb–Sr and some U–Pb data). In contrast, the Sm/Nd model ages are not shifted by more than ~10%.

The U–Pb isotopic data are displayed in Fig. 2. Our analyses confirm the high ^{207}Pb contents reported by Sobotovich *et al.*[6] but do not reproduce the linear array which was the basis of their 4,000 Myr age. The Th and Pb concentrations reported here are similar to those reported by Sobotovich *et al.*[6], but our U concentrations are lower by nearly an order of magnitude (except for sample 28-VII). The data (Fig. 3*c*) would be reasonably consistent with a model of crust formation at ~3,600 Myr ago and metamorphism at 2,500 Myr (3,600–2,500 Myr isochron), but this evidence is not sufficient to fix the crust-formation age.

Discussion

There is little evidence from other areas for metamorphic disturbance of Sm–Nd ages[8,17,19]. Our Sm–Nd data could be interpreted, therefore, to indicate that the protoliths of the Fyfe Hills granulites represent crust formed in multiple events over a large interval of time (3,090–3,870 Myr). However, geochronological data from other areas indicate that crust formation in a given continent or province within a continent is distinctly episodic, typically lasting ~100 Myr (see refs 7, 8 and 22). Thus, we wish to consider the evidence that some of the scatter of T_{DM} ages observed at Fyfe Hills is a result of Sm–Nd redistribution during the granulite-facies metamorphism.

The metamorphic effects can be modelled for a rock sequence having a uniform crust-formation age, τ, for Sm–Nd and subsequently subjected to redistribution of Sm and Nd isotopes at some age $\tau_m < \tau$. We will assume that in the affected volume of rock, V, which has an overall value of the Sm/Nd enrichment

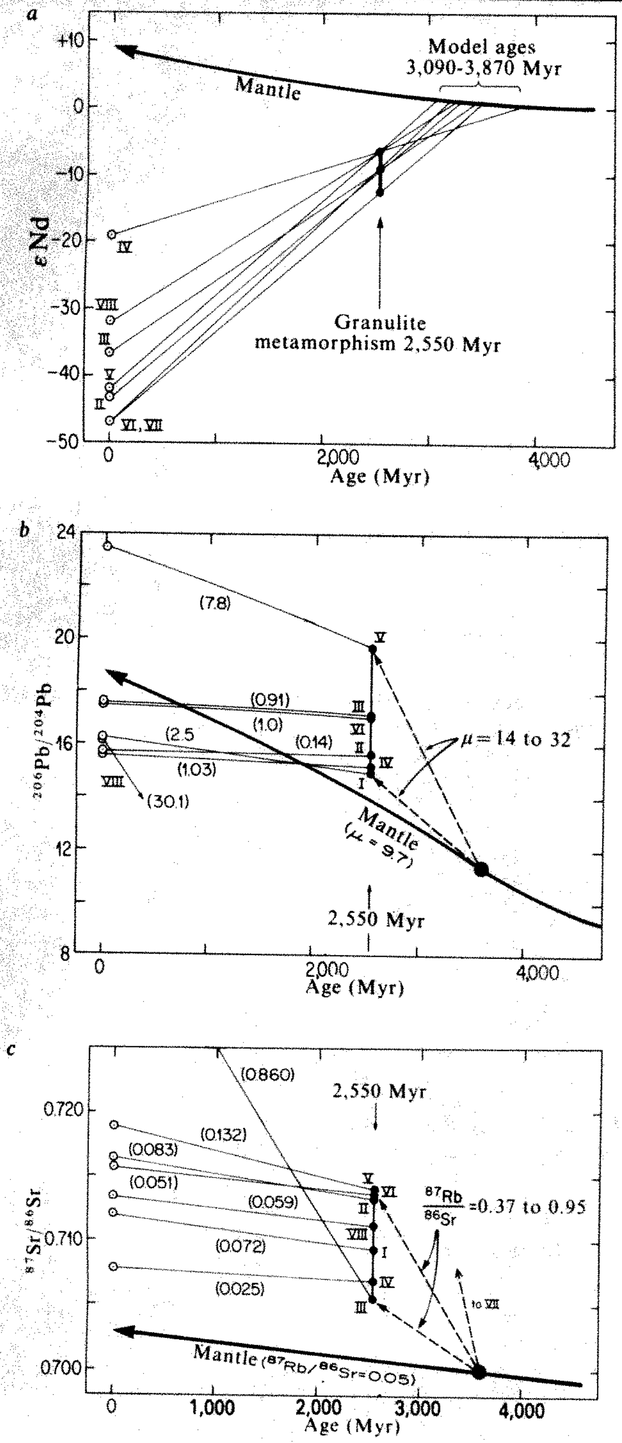

Fig. 3 *a*, Nd isotopic evolution of Fyfe Hills samples, showing model ages. *b*, Evolution of ^{206}Pb/^{204}Pb in Fyfe Hills samples. For illustration, the crustal evolution is shown to commence at 3,600 Myr ago (large ●). The μ ($= ^{238}$U/^{204}Pb) values required during the time interval 3,600–2,550 Myr ago are much higher than the measured μ values, shown in parentheses. Sample VIII shows evidence for recent gain of U. *c*, Evolution of ^{87}Sr/^{86}Sr in Fyfe Hills samples. The range of ^{87}Rb/^{86}Sr ratios required during the interval 3,600–2,550 Myr are given at the right; the measured values are shown in parentheses. Large ●, crust-formation age (see *b*).

factor equal to $f^{V}_{\rm Sm/Nd}$, Nd isotopic redistribution is complete, so that $\varepsilon_{\rm Nd}$ is uniform in V at time τ_m. If the volume of a particular analysed rock specimen is $\nu < V$, then $f^{\nu}_{\rm Sm/Nd}$ may differ from $f^{V}_{\rm Sm/Nd}$ by a factor, β, depending on the mineralogy in the volume, ν. The model age, $T^{\nu}_{\rm DM}$, is related to τ, the crust-formation age, by:

$$\tau \approx \tau_m + (T^{\nu}_{\rm DM} - \tau_m)\beta \qquad (1)$$

If an arbitrary τ value of 3,500 Myr and $\tau_m = 2{,}550$ Myr are used for the Fyfe Hills samples, β is calculated to be 0.72–1.46 for six of the samples, and 1.76 for sample V, the ironstone. With the exception of sample V, the calculated β values are not unreasonable, considering the relatively small sample size (10^{-4} m^3) and the variable mineralogy (Table 1). The β values depend on the assumed age, τ, but are plausible for any τ in the range 3,200–3,800 Myr.

The Fyfe Hills rocks show clear evidence for bulk removal of U and Rb, and thus the volume, V, for redistribution may have been large (km^3). Large-scale transport probably requires either magma or a volatile-rich fluid which can move through the rocks and selectively leach out certain elements. In this situation, which is analogous to ion-exchange chromatography[23], the average transport distance for any element will vary roughly as D^{-1} where D is the solid–fluid distribution coefficient. For a given volume of rock undergoing this metamorphic leaching, the amount of change in the elemental ratios Rb/Sr, U/Pb and Sm/Nd will depend on the absolute value of D for each element and the integrated fluid/rock ratio. For any volume of rock, ν, a bulk rock value of D^{α}_{ν} for element α could theoretically be calculated from the mineralogy:

$$D^{\alpha}_{\nu} = \sum_{p} D^{\alpha}_{p}\omega^{\nu}_{p} \qquad (2)$$

where: ω^{ν}_{p} is the weight fraction of mineral p in volume ν, and where D^{α}_{p} is the mineral–fluid distribution coefficient for element α in mineral p. Assuming local equilibrium, if $D^{\alpha} \ll 1$, even a small amount of fluid would quickly shift the concentration of α, C^{α}_{ν}, to a value of:

$$C^{\alpha}_{\nu} = D^{\alpha}_{\nu} C^{\alpha}_{\rm fluid} \qquad (3)$$

whereas if $D^{\alpha} \gg 1$, C^{α} could be essentially unaffected by the fluid interaction.

For our hand-sized samples from a single large outcrop in the Fyfe Hills, a gauge of mobility for an element would be the extent to which $C^{\alpha} \propto D^{\alpha}$ for all the samples. In practice, this test is difficult because D^{α}_{p} values are poorly constrained, and depend on fluid composition. Nevertheless, an estimate is possible because of the relatively simple mineralogy of the Fyfe Hills samples (Table 1). D^{α}_{p} values are available for mineral/magma partitioning for Rb, Sr, Sm and Nd (refs 24, 25). The absolute values are likely to be very different for an intergranular fluid in rock undergoing granulite-facies metamorphism, but the relative values for different minerals would be similar, except for possible temperature effects ($\log D^{\alpha}_{1}/D^{\alpha}_{2}$ would be approximately proportional to inverse absolute temperature).

Computed values for $D^{\rm Rb}$, $D^{\rm Sr}$ and $D^{\rm Nd}$ based on the modes are given in Table 1. For $D^{\rm Nd}$, modal apatite was calculated from the measured P$_2$O$_5$ (Table 2). For Rb, where the isotopic data clearly indicate mobility, there is a significant correlation between $D^{\rm Rb}$ and $C^{\rm Rb}$ (Table 2); $C^{\rm Rb}$ versus modal K-feldspar + biotite also yields a good correlation. A correlation is also found between $D^{\rm Nd}$ (or P$_2$O$_5$) and $C^{\rm Nd}$. No correlation is evident between $D^{\rm Sr}$ and $C^{\rm Sr}$ for the samples with large values of $D^{\rm Sr}$, but the sample with low $D^{\rm Sr}$ (28-V) has low $C^{\rm Sr}$, as would be predicted. These observations suggest that Nd and Sm, in addition to Rb, were mobile during the metamorphism because they were partitioned into the fluid. On the other hand, Sr was much less mobile because most of the rocks have large $D^{\rm Sr}$ values reflecting abundant plagioclase.

This analysis indicates that disturbance of the Sm–Nd system may have been sufficient to explain the range of observed $T_{\rm DM}$ ages. The Sm–Nd ages are less disturbed than those of Rb–Sr (and U–Pb) presumably because $D^{\rm Nd}$ and $D^{\rm Sm}$ are similar. In

Table 3 U–Pb Concentrations and Isotope ratios of two zircon fractions from sample 28-VIII

Fraction	U (p.p.m.)	Pb (p.p.m.)	$^{206}Pb/^{204}Pb$	$^{206}Pb/^{207}Pb$	$^{206}Pb/^{208}Pb$	$^{206}Pb^*/^{238}U$	$^{207}Pb^*/^{235}U$
>100 mesh	630.8	326.6	1.11×10^4	5.979	6.519	0.4556	10.51
100–200 mesh	590.5	316.5	3.44×10^4	6.096	5.838	0.4662	10.55

general, the least disturbed samples should be those with large values of D for both the parent and daughter element. One of our samples (28-VII) has the requisite large values of D^{Rb}, D^{Nd} and C^{Rb}, C^{Sm} and C^{Nd}. This sample is also the only one with roughly concordant model ages for Sm–Nd (3,490 Myr) and Rb–Sr (3,740 Myr).

The T_{DM} age and the low $^{147}Sm/^{144}Nd$ ratio of sample VII provide independent evidence for some crust ~3,500 Myr old in the Fyfe Hills. An age of crust formation younger than the T_{DM} for this sample requires that $^{147}Sm/^{144}Nd$ increased during the granulite-facies metamorphism. Such an increase is unlikely given the low $^{147}Sm/^{144}Nd$ in this sample. For example, if the crust-formation age were assumed to be 100 Myr younger than T_{DM}, the protolith would have to have had $f_{Sm/Nd} = -0.63$ [equation (1)]. Rocks with such low values of $f_{Sm/Nd}$ are extremely rare; the lowest value reported is −0.61 (ref. 26) and the mean for crustal rocks is about −0.35 (ref. 11).

Conclusions

The evidence for Nd mobility during granulite-facies metamorphism demonstrates that Sm–Nd model ages cannot be taken at face value in high-grade terranes. However, because of the relatively small net shifts in the model ages, Sm–Nd still provides a much better means of determining crust-formation ages than does either Rb–Sr or U–Pb. We have too few data from the Fyfe Hills to fix precisely the crust-formation age or determine the number of crust-forming events. Based on our analysis, the best indication of the crust-formation age is probably provided by T_{DM} of 3,500 Myr for sample VII. It is not clear whether this age, if correct, would apply to all of the rocks sampled. Reported isotopic evidence for an additional event at ~3,000 Myr ago[18,32] allows the possibility that crust formation occurred at that time also.

We conclude that the geological history of the Fyfe Hills commenced with the differentiation of magmatic rocks from the mantle at a time tentatively estimated to be ~3,500 Myr ago. The igneous crust must have become chemically layered at or about the time of formation with enrichment of Rb, U and K, and high Rb/Sr and U/Pb in the upper crust. During granulite-facies metamorphism ~2,500 Myr ago, the rocks lost most of their Rb and U, profoundly disturbing the isotopic systematics of Sr and Pb.

Our data show that a granulite-facies metamorphism post-dated crust formation by ~1,000 Myr in these rocks. Comparable time separation between crust formation and granulite-facies metamorphism has been demonstrated previously for Proterozoic granulite events[7,27], but not for an Archaean (>2,500 Myr) event. In the Archaean granulite terranes for which sufficient geochronological data are available[22,28], crust formation and granulite-facies metamorphism appear to have been contemporaneous within the resolution of the dating techniques (~100 Myr). Hamilton *et al.*[28] have attributed this to rapid heating after crust formation caused by *in situ* radioactive decay of U, Th and ^{40}K. Such a heat source is a possible cause for granulite-facies metamorphism that does not require plate tectonics. However, the conclusion was based on an erroneous heat flow calculation. Hamilton *et al.*[28] modelled the crust as a semi-infinite solid, whereas it should be modelled as a finite-thickness slab. In either case, *in situ* radioactive decay is not a satisfactory heat source for a granulite-facies metamorphic event post-dating crust formation by 1,000 Myr.

In general, the continental crust cannot reach granulite-facies conditions at depths corresponding to pressures of 7–10 kbar unless there is heat supplied from deeper levels. One possible heat source is magma, which in orogenic zones rises from the mantle into the crust on a regional scale over an extended period of time[29]. Another mechanism for generating granulite-facies conditions is large-scale underthrusting in a Himalayan-type continental collision zone[30]. Either of these mechanisms can account for a long time delay before metamorphism, and both require plate tectonics. In orogenic zones associated with subduction (magmatic arcs), granulite-facies metamorphism would be closely associated with crust formation, and at Andean-type continental margins old rocks comprising the continent may also be metamorphosed at a time much later than the time they were differentiated from the mantle. The Napier complex may represent the site of a former continental margin magmatic arc, or a continental collision zone that was active ~2,500 Myr ago, and resulted in metamorphism of ~3,500-Myr-old continental crust. If it were a magmatic arc, we would expect to find evidence in the Napier complex for the production of new crust in the form of magma ~2,500 Myr ago. Rocks of possible plutonic origin in the Napier complex, such as intrusive charnockite (Fig. 1 and ref. 3) should be investigated. Further isotopic studies of the Napier complex and other Archaean granulite terranes presently exposed in crystalline shields could provide important evidence that a plate tectonic regime similar to the Wilson cycle was operative in Archaean time.

We thank G. E. Grikurov and Ye. N. Kamenev for the samples from Fyfe Hills, G. Stummer for the X-ray fluorescence analyses, and B. Nelson for comments. NSF grants DDP76-80957, DPP80-19527 and EAR78-12966 are gratefully acknowledged.

An inter-laboratory comparison of radiocarbon measurements in tree rings

International Study Group[*]

Results from a collaborative study designed by the Glasgow ^{14}C laboratory to assess experimental variability in radiocarbon dating are presented. A series of eight replicate samples from one tree were dated independently by 20 ^{14}C laboratories. While the results are in general agreement they reveal the existence of systematic bias and unexplained variability. Thus as a general guideline for users of ^{14}C dates, quoted errors, particularly those derived solely on the basis of the counting procedure, should be multiplied by a factor of between 2 and 3.

THE method of radiocarbon dating, since its practical inception ~30 yr ago, has seen considerable development in methods of ^{14}C assay and in archaeological and geological applications requiring ever-more precise measurement[1-3]. The corresponding increase in the number of laboratories performing such work has not, however, produced an equivalent emphasis on a necessary programme of inter-laboratory checks on analytical methods. Thus the normal procedure for assessing errors in laboratory procedures using replicate sample analysis has been long neglected in the radiocarbon dating field. This project represents the first collaborative attempt to rationalize and quantify by experiment the uncertainty involved in ^{14}C dating of a typical sample and thus its major aims have been to collect quantitative information on the variability of ^{14}C dates and to estimate the extent of inter-laboratory variability.

Organization and design of the study

Although there are at present over 100 laboratories[4] providing a ^{14}C dating service using various analytical techniques, the logistics of the study required initial selection, at a fairly arbitrary level, of an, at least approximately, representative subgroup of laboratories, covering most, if not all, of the common experimental procedures. To this end, 30 laboratories were invited to participate in the study, with ultimately, results from 20 laboratories being submitted. The participants are listed in Table 1. It was agreed, as a prerequisite of participation, that because the aims of the study were not directed towards assessing errors in individual laboratories but rather towards monitoring group performance, anonymity would be preserved and laboratories would be assigned code letters A–T. Included in the original group of 30 was a smaller subgroup of 'high precision' laboratories, three of which agreed to take part.

The design of the study envisaged that each laboratory would date eight samples, hereafter referred to as time points 1–8, selected from a wood section spanning ~200 yr growth. Each sample, of 10 rings width, would be identified on a tree ring width plot to ensure that the same samples would be assayed by each laboratory. The sections of oak were themselves taken from one tree trunk from a submerged forest exposure at Stolford, UK (51°12′ N, 3°06′ W). The wood was well preserved, available in considerable quantity and sensitive ring patterns enabled accurate cross-matching of subsections. Each European laboratory received a complete section, while for reasons of postal economy non-European laboratories received the samples already extracted from their sections.

To reduce possible sources of variability in the results, each laboratory was asked to extract and date the cellulose fraction of the samples, and to this end, a standard recipe[5] involving KOH digestion followed by $NaClO_2/HCl$ bleaching, was circulated. A few laboratories chose not to extract cellulose preferring to adopt alternative procedures. However, subsequent additional work by both the La Jolla and Uppsala laboratories indicated that the method of pretreatment was, in this case, not important. Apart from pretreatment, each laboratory was asked to treat the replicate samples routinely and, in addition, to spread the measurements over as long a time period as possible to model more precisely the normal mode of operation.

The information requested from each laboratory included $\delta^{13}C$, which is the per mil deviation of the $^{13}C/^{12}C$ ratio from the PDB (belemnite) standard ratio, d ^{14}C, the per mil depletion or enrichment in ^{14}C with regard to the NBS oxalic acid standard, D ^{14}C which is d ^{14}C normalized for isotopic fractionation, conventional radiocarbon age (using the 5,568 yr Libby half life) and its error (based solely on the counting statistics), the overall error on the result, if different, and details of the counting method. One area in which it was considered necessary to provide clear instructions to participants concerned the age and error calculations themselves. The method of age calculation was constrained to the convention recommended by Stuiver and Polach[6]. However, no similar series of instructions exists for error calculations, some laboratories commonly quoting errors based solely on theoretical estimates of the uncertainty resulting from the radioactivity measurement process alone and others including additional error terms. Thus to ensure that results would be directly comparable a method of calculating a common error term was described, the final error being arrived at through propagation of the counting uncertainties on the sample, standard and background activities alone.

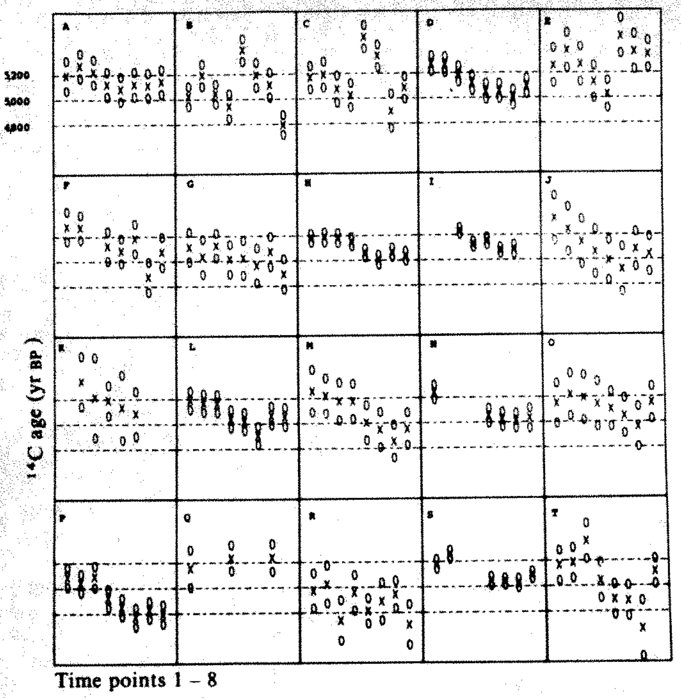

Fig. 1 Radiocarbon age (yr BP), along with 2σ error estimates versus time point for each laboratory. – – –, Reference lines at 5,200, 5,000 and 4,800 yr BP.

Before discussing the results it is important to mention their limitations, these being due primarily to the small sample numbers per laboratory—eight—and to the short study period—6–9 months. Conclusions concerning individual laboratory performance can therefore only be tentative and the more general conclusions can be drawn only for this one type of material and for this specific age. In addition, only short-term variability could contribute to the observed errors. Further results, however, reported by Stenhouse and Baxter[7] point to the relevance of the study results to routine archaeological dating over a wider range of sample types, artefact ages and laboratory time.

Results and preliminary comments

Of the results received from 20 laboratories six sets were for various reasons incomplete and thus a total of 143 measurements was obtained for this single tree. The results for each laboratory are shown in Fig. 1, the ^{14}C data across the eight time points being graphed for each laboratory, along with ± twice the quoted errors on each date. Horizontal reference lines at 5,200, 5,000 and 4,800 yr BP are shown to aid comparison. Figure 1 shows that the laboratory results all overlap in the age-range 5,000–5,200 yr BP and are thus in broad agreement. However, inspection of the results indicates the existence of considerable variability; for individual time points, results differ by between 316 and 724 yr, while, for individual laboratories, age differences of between 190 and 690 yr are observed.

The first stage of data analysis involved a preliminary estimation of the time trend through the results by calculating their weighted average at each time point, the weights in the averaging process being inversely proportional to the quoted error. The results are presented below, the trend showing the effect of ^{14}C decay during wood growth and implying the existence of a small fluctuation in mid-section.

Time point	1	2	3	4
Mean	5,168.5	5,196.1	5,173.1	5,094.4
s.e.m.	8.9	9.5	8.9	7.9
Time point	5	6	7	8
Mean	5,070.0	5,031.4	5,025.2	5,030.7
s.e.m.	7.6	7.0	8.1	8.5

Of primary interest, however, was an assessment of the variability observed about this trend relative to the claimed variability as measured by quoted errors. This analysis was performed by estimating the 'standardized residuals'—the differences between the observed and estimated time trend divided by the quoted errors. By normalizing results in this way it is reasonable to postulate that if the quoted error does measure the true error then most, if not all, of such residuals should be within the range −2 and +2. Figure 2 shows the series of standardized residual plots, with horizontal reference lines at −2, 0 and 2. Such plots visually confirm the impressions of the existence of bias for some laboratories and of the more variable nature of others.

The relative wealth of data available, however, offers the opportunity to provide (1) a more rigorous assessment of bias and additional variability for individual laboratories (of particular interest to the ^{14}C analyst), and more importantly (2) an estimate of the variability in a typical ^{14}C date for the benefit of an archaeologist or other user.

Evaluation of results

Throughout the interpretation of the results we have chosen to model the true variability using a multiplicative factor θ, such that $\theta \times$ quoted error gives a more realistic measure of reproducibility. There are two main reasons for the choice of a multiplicative factor rather than an additive term: (1) that a multiplicative factor gives a more immediate and simple understanding of the relative magnitude of the true error involved; and (2) the estimation of such a factor θ is mathematically slightly more straightforward, particularly for interval estimates. (The intervals are a range of plausible values for θ, a property of the method being that 95% of the time they will contain the true θ value.)

Nevertheless we concede that in reality any extra variability is almost certainly additive in nature. Use of a θ factor, however, effectively produces the same results as an additive term since each laboratory has more or less constant quoted error over these samples.

The significance of θ is such that $\theta = 1$ implies that the quoted error adequately represents the true error, while $\theta < 1$ and $\theta > 1$ imply over- and under-estimation respectively by the quoted error. Point and interval estimates for θ are produced throughout by use of likelihood methods[8].

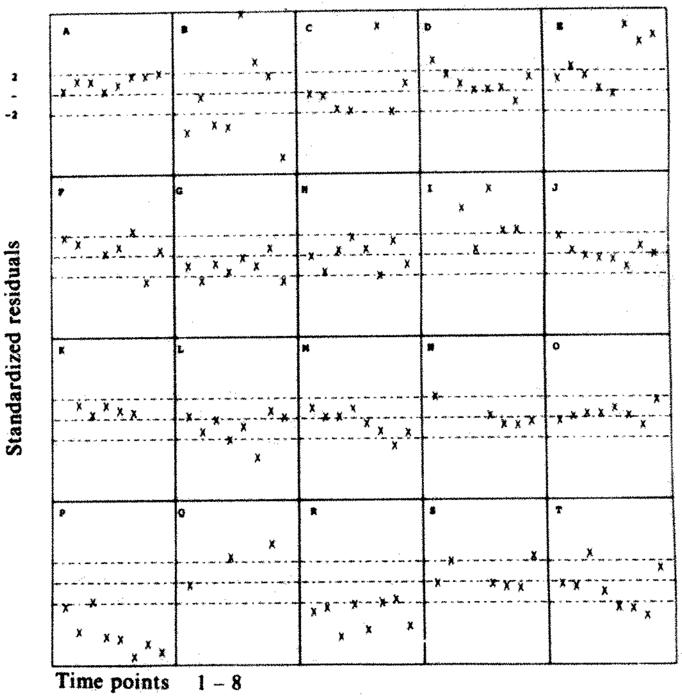

Fig. 2 Standardized residuals plotted against time point for each laboratory. – – –, Reference lines at −2, 0 and 2.

Table 2 Point and interval estimates for bias relative to baselines (1), (2) and (3)

	Baseline (1)		(2)		(3)	
Lab.	Bias	Interval estimate	Bias	Interval estimate	Bias	Interval estimate
A	53.02	(15.90)	56.28	(35.5, 85)	52.5	(13,87)

J	−3.35	(−65,50)	−6.85	(−70,50)	–	
K	72.36	(25,115)	73.71	(40,110)	72.65	(28,113)
L	−33.70	(−70,0)	−38.65	(−80,0)	−35.19	(−72,0)
M	−43.85	(−112,20)	−48.44	(−115,20)	−45.09	(−106,14)
N	6.17	(−50,60)	−4.91	(−45,30)	–	
O	21.51	(−25,70)	14.82	(−30,55)	–	
P	−189.63	(−240,−145)	−194.11	(−245,−150)	−191.2	(−237,−150)
Q	94.37	(−25,205)	123.19	(−10,250)	98.86	(−37,225)
R	−216.35	(−295,−145)	−219.57	(−300,−45)	−215.97	(−295,−144)
S	25.12	(−20,65)	7.40	(−25,35)	17.56	(−12,50)
T	−37.09	(−135,63)	−46.26	(−150,55)	−41.14	(−137,54)

The analysis falls into two main sections, relevant to individual laboratory and group performances. First, individual laboratories were assessed for possible bias and θ factors.

Two obvious choices of baseline and one other justifiable choice were: (1) results from high precision laboratories; (2) the weighted average of all the results, that is as before; and (3) the new weighted average of results from laboratories with identifying letters H, J, N and O giving the following results at each time point:

Weighted average	5,186	5,176	5,165	5,134
Standard error	15	19	19	18

Weighted average	5,044	4,997	5,035	5,029
Standard error	15	16	15	17

(In all cases the error on the estimates of true age were assumed to be adequately measured by the quoted errors, that is either counting errors for baseline (1) or standard errors for baselines (2) and (3).) With respect to baseline (1) only one high precision laboratory's results were used, that is H, since it had provided a complete set of eight results, while laboratory S was not quite in statistical agreement with H and I appeared systematically biased with respect to H and S). For baseline (2) no results were rejected from the study, the main reason for this being the assumption that the laboratories in the study form a representative cross-section of ^{14}C laboratories as a whole. However, laboratories showing a great deal of variability and/or bias may influence age results excessively and the baseline for the data may then best be defined by considering only laboratories whose quoted errors measure their true error and which are unbiased relative to each other. Any criterion used for rejection of results is necessarily subjective (partly due to lack of absolute knowledge about the chronology and the inadequacy of additional information concerning each laboratory's replicate error). Our approach has been to consider the two groups of laboratories which were consistent with the baselines described in (1) and (2) (the definition of consistent being that there is inconclusive evidence that bias and θ factor are different from 0 and 1 respectively). The laboratories contained in both groups were used to provide a basis for calculation of the new weighted average for baseline (3).

Results for each laboratory relative to these baselines are shown in Tables 2 and 3, the major conclusions being that:

(1) Many laboratories show bias estimates ranging up to 200 yr. Only six, however, have statistically significant biases at the 5% level while three have point estimates of <20 yr. It is, of course, conceivable that, for any laboratory, bias itself may be variable with time when factors such as different standardizations and laboratory procedures are employed. The results imply that for most laboratories greater intercalibration efforts are necessary. (2) Individual θ factor estimates range from 0.35 to 4.3, with a median value of 1.4, and thus, in general, quoted errors do not adequately express true variability. This seems to be the case even if detailed intercalibration could remove bias factors for a given laboratory. Increased emphasis on assessment of θ factors by routine replicate assays seems necessary for each laboratory.

(3) Variability in laboratories quoting errors ⩾80 yr (that is, laboratories J, K and O) is considerably less than expected. High precision laboratories (H, I and S) are not in agreement, either through existence of a bias or through their true errors being in excess of their quoted errors. (Relative to baselines (1) and (3), $\hat{\theta}$ factors for I and S are 2.6 (I), 2.0 (S) and 2.57, 1.70 respectively; relative to baseline (2), $\hat{\theta}$ factors for H, I and S are 1.27, 1.08 and 1.72.)

Reasons for the differing levels of performance were investigated by considering results for each laboratory relative to baseline (1) (since results relative to other baselines do not differ significantly). The factors evaluated included type of pretreatment and method of counting. As mentioned previously, differences due to pretreatment were small. However, the method of counting did appear to be relevant, most gas laboratories having a positive bias, the liquid scintillation laboratories having a tendency to be negatively biased and most interestingly gas laboratories having smaller $\hat{\theta}$ factors than liquid scintillation laboratories.

Summary statistics on the $\delta^{13}C$ measurements from each laboratory were also prepared. The average laboratory measurements ranged between −23‰ and −26‰, with most clustered around −24‰. Correlations between $\delta\ ^{13}C$ and quoted ^{14}C ages were also calculated, several being significantly different from zero. Due to the small nature of these deviations and the both natural- and laboratory-induced sources of fractionation, no further analysis of these measurements was performed.

Analysis of the group results is, however, of greater significance to a user of ^{14}C dates because he is often required to interpret results from several laboratories and must do so with a realistic awareness of analytical errors. The subsequent analysis was therefore aimed at assessing the variability of results in small subgroups formed on the basis of level of median quoted error (m.q.e.) or method of counting. The subgroups considered were (1) m.q.e. ⩽20; (2) 20<m.q.e. ⩽45; (3) 45< m.q.e. ⩽75; (4) m.q.e. ⩾80; (5) gas counting laboratories; and (6) liquid scintillation laboratories (the latter two groups excluding high precision results).

The first analysis of the group results involved treating each subgroup separately, producing an estimate of bias for each individual laboratory and culminating in a common θ factor estimate for all members of the group. The results are shown

Table 3 Point and interval estimates for multiplicative factor θ relative to baselines (1), (2) and (3)

		Baseline (1)			(2)			(3)

in Table 4*a*. Time trends through the eight samples for each group were also estimated and found, in some cases, to differ significantly. The explanation of such differences, however, is related to the presence, in some groups, of laboratories with large biases which thus affect the overall group trend.

More importantly the major implications of the Table 4*a* results are as follows:

(1) For the study group as a whole, the best estimate of θ is 1.85 (1.65–2.1) so that, if the laboratories in the study are representative of all ^{14}C laboratories the true error on a typical ^{14}C date may be approximately double the quoted error for a sample of ~5,000 yr age.

(2) Excluding the high precision laboratories, the value of θ decreases as quoted error (m.q.e.) increases. The value for laboratories of high m.q.e. ($\geq$80) is surprisingly low, the interval estimate being completely <1 and the true error in years being actually less than that for laboratories quoting m.q.e.s of 30–75 yr. It seems likely therefore that, for these high m.q.e. laboratories, quoted errors are being calculated on a highly conservative basis and indeed do represent overestimates. In fact, much of the importance of this inter-calibration exercise centres on the significance of quoted errors and on the lack of a universal method of error calculation. It is therefore to be desired that, some time in the future, ^{14}C laboratories should adopt a universal method of error estimation.

(3) For high precision (low m.q.e.) laboratories, while we cannot reject the possibility that the quoted error does quantify the observed variability, it is likely that, with a $\hat{\theta}$ of 1.30 and an interval estimate of 0.98–1.88, it does underestimate the true error slightly. Nevertheless, from the value for $\hat{\theta}\times$m.q.e. of 23.4 it is evident that the procedures inherent in high precision analysis are highly significant in reducing errors; the value of 23.4 is considerably lower than the corresponding value for other groups.

(4) The estimate of θ for gas proportional laboratories is approximately half that for liquid scintillation laboratories, the implications being that, in general, the latter are more variable and that perhaps in the future some attention might be paid to identifying the apparently uncorrected sources of variability in liquid scintillation methodology.

From (3) above, it seems likely that many of the answers may be found in the high precision procedures already adopted in the Belfast liquid scintillation laboratory.

For a user, however, information concerning relative laboratory bias is generally unknown and thus a more realistic analysis would discount possible laboratory bias and would attempt to assess the scatter of results purely in terms of θ. This is also particularly relevant since bias for any particular laboratory may well be variable through time. Using the same grouping as in the previous analysis the estimated θ values are presented in Table 4*b*. The values for θ have all increased as would be expected, the difference in θ estimates reflecting the effective reduction in unexplained variability when information about bias is available. The conclusions can be summarized as follows:

(1) Quoted errors are inadequate for the study group as a whole, with an interval estimate for θ of 2.3–3.0, and for all subgroups other than the high m.q.e. group. The latter in fact seems to be more accurate than all but the high precision laboratories. It is clear from the range of values for θ that its value is highly dependent on the size of the quoted error and thus it is difficult to give a single 'best' value for it; use of the factor θ for the entire group supposes no information about the dating laboratory.

(2) For the high precision laboratories, a θ multiple of 1.8 is suggested and, because the interval estimate excludes 1, the quoted error represents an inadequate measure of true error.

(3) The value of θ for gas laboratories is approximately half the value for liquid scintillation laboratories so that values of 1.7 and 3.5 respectively might be recommended for users of each (for normal precision laboratories only, that is m.q.e. > 20).

Conclusions

The results from the study group provide clear indications for some laboratories at least of the existence of systematic labora-

Table 4 Group estimates of θ

	a After bias removal				*b* No bias removal		
Groups	No. of labs in group	$\hat{\theta}$	Interval estimate for $\hat{\theta}$	$\hat{\theta}\times$m.q.e.	θ	Interval estimate	$\theta\times$m.q.e.
1 m.q.e. $\leq$ 20	3	1.30	0.98–1.88	23.4	1.73	1.35–2.2	31.1
2. 20 $\leq$ m.q.e. $\leq$ 45	5	2.14	1.87–2.63	81.3	3.01	2.42–3.87	114
3. 45 < m.q.e. $\leq$ 75	9	1.90	1.62–2.30	114	2.57	2.21–3.1	154
4. m.q.e. $\geq$ 80	3	0.60	0.46–0.85	54	0.71	0.54–1.01	64
5. All gas laboratories (non-high precision)	9	1.23	1.04–1.48	74	1.65	1.4–2.0	99
6. All liquid scintillation (non-high precision)	8	2.29	1.93–2.78	126	2.97	2.5–3.62	169.3
7. Entire study group	20	1.85	1.65–2.1	92	2.60	2.33–2.95	143

tory bias (both gas and liquid scintillation laboratories being equally susceptible) and of a level of variability not entirely explained by the quoted errors. One possible indicator of level of true error compared to quoted error is provided by the factor θ. The appropriate value for θ is found to be dependent on the information available; first, concerning the dating laboratory itself (knowledge of bias, counting method, size and derivation of quoted error) and, second, concerning the sample context. For the study group as a whole, the interval estimates for θ are (1) 1.65–2.1 with a point estimate of 1.85 and (2) 2.30–3.0 with a point estimator of 2.6 for situations in which (1) laboratory bias is known and has been removed and (2) no bias has been removed. In both these situations differences in performance (as measured by θ) have been observed between normal precision gas and liquid scintillation laboratories: in situation (1) above, for gas and liquid scintillation laboratories, point and interval estimates for θ are 1.23 (1.04–1.48) and 2.3 (1.93–2.78) respectively and in (2) 1.65 (1.4–2.0) and 3.0 (2.5–3.6) respectively. Thus for gas and liquid scintillation laboratories we would propose quoted error multiples of 1.2 and 2.3 for situation (1) and 1.65 and 3.0 for situation (2), the latter condition being presumably more commonly relevant.

With respect to the three high precision laboratories, there seems to be some indication that their results are more variable than claimed, but, nevertheless, their procedures do produce significant improvements in levels of precision.

Note that this study is only a first step towards rationalization of $^{14}\mathrm{C}$ dating variability. No conclusions should be overstated as each laboratory performed at most eight analyses on only one wood sample and because a great many variables remain unknown. There is, however, considerable need for further research of an intercalibrative nature involving different sample types and ages. There is apparent need also for investigation of internal replicate errors and of additional error sources (in liquid scintillation methods particularly) and for adoption of a universally acceptable method of error calculation. One should also bear in mind that in many ways the sample and laboratory procedures in this short study were close to ideal, with well preserved and sufficient sample assayed over a short period of laboratory time. Most laboratories extracted cellulose before assay, thereby presumably removing any minor cross-contamination effects. It might seem therefore that the error estimates discussed here represent minimum values which would possibly require enlargement for: degraded/small/contaminated materials; different sample types; and replicate samples counted over a longer time period. The results urge increased caution in attempting to resolve $^{14}\mathrm{C}$ differences of <200 yr.

We thank Dr A. Heyworth for supplying the samples of dendrochronologically dated wood. E. M. Scott acknowledges financial support of the NERC.

De novo methylation and expression of retroviral genomes during mouse embryogenesis

Detlev Jähner, Heidi Stuhlmann, Colin L. Stewart, Klaus Harbers, Jürgen Löhler, Iva Simon & Rudolf Jaenisch

Heinrich-Pette-Institut für Experimentelle Virologie und Immunologie an der Universität Hamburg, Martinistrasse 52, 2000 Hamburg 20, FRG

Retrovirus genomes introduced into mouse zygotes by microinjection of cloned DNA, or into morula stage pre-implantation mouse embryos by infection with Moloney murine leukaemia virus (M-MuLV), became de novo *methylated and were blocked in expression. No restriction of virus expression and no* de novo *methylation were observed when post-implantation mouse embryos were infected with virus. Efficient* de novo *methylation activity may be an important characteristic of gene regulation in early mouse embryos.*

THE introduction of foreign cellular and retroviral genomes into early mouse embryos has been used to investigate the regulation of gene expression in mammalian development[1-10]. Early mouse embryos and embryonal carcinoma cells have been shown to be non-permissive for DNA virus as well as retrovirus gene expression[11-16]. Recently, we correlated the lack of expression of genetically transmitted Moloney murine leukaemia (M-MuLV) proviral genomes with their high degree of methylation[17,18]. As the retroviral genomes introduced into the germ line of these mice were unmethylated, *de novo* methylation of the proviral genomes must have occurred at some point, either during the development of the infected embryo and/or as a consequence of their transmission through the germ line. To investigate this, we have introduced M-MuLV genomes into pre- and post-implantation embryos. Here we show that efficient *de novo* methylation occurred after the introduction of virus into pre-implantation but not into post-implantation embryos. The resulting *de novo* methylated genomes were not active in a DNA transfection assay and were apparently not expressed in early embryos.

Integration of M-MuLV genomes into mouse embryo

M-MuLV genomes were introduced into mouse embryos at different stages of embryogenesis (see Table 1). Pre-implantation embryos were infected at the zygote stage by injecting the cloned M-MuLV-containing *Eco*RI fragment from Mov-3 mice either into the male pronucleus (animal 69) or into the cytoplasm (animal 158)[6] and, at the 4–16-cell stage, by exposure to M-MuLV virus[4]. Post-implantation embryos were injected at day 8 of gestation with purified M-MuLV virus as described previously[19].

The number of M-MuLV genomes present in mouse DNA extracted from 2–4-month-old animals was determined by digestion with *Sst*I (see Fig. 1). The intensities of the M-MuLV-

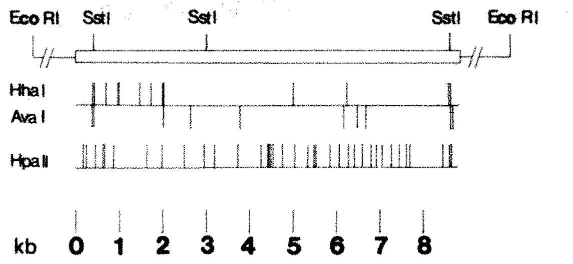

Fig. 1 Restriction enzyme map of a M-MuLV provirus. The open bar represents a M-MuLV provirus within flanking mouse DNA. Restriction sites of M-MuLV were taken from published maps[44] and sequences[45].

specific *Sst*I fragments of 5.6 and 2.6 kilobases (kb) from DNA of the experimental mice were compared with those from DNA of Mov-1 mice, thus permitting estimation of the total number of M-MuLV copies present per cell, as described elsewhere[6]. Figure 2 shows the presence of approximately 10 M-MuLV copies per cell in the DNA from mouse 69 and one copy in the DNA from mouse 158. Animals infected at day 3 of development carried between one and three copies and animals infected at day 8 of development carried between one and eight M-MuLV copies per cell in different tissues (Fig. 2, Table 1; compare ref. 19).

M-MuLV proviruses become integrated at multiple sites into pre-implantation embryos[4,5], mouse lymphocytes[20] and fibroblasts[21]. Because *Eco*RI does not cut within the M-MuLV genome, different integration sites of individual proviruses are characterized by different sizes of M-MuLV-containing *Eco*RI fragments. The number and intensities of such *Eco*RI fragments were used here to determine the time at which provirus integration took place in embryonal development. A single proviral copy inserted into the genome of the zygote will subsequently be present in every cell in all tissues of the mouse, resulting in an *Eco*RI fragment with the same intensity as the fragment which represents the single-copy M-MuLV genome in Mov mice. This has, indeed, been demonstrated for mouse 158 (Fig. 3, lane *b*, and ref. 6). DNA from mouse 69, which was derived from a zygote microinjected with cloned Mov-3 DNA into the male pronucleus, contained a strong band of 17 kb representing approximately 10 M-MuLV copies and a single copy fragment of higher molecular weight (Fig. 3, lane *a*). Further restriction enzyme analysis indicated tandem head-to-tail integration of the injected Mov-3 DNA, the single copy band representing Mov-3 DNA together with flanking mouse DNA (data not shown).

Table 1 Organization of M-MuLV copies introduced into mice at different stages of embryogenesis

Time of infection	Animal	Organ	No. of copies	No. of integration sites
Pre-implantation stage				
Day 1	69	Li	10–15	1
	158	Li	1	1
Day 3	58–1, 58–2 61, 62 100–19, 100–21	Li, Ki, Br	1–3	1–3
Post-implantation stage				
Day 8	B58, B59	Li	0.5–1	Multiple
		Ki	2–4	
		Br	4–8	
Control	Mov-13	Li	1	1

M-MuLV genomes were introduced into pre-implantation mouse embryos by DNA injection at day 1 or virus infection at day 3 of gestation. Microinjection of the cloned 16.8-kb *Eco*RI fragment from Mov-3 mice into the male pronucleus (animal 69) or into the cytoplasm (animal 158) of mouse zygotes at the day of fertilization was performed as described for mouse 158 (ref. 6). Four- to eight-cell embryos (that is, day 3 embryos) were infected *in vitro* as described for animal 62 (ref. 4). Post-implantation embryos were injected with virus *in utero* at day 8 of gestation as described elsewhere[19]. The data from mice B58 and B59 were representative of several similarly infected mice. The number of M-MuLV copies per cell was obtained by *Sst*I digestion with DNAs from liver (Li), kidney (Ki) or brain (Br) by comparison with the Mov-13 DNA (see Fig. 2). This DNA contained one M-MuLV genome per diploid genome. *Eco*RI digestion of DNA was used to determine the number of integration sites of M-MuLV in a given organ (see Fig. 3). All embryos were of strain C57BL/6 except animals 62, 100–19 and 100–21, which were ICR and 129 mice, respectively.

When exposure to virus takes place at a later stage (the 4–16-cell stage), integration can occur at different chromosomal sites as well as in different blastomeres. This will lead to less intense *Eco*RI fragments, depending on the segregation of the descendants of the infected blastomere during later development and their contribution to a given organ. Several *Eco*RI fragments of varying intensity were, indeed, observed in the DNA of such animals (Fig. 3, lanes *c*, *g*), indicating that these animals were mosaics with respect to the integrated M-MuLV copies (compare ref. 4). Germ-line mosaicism of such mice had been demonstrated previously[3–5]. The results shown in Fig. 3 revealed that the M-MuLV genomes present in the DNA of mice that were infected as pre-implantation embryos integrated in only a few chromosomal sites in a given animal. This indicated that the integration of M-MuLV genomes in these embryos occurred soon after the time of infection. Little or no reintegration of viral genomes had occurred during later stages of development (see below).

A different pattern of M-MuLV-specific *Eco*RI fragments was observed after infection with M-MuLV at a later stage, for example, day 8 of development, when the embryo consists of 10^4–10^5 cells. A broad smear of hybridization was seen and no discrete *Eco*RI fragments were detectable in any organ of such animals (Fig. 3, lanes *i*, *k*). This suggested that integration of virus took place at multiple sites in a heterogeneous population of cells. Each infected cell divided to form only a small fraction of the total number of cells in the respective tissue. We have shown previously that after postnatal infection of mice with M-MuLV, significant amounts of proviruses were not found in cells other than those of lymphopoietic origin[19]. The copies of M-MuLV in the non-lymphatic organs liver, kidney and brain of day-8 infected mice (Fig. 2*b*) therefore indicated prenatal virus spread. This conclusion was supported by *in situ* hybridization experiments (Fig. 4). At 4 days after injection of virus, multiple foci of cells expressing viral RNA were detected in liver and brain cells as well as in cells of other tissues. Viral proteins were detected similarly in multiple cells by immunofluorescence (not shown). Thus, efficient virus replication and infection took place at mid-gestation. These results, summarized in Table 1, suggested that the M-MuLV DNA detected in the adult integrated into the mouse genome at or soon after the time of the introduction of viral genomes.

De novo methylation of M-MuLV proviruses

The methylation of CpG dinucleotides in M-MuLV genomes present in the DNA of animals infected during different stages of embryogenesis (see Table 1) was analysed with methylation-sensitive enzymes[22–24]. Because newly synthesized retroviral DNA, the precursor of the provirus, is not methylated, the presence of 5-methylcytosine will reveal that *de novo* methylation has occurred between the time of integration and the time of DNA preparation. A given site can either be methylated or unmethylated. However, when studying the DNA from a population of cells, the same restriction site can be methylated in some molecules and unmethylated in the rest. Due to this heterogeneity, intermediate levels of methylation have been found in several analyses[25–28]. The presence of methyl groups in M-MuLV genomes was analysed by the resistance of the M-MuLV-specific *Sst*I or *Eco*RI fragments to digestion with the methylation-sensitive enzymes *Hha*I, *Ava*I or *Hpa*II (see Fig. 1). In all the DNAs from animals infected as pre-implantation embryos, the 2.6-kb *Sst*I fragment was highly resistant to digestion with all three enzymes (see Fig. 5). The 5.6-kb *Sst*I

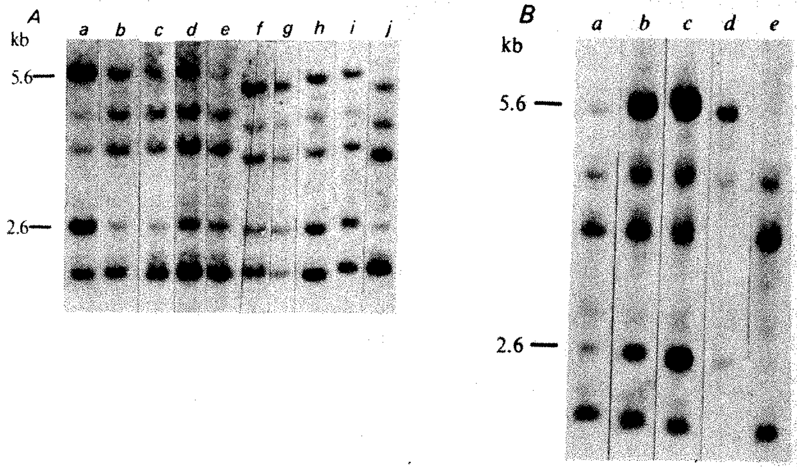

Fig. 2 Estimation of M-MuLV copies in DNAs from mice infected during embryogenesis. High molecular weight DNA was prepared, samples of 5–10 μg were cleaved with *Sst*I, separated on a 0.7% agarose gel and transferred to a nitrocellulose filter as described previously[17]. The filters were hybridized with a cDNA enriched for sequences specific for M-MuLV and washed after hybridization at 50 °C as described elsewhere[20]. *A*, DNAs from animals infected as pre-implantation embryos. Lanes *a*, *b*, liver DNA from animals 69 and 158, respectively; lanes *c*–*e*, DNA from liver, kidney and brain, respectively, of animal 58–1; lanes *f*, *g*, DNA from liver and brain, respectively, of animal 58–2; lanes *h*, *i*, liver DNA from animals 100–19 and 100–21, respectively; lane *j*, embryo DNA from Mov-13 mice[5], containing one copy of M-MuLV per cell. *B*, DNAs derived after infection of post-implantation embryos. Lanes *a*–*c*, DNAs from liver, kidney and brain, respectively, of animal B58; lane *d*, embryo DNA from Mov-1 mice, containing two copies of M-MuLV per cell; lane *e*, DNA from C57BL/6 mice. The bands present in all DNAs are due to cross-hybridization of the probe to DNA of endogenous retroviral genomes of the mouse[20]. These bands served as an internal standard for the amount of DNA present in each lane. The intensities of the 5.6- and 2.6-kb M-MuLV-specific *Sst*I fragments in DNAs from Mov mice, *A*, lane *j* and *B*, lane *d*, were used to estimate the number of M-MuLV copies in the other DNAs (see Table 1). As Mov-1 is of BALB/c background, bands derived from endogenous viruses are weaker with this probe than in C57BL/6 (compare lane *d* with lane *j*, *A*).

fragment was similarly resistant to cleavage with *Hha*I and *Ava*I and to some extent with *Hpa*II.

From the results shown in Fig. 5*A* we calculated that 70–95% of each of the sites had become *de novo* methylated in these DNAs (see Table 2). Our calculation was based on the assumption that every site was methylated to the same extent. This is supported by the following observations: (1) The resistance of both *Sst*I fragments did correspond to the number of cleavage sites present. Such a cumulative effect of multiple sites argued against the presence of certain sites with low levels of methylation. (2) No digestion products were found in the digests with the methylation-sensitive enzymes. Therefore, no detectable fraction of the total M-MuLV genomes had remained completely unmethylated, nor was there evidence for a number of sites methylated to a low degree. The latter conclusion was valid only for the *Hha*I and *Ava*I digestions, as *Hpa*II digestions could result in many undetectable digestion products (see Fig. 1). The above results suggested that the observed digestion of *Sst*I fragments of M-MuLV with *Hpa*II was only due to the presence of multiple sites, all of them methylated at a high level (see Table 2 for calculation) rather than to a lower level of methylation at such sites in a fraction of genomes. *Eco*RI/*Hha*I digestions of these DNAs revealed that some of the *Eco*RI fragments containing a M-MuLV provirus and several kilobases of flanking mouse DNA were highly methylated in all *Hha*I sites present (see Fig. 3, lanes *d*, *f*, *h*).

Table 2 *De novo* methylation of M-MuLV genomes at *Hha*I, *Ava*I and *Hpa*II sites in organs of animals infected during embryogenesis

Time of infection	DNA	Level of methylation at individual sites (%)	No. of sites
Pre-implantation stage	69 Li	70–95	44
	158 Li	70–90	44
	58–1 Li	70–95	22
	58–1 Ki	70–95	22
	58–1 Br	70–95	22
	58–2 Li	80–95	44
	58–2 Ki	70–90	22
	58–2 Br	70–90	22
	61 Li	70–95	44
	62 Li	70–95	22
	100–19 Li	70–95	44
	100–21 Li	70–95	44
Post-implantation stage	B58 B59 Li	<20	11
	Ki	<20	11
	Br	<20	11

See Table 1 legend fo details of infection and organ description. The level of *de novo* methylation in M-MuLV genomes present after infection of pre-implantation embryos was determined by the resistance of the M-MuLV-specific 5.6- and 2.6-kb *Sst*I fragments to digestion with *Hha*I, *Ava*I or *Hpa*II (see Fig. 5). Only sites sufficiently distant from the *Sst*I sites to reduce the size of the *Sst* fragments are included in the results. The 5.6-kb fragment has 25 *Hpa*II sites, the 2.6-kb fragment 7 *Hpa*II and 7 *Hha*I sites (see further in Fig. 1). With the exception of some *Ava*I sites in liver DNA of animal 69 (Fig. 5*A*, lane 1*c*), no preferential sensitivity of any site was seen. Therefore, assuming similar levels L of methylation in all n sites of a given enzyme present in an *Sst*I fragment, $L = \sqrt[n]{I}$, where I is the resistant fraction of the fragment obtained from the autoradiogram by visual inspection. If a fragment containing two sites for, for example, *Hha*I, is 70% resistant to cleavage with *Hha*I, then the level of methylation in both sites is 84%. The range in the percentage of methylation is due to differences observed with several enzymes and to the inaccuracy of determination of intensities. The level of *de novo* methylation in DNAs from animals infected at the post-implantation stage was estimated from the intensity of fragments appearing after digestion with *Hha*I or *Ava*I. The intensity of each fragment appearing is dependent on the presence of two unmethylated sites, thus $L = 1 - \sqrt[2]{I}$. I was >70% for all the M-MuLV fragments, compared with fragments of similar size derived by methylation-insensitive enzymes from the same DNA (see Fig. 6). In some cases no results for the *Hpa*II digestion of the 5.6-kb fragment are given, because a low number of M-MuLV copies per cell does not allow determination due to the multiple sites (see above). Four *Hha*I and seven *Ava*I sites resulting in fragments >0.6 kb were included in the analysis of appearing fragments (see Figs 1, 6).

In contrast to the above results, the M-MuLV genomes that integrated in post-implantation embryos showed a low degree of *de novo* methylation. The *Sst*I and *Eco*I fragments (see Fig. 5*B* and Fig. 3, lanes *j*, *l*) were almost completely digested with methylation-sensitive enzymes. No digestion products due to partial methylation of sites were visible. The levels of methylation in these DNAs were determined by digestions with *Hha*I or *Ava*I (see Table 2 for calculation). The intensities of the fragments appearing were compared with those of fragments of similar length derived from digestion of the same DNAs with the methylation-insensitive enzyme *Sst*I (see Fig. 6). Methylation of some of the sites would reveal fragments

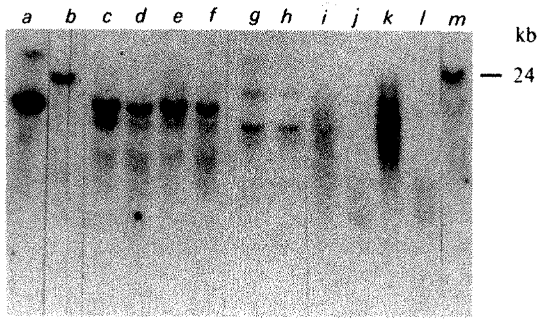

Fig. 3 Integration sites of M-MuLV genomes introduced into mouse embryos. The DNA samples were digested with *Eco*RI (lanes *a*, *b*, *c*, *e*, *g*, *i*, *k*, *m*) or *Eco*RI plus *Hha*I (lanes *d*, *f*, *h*, *j*, *l*). The completeness of the digestions was tested by addition of cloned M-MuLV DNA to a part of each digestion mix. The DNAs were separated on 0.5% agarose gels, a M-MuLV-specific cDNA being used for hybridization. Lane *a*, 5 μg of liver DNA from mouse 69; lane *b*, 10 μg of liver DNA from animal 158; lanes *c*–*f*, 20 μg DNA from animal 58–2, from kidney (*c*, *d*) and brain (*e*, *f*). Lanes *g*, *h*, 10 μg of DNA from kidney of mouse 100–21; lanes *i*–*l*: 10 μg DNA from animal B58, from kidney (*i*, *j*) and brain (*k*, *l*); lane *m*, 10 μg of embryo DNA from Mov-13 mice, containing one copy of M-MuLV per cell.

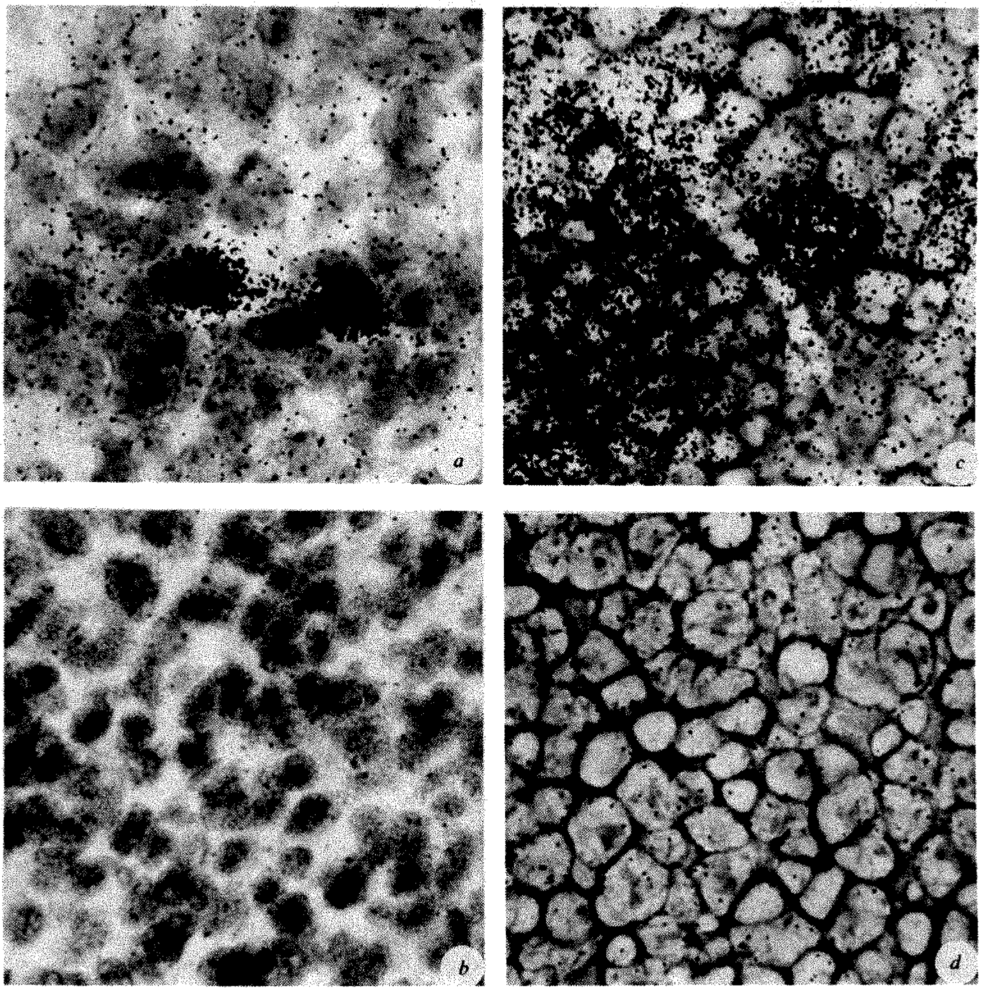

Fig. 4 Detection of M-MuLV RNA in post-implantation mouse embryos by *in situ* hybridization. Mouse embryos were infected *in utero* at day 8.5 of gestation with M-MuLV (see Table 1). Four to five days after infection, frozen sections of whole embryos were prepared, hybridized *in situ* with ^{3}H-labelled M-MuLV cDNA, and finally counter-stained with Giemsa stain as described previously[46]. *a*, Mantle layer of cerebral cortex showing focal expression of M-MuLV RNA; *b*, cerebral cortex of control embryo; *c*, foci of viral RNA in liver tissue; *d*, liver of control embryo. ×486.

differing in length and intensity from those derived from a completely unmethylated (that is, cloned) genome. Our analysis showed that at least 80% of the genomes introduced into post-implantation embryos remained completely unmethylated in 11 sites analysed. Because no partial digestion products or completely methylated genomes were visible (see also Fig. 5), we conclude that all 11 sites were methylated to less than 20% (see Table 2). Thus, these experiments demonstrated a striking difference in *de novo* methylation of M-MuLV genomes: a highly efficient *de novo* methylating activity is present only in pre-implantation embryos but not in post-implantation embryos or after birth. Furthermore, the methylation of M-MuLV genomes introduced into pre-implantation embryos was maintained over many cell generations.

Table 3 Infectivity of DNA from organs of mice infected with M-MuLV during embryogenesis

Time of infection	DNA	No. of XC PFU	Specific infectivity $\times 10^6$
Pre-implantation stage	69 Li	0	<0.01
	58–1 Li	0	<0.1
	58–1 Ki	0	
	61 Li	0	
	100–19 Li	0	
Post-implantation stage	B58 Li	8	1.4
	B58 Ki	24	0.7
	B58 Br	46	1.0
Controls	Mov-1 Sp	10–20	1.8
	C57BL Li	0	0
	1 ng pMov-3	500	8

The number of XC plaque-forming units (PFU) is given as a mean value from 30 μg DNA tested in two independent transfection assays as previously described[17]. Specific infectivity of DNA, defined as the number of XC PFU per viral genome, was calculated from the number of M-MuLV copies present in the respective DNA (compare Table 1). Infectivity of DNA from preleukaemic Mov-1 spleen is due to one to two M-MuLV copies acquired postnatally[17]. DNA from the highly infectious pMov-3 clone (specific infectivity 8×10^{-6} PFU per viral genome)[18], which was used for injection into zygotes (animal 69), was included as a control.

Expression of M-MuLV in infected embryos correlates with the infectivity of proviral DNA in the adult

Previous results have shown that pre-implantation mouse embryos are not permissive for virus replication[2,6,16]. The *Eco*RI pattern of M-MuLV-specific fragments indicated that infection with M-MuLV and integration of viral DNA did occur; however, virus spread, that is, virus expression, was not detectable in early mouse embryos, but did occur later in development in an unknown population of cells, leading to viraemia in the adult (compare ref. 5). In contrast, virus integration into cells of mid-gestation embryos led to expression and efficient spread throughout cells of all tissues of the infected embryo (Fig. 4). Therefore, those viral copies found in adult animals derived from infections of post-implantation embryos have been actively expressed after integration in most of the cells.

DNA transfection was used to study the biological activity of the same M-MuLV genomes as were analysed in previous sections. Table 3 shows that DNA containing M-MuLV genomes integrated in pre-implantation embryos was not infectious. The DNA from animal 69 carried 10–15 copies of pMov-3 DNA per cell. Thus, the injected DNA was several hundredfold less infectious after passage in the mouse than before injection. In contrast, the copies that were introduced

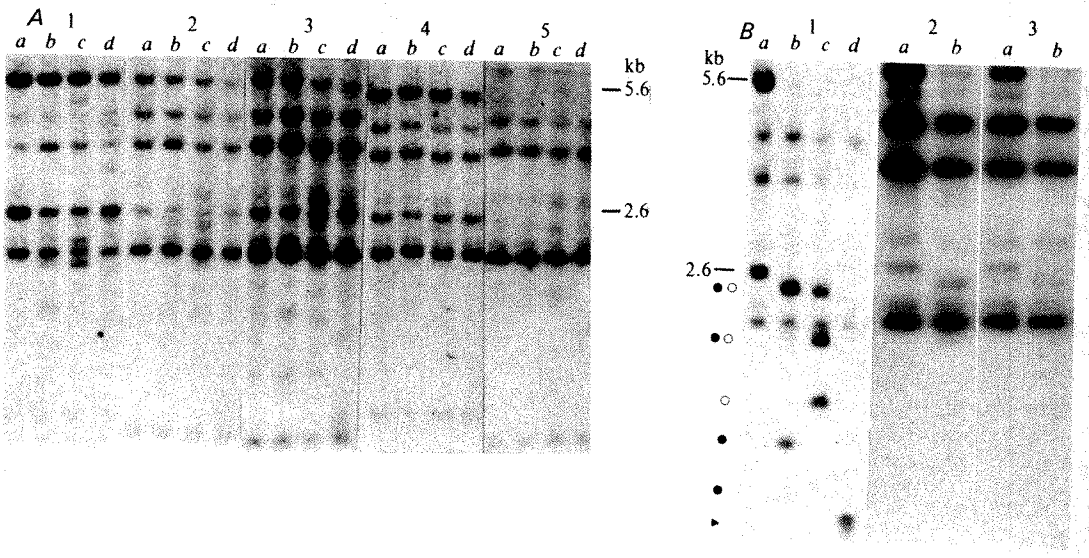

Fig. 5 Methylation of M-MuLV genomes. DNAs were analysed from mice infected as pre-implantation (*A*) or as post-implantation (*B*) embryos. All samples were digested with *Sst*I and also with: *b*, *Hha*I; *c*, *Ava*I; *d*, *Hpa*II. *A*, DNA from liver of mouse 69 (1*a*–*d*), liver of mouse 158 (2*a*–*d*), kidney of mouse 58-1 (3*a*–*d*), liver of mouse 58-2 (4*a*–*d*), C57BL/6 mice (5*a*–*d*). *B*, DNA from kidney of mouse B58 (1*a*–*d*), kidney of mouse Bv11 (2*a*, *b*), brain of mouse Bv12 (3*a*, *b*). The positions of DNA fragments of M-MuLV derived after double digestion with: ●, *Hha*I; ○, *Ava*I; ►, *Hpa*II are indicated. The cDNA was not representative of all sequences of M-MuLV; therefore, the intensities of the fragments did not correspond to their sizes (compare ref. 4).

into post-implantation embryos were as infectious as those integrated after birth. Previous results from this laboratory have correlated DNA methylation and expression of M-MuLV genomes with infectivity in a transfection assay[17,18,29]. The results described in Table 3 indicate that viral genomes which were *de novo* methylated after integration into pre-implantation embryos are non-infectious in the adult animal. Thus, both persistence of viral genome methylation and non-infectivity may be sustained by a maintenance methylase activity[24,30,31] for as long as 5 months after birth. In contrast, viral genomes inserted in cells of mid-gestation embryos are expressed, remain unmethylated and are infectious in a transfection assay when isolated from the adult.

Discussion

We have shown previously that pre-implantation mouse embryos are not permissive for replication of M-MuLV[2,6]. Viral DNA, however, can integrate efficiently into the embryo DNA and mouse substrains designated as Mov-1 to Mov-13 that carry M-MuLV in their germ line have been derived from infected embryos[3–5]. Virus is activated in some of these substrains and the available evidence suggested that the developmental stage at which virus activation occurs depends on the chromosomal position of the provirus[5]. Further analysis showed that the genetically transmitted proviral genomes in several organs of Mov substrains were highly methylated and non-infectious in a transfection assay[17,18].

We have shown here that retroviral DNAs become *de novo* methylated on integration into the genome of pre-implantation embryos as assayed in organs of the adult derived from the infected embryo. This was observed after exposure of the embryos to infectious virus as well as after microinjection of cloned viral DNA with flanking mouse sequences. In contrast, virus introduced into post-implantation embryos replicated efficiently in most or all embryonal cells and the integrated proviral genomes remained largely unmethylated when assayed in the adult animal. The difference in *de novo* methylation was also reflected in the transfection assay: DNA from animals exposed to virus at the pre-implantation stage was not infectious, in contrast to DNA from animals exposed to virus at mid-gestation. Thus, our results suggest that an efficient *de novo* methylation activity may be characteristic of cells of the pre-implantation stage and may be absent or less effective in cells of later embryos. This activity correlates with non-permissivity to virus expression. Furthermore, our results show that the maintenance methylation activity is faithful in preserving the respective methylation pattern of the proviral genomes throughout the life of the animal. The *de novo* methylation activity in embryonal cells may be of general significance, as not only viral but also globin DNA (F. Costantini and E. Lacy, personal communication) and a metallothionein–thymidine kinase fusion plasmid[32] became *de novo* methylated after microinjection into mouse zygotes..

Recent experiments obtained in tissue culture systems have demonstrated that embryonal carcinoma cells have an efficient *de novo* methylation activity, in contrast to differentiated cells[33], and that methylation correlated with gene expression. In these experiments we analysed the fate of the infecting DNA: the viral DNA remained unmethylated as long as it was unintegrated and became *de novo* methylated soon after genomic integration. This is relevant for the observation that DNA microinjected into mouse zygotes[6,34] or into *Xenopus* eggs[35] is

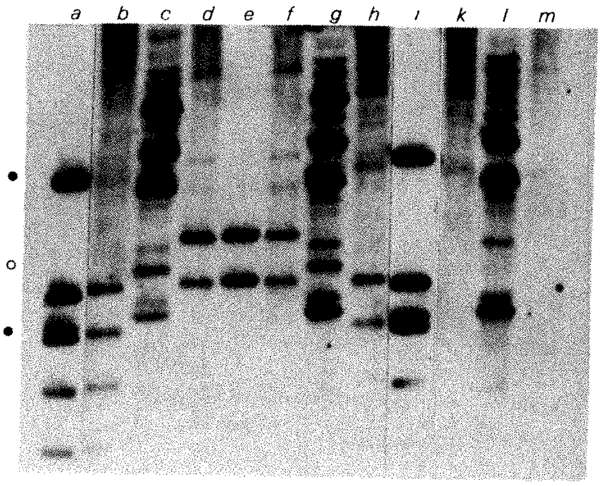

Fig. 6 M-MuLV genomes are not methylated in DNA from mice infected at the post-implantation stage. Lack of methylation was demonstrated by (1) appearance of equimolar M-MuLV-specific fragments after digestion of DNAs from mouse B59 and cloned M-MuLV DNA with *Ava*I and *Hha*I and (2) by comparing the intensity of the 2.6-kb fragment derived from digestion of DNAs from B59 with the methylation-insensitive enzyme *Sst*I to the intensity of fragments of similar size derived from digestion of the same DNAs with the methylation-sensitive enzymes *Hha*I and *Ava*I. DNA (10 μg) from brain and kidney of animal B59 were separated on a 0.8% agarose gel. The hybridization was performed with a nick-translated M-MuLV DNA. Lane *a*, *Ava*I- digest of plasmid p9-2, containing M-MuLV DNA[29]; lanes *b*–*d*, *Ava*I-, *Sst*I- and *Hha*I- digested brain DNA, respectively; lane *e*, *Hha*I digest of 9-2; lanes *f*–*h*, *Hha*I-, *Sst*I- and *Ava*I- digested kidney DNA, respectively; lane *i*, *Ava*I digest of p9-2; lanes *k*–*m*: *Ava*I-, *Sst*I- and *Hha*I- digested C57BL/6 DNA, respectively. The positions of the M-MuLV-specific 2.6-kb *Sst* fragment (○) and of the two plasmid sequences containing *Ava*I fragments of p9-2 (●), which are therefore not found in DNA from B59, are indicated.

expressed as long as it remains in an episomal state. Unintegrated DNA injected into *Xenopus* eggs was shown to remain unmethylated[36]. So far, *de novo* methylation activity has only been observed as a rare event in differentiated cell lines after long-term cultivation to select cell clones[37–40].

If the *de novo* methylation activity in embryonal and efficient maintenance methylation in later cells are involved in repression of proviral genomes, what is the origin of infectious virus in mice derived from pre-implantation embryos exposed to virus? Because virus, once activated, will infect all susceptible cells and spread throughout the animal, demethylation and activation of virus at a given stage of development and in a specific, as yet unidentified, population of cells would be sufficient to lead to viraemia. Demethylation of a given provirus in specific cells may depend on the chromosomal position where integration took place, and proviral genome activation may thus be regulated by similar mechanisms to those proposed for the tissue-specific activation of developmentally regulated genes[41,42]. Gene activation of the proviral genome in Mov-1 mice seems to be compatible with such a hypothesis[43].

Our results suggest that embryonal cells may possess an efficient *de novo* methylation activity that inactivates any DNA which is introduced into the early embryo. This may have evolved as a mechanism to protect the developing embryo against the deleterious consequences of virus infections. Finally, our results pose intriguing questions concerning the control of gene expression during early development, and it will be of great interest to study the methylation of genes that are active in pre-implantation embryos and embryonal carcinoma cells.

Single base substitution in an intron of oxidase gene compensates splicing defects of the cytochrome *b* gene

Geneviève Dujardin, Claude Jacq & Piotr P. Slonimski

An extragenic suppressor mutation, mim2-1, *which compensates yeast mitochondrial mutants deficient in splicing of the cytochrome* b *gene, has been mapped and sequenced. The mutation is due to a single G → A transition in the long open reading frame of the fourth intron of the oxidase subunit one gene. It causes the replacement of a glutamic codon by a lysine codon and the expression of a novel mRNA maturase active in splicing. Evolution and regulatory connections between homologous introns of nonhomologous genes are discussed.*

THE mitochondrial gene *cob-box* of *Saccharomyces cerevisiae*, which specifies the apocytochrome *b*, exhibits a mosaic organization of exons and introns[1–6]. Respiration-deficient mutants have been mapped in both the exons and introns of this gene. Exon mutants belong to a single complementation group while intron mutants belong to separate complementation groups[7]. Intron mutations have been shown to block the processing of mRNA[8,9]. DNA sequence analyses of *trans*-recessive intron mutations and characterization of the mitochondrial translation products suggest that *trans*-acting proteins, 'mRNA maturases', involved in splicing are encoded by the two long open reading frames present in the two main introns of the *cob-box* gene,

0028-0836/82/320628—05$01.00

bI2 and *bI4* (refs 6, 10). The mRNA maturase model of splicing homeostasis can be used as a paradigm of the regulation of split genes in yeast mitochondria[6,10,11].

Numerous intron mutations of the *cob-box* gene result in a pleiotropic phenotype: they prevent not only the synthesis of cytochrome *b* but also that of subunit I of cytochrome oxidase. This protein is itself encoded by another mosaic mitochondrial gene, *oxi3*. The lack of expression is due to a block in the correct processing of the oxidase pre-mRNA[8]. More precisely, the fourth intron *bI4* of the *cob-box* gene has been shown to control the expression of *oxi3*[12,13]. The fourth intron *aI4* of the *oxi3* gene displays a very striking sequence homology to the intron *bI4* but no sequence homology is found between the exons of the two genes[14]. There is evidence that the mRNA maturase encoded by the intron *bI4* is involved in excising the two introns *bI4* and *aI4* of the two distant genes[10].

To investigate the function of introns and various components of the mitochondrial splicing machinery, we have developed a general method of selecting and genetically characterizing extragenic suppressors of splicing-deficient mutations located in introns[15]. The suppressor *mim2-1* is particularly interesting as (1) it is localized in mitochondrial (mt) DNA; (2) it compensates all the *trans*-recessive *box7*$^{-}$ mutations in intron *bI4*, but does not compensate any of some 450 mutations located elsewhere in the mitochondrial genome; (3) when *mim2-1* is associated with a complete deletion of the *cob-box* gene (leading to a total deficiency of cytochrome *b* and oxidase) oxidase synthesis is partially restored while cytochrome *b* is still absent[16]. These observations suggest that in the presence of *mim2-1*, the *cob-box* gene and the mRNA maturase encoded by it are no longer required for splicing and expression of the oxidase gene.

We have now localized the suppressor *mim2-1* in the intron *aI4* of the *oxi3* gene, determined its nucleotide sequence and compared it with that of the wild type. We show here that the suppressor mutation is due to a single base substitution in the intron open reading frame and we suggest that it brings about the synthesis of an active compensating mRNA maturase encoded by intron *aI4*.

Suppressor mutation is on mitochondrial DNA in the oxidase gene

The suppressor mutation *mim2-1* was localized on the mitochondrial genome by using *rho*$^{-}$ deletion mapping according to the first procedure described in ref 15. Three *rho*$^{-}$ (respiratory-deficient mutants that have large deletions of the mitochondrial genome) clones which retained the *mim2-1* mutation were obtained (see Fig. 1) and genetically characterized for the retention or loss of various markers that had previously been mapped in different mitochondrial genes. The *rho*$^{-}$ clones were able to restore, in crosses, the respiratory sufficiency of two classes of mitochondrial mutations from two distinct regions. (1) They successfully restored all *box7*$^{-}$ mutations of the cytochrome *b* gene at 28 °C and poorly or not all at 18 °C. This is consistent with the observation that the *mim2-1* suppressor, which they carry, is cryosensitive[15]. (2) The clones restored equally well at both 28 °C and 18 °C several *oxi3* mutations of the oxidase gene, showing that they have always retained the suppressor *mim2-1* and several *oxi3* markers which can be introduced by recombination. We conclude that the *mim2-1* mutation is located in or near the *oxi3* gene.

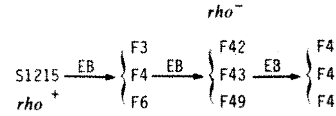

Fig. 1 Genealogy of *rho*$^{-}$ derivatives carrying the suppressor mutation. *rho*$^{-}$ were selected after ethidium bromide (EB) mutagenesis of the revertant *rho*$^{+}$ S1215 and subcloned as described in ref. 15.

Additional *rho*$^{-}$ subclones with smaller mitochondrial genomes, but still carrying the suppressor, were generated (see Fig. 1). Table 1 represents a simplified genetic map of the *oxi3* gene and the segments of mitochondrial genome retained by the nine *rho*$^{-}$ clones studied. The clones display distinctive genotypes but have retained a coherent region of mtDNA with no internal rearrangements. The retained segments of the *rho*$^{-}$ clones overlap a precise region, located approximately in the middle of the genetic map of the *oxi3* gene, where the *oxi3*$^{-}$ mutations *oxi3-G192* and *oxi3-G2190* are also located[17].

Thus the suppressor *mim2-1* can be localized in the *oxi3* gene near the *oxi3* mutations *G192* and *G2190*.

Suppressor mutation is in the fourth intron of oxidase gene

To determine which segment of the *oxi3* gene contains *mim2-1* we prepared mtDNAs of the two overlapping and genetically simple *rho*$^{-}$ clones carrying *mim2-1*, F431 and F439. We performed restriction analyses of the two genomes and compared the results with detailed restriction maps of the wild-type *oxi3* gene[14,18–20]. The genomes of these two *rho*$^{-}$ clones exist as tandem repeats with unit lengths of 2.2 (F439) and 5 (F431) kilobases (kb). The restriction maps of the two clones are completely consistent with the *rho*$^{+}$ maps already reported. They have retained contiguous segments of mtDNAs with no internal deletions or inversions. The absence of a *Hae*III site in F439 and any *Hin*dIII site in F431 shows that the overlap between the two genomes spans the segment between the *Hae*III and the *Hin*dIII sites (Fig. 2). This 865-base pair (bp) fragment contains an internal *Hph*I site present both in F439 and F431. The *mim2-1* mutation can thus be assigned to this

Table 1 Genetic mapping of the suppressor mutation in the oxidase gene

	oxi3 mutants														
rho^{-}	G20	G789	G2342	G656	G2133	G2027	G2508	G2190	G192	G3015	G1979	G421	G433	G1683	G922

F43	−	−	−	−	+	+	+	+	+	+	+	+	+	+	−
F431	−	−	−	−	−	+	+	+	+	−	−	−	−	−	−
F434	−	−	−	−	−	−	−	+	+	+	+	+	+	−	−
F439	−	−	−	−	−	−	−	+	+	+	+	−	−	−	−

rho^{-} clones which have retained the *mim2-1* mutation have been crossed with different *rho*$^{+}$*oxi3*$^{-}$ mutants; +/− denotes presence/absence of wild-type *rho*$^{+}$ *oxi3*$^{+}$ recombinants in the diploid progeny. As expected from their lineage (Fig. 1), the genomes F42, F43 and F49 are included within the larger genome F4 and the genomes F434, F439 and F431 within the genome of F43. The *oxi3* map is consistent with previous results[17]. Strains and genetic methods have been described previously[15,16].

Fig. 2 *a*, Physical mapping of the suppressor mutation in intron *aI4* of the oxidase gene and strategy for sequencing. The two upper bars represent the segments of mitochondrial genome retained in *rho*⁻ clones F431 and F439 both carrying the *mim2-1* mutation. The uncertainties due to junction fragments are represented by slanted edges. The middle bar represents the general organization of intron *aI4* and flanking exons *A4* and *A5* (solid area). The restriction sites used for physical mapping, cloning and sequencing are shown. The bottom panel represents the DNA sequencing strategy: arrows indicate the direction and approximate length of the fragments sequenced, the restriction sites used for 5′-end-labelling are denoted by a short vertical bar. Nucleotide distances are given from the *Hae*III site (0) located at the beginning of intron *aI4*. The mutation *mim2-1* is at position +354. Mitochondrial DNAs were prepared according to ref. 10. A 1,440-bp fragment between the cleavage sites of *Bam*HI and *Hin*dIII was isolated from the *rho*⁻ genome F43 (Fig. 1, Table 1) and inserted into the plasmid vector pBR322 by *in vitro* recombination following the method described in ref. 24. Plasmid DNAs were prepared according to ref. 25. The recombinant DNA was digested with *Hae*III and *Hin*dIII and an 865-bp fragment was isolated by agarose gel electrophoresis. This fragment was entirely sequenced by the method of Maxam and Gilbert[26]. The *Hae*III–*Hin*dIII fragment was then further digested by *Sau*3A (= *Mbo*I), or by *Hph*I and labelled at the 5′ ends with [γ-^{32}P]ATP. Three of the four resulting fragments were then denatured and separated by gel electrophoresis. The fourth one (the largest 347-bp *Mbo*I fragment) was recut by either *Alu*I or *Mnl*I, allowing a good sequencing across the central part of the fragment. *b*, Nucleotide sequence of the intron fragment carrying the suppressor mutation *mim2-1*. Upper-case letters represent the nucleotide sequence established in the present work of the 865-bp fragment carrying the suppressor *mim2-1* between the *Hae*III and *Hin*dIII sites in intron *aI4* (see *a*). The sequence of the sense strand is displayed in the 5′→3′ orientation. The amino acid sequence of the intron open reading frame is indicated in lower case. The two lines represent the corresponding wild-type sequence established by Netter *et al.*[20]. The first rectangle shows that the suppressor mutation is due to a G→A substitution; the second shows the polymorphic variation between different wild types (see refs 14 and 20).

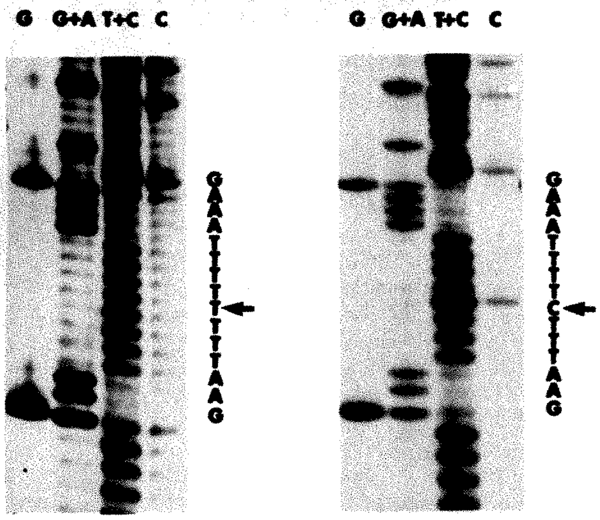
*Hin*dIII–*Hae*III segment in the *oxi3* gene. According to Bonitz *et al.*[14], this fragment is part of the fourth intron *aI4* of the *oxi3* gene: the *Hae*III site is located 9 bp downstream from the beginning of the intron and the *Hin*dIII site is located well inside the intron. The 865-bp fragment carrying the *mim2-1* mutation is therefore entirely within intron *aI4*. This physical location is in good agreement with the genetic one, as Netter *et al.*[20] have shown by sequence analysis that the mutations *oxi3-G-192* and *oxi3-G2190* are placed inside the intron *aI4* and, as discussed above, the *mim2-1* is linked to *G192* and *G2190*. We conclude that the suppressor *mim2-1* is located completely inside intron *aI4* of oxidase gene.

Suppressor mutation results from single base substitution in intron open reading frame

We have sequenced the *Hae*III–*Hin*dIII fragment containing the *mim2-1* mutation according to the strategy described in Fig. 2. This sequence was compared with the corresponding wild-type sequence of the isomitochondrial strain 777-3A (ref. 20). The suppression is due to a single G→A transition (Fig. 3) in the intron open reading frame at position +354 (Fig. 2). This substitution replaces a glutamic acid codon in the wild type by a lysine codon in the suppressor. No other changes occur in the entire sequence.



oxi3-mim2-1 oxi3⁺

Fig. 3 Sequencing gel demonstrating the base substitution of the suppressor mutation. The mutated *mim2-1* and corresponding wild-type sequences are shown on 8% acrylamide sequencing gels. Both strands of *Mbo*I fragment were sequenced. The base change corresponding to the *mim2-1* mutation that is 36 bp distant from the *Mbo*I site is more visible on the sequence of the nonsense strand. The mutation corresponds to a substitution on the nonsense strand of a C in the wild type by a T in the mutant. On the sense strand this gives a G→A substitution at position +354 (Fig. 2).

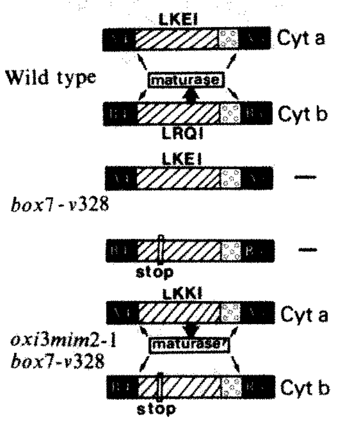


Fig. 5 A model for the normal, deficient and compensatory regulations between the introns of two genes. The drawing represents pre-mRNA molecules transcribed from two genes. The oxidase subunit I (Cyt a) and cytochrome *b* (Cyt b) exons are shown in solid and intron open reading frames in hatched areas. The reading frames are 966 and 1,158 bp long respectively. In the wild type (top), intron *bI4* encodes (thick arrow) a *trans*-acting mRNA maturase which is involved in splicing of both introns, *bI4* and *aI4* (thin arrows). A *box7* mutation (middle) that creates a stop codon at position 405 (AAA→TAA) in *bI4* prevents the synthesis of the maturase and the two introns are no longer excised[10]. The unspliced pre-mRNA of *aI4* accumulates and could be translated into a p56 protein devoid of maturase activity (see text). In a double mutant carrying the *oxi3–mim2-1* mutation (bottom), the protein translated from *aI4* has acquired the maturase activity due to the replacement of the glutamic (E) by the lysine residue (K). This novel protein permits splicing and expression of both genes.

Novel mRNA maturase translated from oxidase intron replaced normal maturase translated from cytochrome *b* intron

There is recent evidence that, in the wild type, the splicing of both introns *aI4* of the oxidase gene and *bI4* of the cytochrome *b* gene is controlled by a pleiotropic mRNA maturase translated from *bI4* (refs 10, 20). The activity of this maturase, designated *bI4* maturase, involves the same set of *cis*-acting signals present in both introns, in particular *box9*⁺ and *box2*⁺ nucleotide sequences in *bI4* and their equivalents in *aI4* (see Fig. 4 and refs 10, 20). We propose that the *mim2-1* mutation induces the synthesis of an active *aI4* maturase that would not occur in the wild type and that it is translated from the oxidase intron. This novel maturase would act as a substitute for a deficient *bI4* maturase, using the same set of critical sequences present in both pre-mRNAs. Such a hypothesis (summarized in Fig. 5) explains all the known facts: the suppression by *mim2-1* of *bI4* maturase-deficient mutants and the absence of suppression of *box9*⁻ or *box2*⁻ mutants; the synthesis of oxidase in the presence of a complete deletion of the cytochrome *b* gene[16]; and sequence homology between *aI4* and *bI4* (refs 10, 14, 20).

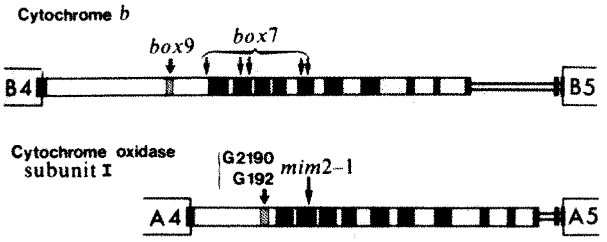

Fig. 4 General organization of the two homologous introns, *bI4* and *aI4*, of cytochrome *b* and cytochrome oxidase genes. *B4, B5* and *A4, A5* represent respectively the exons of cytochrome *b* and cytochrome oxidase genes. The regions of extensive sequence homology betweem the introns *bI4* and *aI4* are depicted by solid and hatched segments. Both introns are physically composed of two distinct regions: a long open reading frame (large rectangle) followed by a blocked frame (narrow rectangle)[10,14,20]. In intron *bI4*, two clusters of *box*⁻ mutational sites, which prevent splicing[8,9,27], have been mapped: (1) *box7* cluster composed of *trans*-recessive mutations[7] which generate nonsense codons in the intron's open reading frame[10]; (2) *box9* cluster composed of *cis*-dominant mutations[7] which are all localized in a dodecanucleotide signal sequence[10]. In intron *aI4*, two *cis*-dominant mutations have been localized in the homologous signal sequence (hatched area)[20]; no *oxi3*⁻ *trans*-recessive mutations have been found until now. The *oxi3–mim2-1* mutation occurs 150 bp downstream from the *cis*-acting signal sequence.

How is a new maturase formed from an inactive intron?

One could imagine, for example, that, in the wild type, intron *aI4* is not translated at all because an internal splice destroys the continuity of its open reading frame; the *mim2-1* mutation would remove the internal splice point and modify the splicing pathway such that the continuity of the reading frame would be restored. It might also be possible that, in the wild type, intron *aI4* is translated but the protein is destroyed by proteolysis; the *mim2-1* mutation could have removed a specific proteolytic site. Alternatively, the wild-type protein could be inactive and the *mim2-1* mutation, by creating a proteolytic site, would permit the formation of an active fragment involved in splicing. We find these conjectures unattractive, however, because they do not explain why an open reading frame is preserved in the wild-type oxidase intron *aI4*. We therefore favour the hypothesis that *aI4* is normally translated into a protein. If this is the case, what is its function in the wild type, why is it not *trans*-active in splicing (while *bI4* is) and how does *mim2-1* restore the splicing activity?

We believe that the ability of *mim2-1* to restore splicing activity is due to a local increase of positive charges in a part of a protein that is essential for its catalytic activity. Arguments favouring this idea are: (1) *mim2-1* causes a replacement of a glutamic codon by a lysine codon and thus increases the charge by +2. Interestingly, this change occurs in an α-helical region as shown by our calculation of the secondary structure carried out according to ref. 21 (data not shown). This α-helix is the longest (15–18 amino acids) that can be traced in the translation products of introns *bI4* and *aI4*, and occupies homologous positions in both proteins. The α-helix of the wild-type *bI4* translation product (active) is more basic than that of the wild-type *aI4* product (inactive) by two or four charges (depending on the local polymorphism between the strains D273-10B and 777-3A)[10,20]. The *mim2-1* mutation, by increasing the charge by +2, renders the *aI4* translation product more similar to its normal *bI4* counterpart and we believe that this change is sufficient to explain the acquisition of splicing activity. That a protein which interacts with nucleic acids should be positively charged is plausible, and other active mRNA maturases, such as that of *bI2*, are overall highly basic[6,13].

(2) A second line of evidence favouring the idea that *aI4* can be translated even in the absence of *mim2-1* mutation comes from the analysis of mitochondrially synthesized proteins in splicing-deficient mutants resulting from *bI4* maturase-deficient mutation or $oxi3^{-}$-*G192* and -*G2190* mutations in *aI4* (O. Groudinsky, personal communication). These mutants accumulate a protein of apparent molecular weight 56,000 (referred to as p56). We conjecture that p56 results from translation of the previously fused oxidase exons *A1–A4* with the *aI4* open reading frame. The size of p56 is consistent with this idea and fingerprint comparisons show that p56 displays some peptide homologies with the subunit I of cytochrome oxidase[22]. Analyses of double mutants indicate that the N-terminal sequences of the *oxi3* exons control the synthesis of p56 (O. Groudinsky, unpublished results) and this protein disappears in an *oxi3* deletion mutant[23]. All these data are easily explained by the model shown in Fig. 5: in the wild type, splicing of *oxi3* mRNA is efficient and no p56 accumulates because the *oxi3* pre-mRNA does not accumulate. In mutants deficient for the *bI4* maturase ($box7^{-}$ mutants[10]) or *cis*-dominant *aI4* mutants, such as $oxi3^{-}$-*G192* (ref. 20), the pre-mRNA containing the non-excised intron *aI4* would accumulate and its translation would lead to an accumulation of p56. In a double mutant carrying simultaneously a $box7^{-}$ mutation and a *mim2-1* mutation, a p56 protein should still be detectable because the suppression is only partial, probably because the *aI4* maturase is less efficient than its normal *bI4* counterpart; this has indeed been observed[16]. Our model predicts that p56 from an *oxi3 mim2-1* strain should differ slightly from the $oxi3^{+}$ in its fingerprint pattern, and preliminary experiments (O. Groudinsky *et al.*, unpublished results) suggest that this is indeed the case.

Evolution of two homologous introns in two non-homologous genes

Sequence homologies between *bI4* and *aI4* (refs 10, 14, 20) and functional compensations between their translation products (this work) strongly suggest that the two introns are derived from a common ancestral sequence. We do not know when this duplication, transposition or insertion took place, but depending on whether it is recent or ancient even, two evolutionary histories can be proposed. If it is a recent event, then the fact that *aI4* still has an open reading frame could be purely accidental. The *bI4* descendant of the common ancestor would have kept the splicing function and the *aI4* descendant would have lost it by accumulating missense mutations. The divergence would not have been large enough to prevent a single base substitution, such as in *mim2-1*, still being able to restore or readjust the function. In other words, *aI4* may have just become (or be in the process of becoming) a pseudogene and we have caught it during the very early part of its evolutionary drift! Although this hypothesis cannot be formally excluded, we do not find it plausible and prefer to think that the duplication, transposition or insertion event took place a long time ago. We propose the following evolutionary scheme.

An identical ancestral base sequence, encoding a protein, was originally present or has been inserted, in two non-identical genes. This sequence has diverged during evolution in two directions: the first one has led to a diffusible protein endowed with a pleiotropic splicing activity (the *bI4* sequence) and the second to a protein with no catalytic splicing activity (the *aI4* sequence). Numerous missense mutations have been fixed during this period: for the region of strongest homology between *aI4* and *bI4*, which is 170 residues long, some 38–40 amino acid replacements have taken place[10,14,20]. With such an amount of evolutionary divergence there must be a selective pressure that has prevented the accumulation of nonsense mutations in *aI4*. What is the role of *aI4*? One hypothesis is that the normal translation product of *aI4* has a different and unknown function. It could, for example, be a structural part of the mitochondrial splicing and/or translation apparatus, it could be used as a handle to position correctly, by quaternary interactions, the *bI4* maturase on its second substrate, that is, on the pre-mRNA of oxidase. Alternatively, the travelling of a ribosome through *aI4*'s open reading frame could be a necessary but insufficient condition for the processive splicing (see refs 10, 20). In both hypotheses, the splicing of the two genes will be catalysed by a single maturase and not by two independent ones. This could confer a selective advantage because a coordinate expression of both genes would be facilitated.

Evolutionary conjectures are not easy to test. The finding of a converse situation to the normal one and the demonstration that it results from a single base change in an intron do, however, provide a striking example of intergeneic communications through intron-encoded proteins. It is thus of interest for the evolutionary history of mosaic genes.

We thank P. Netter and O. Groudinsky for helpful discussions and personal communications, B. Poirier and M. Even for help in preparing the manuscript. This work was supported by grants from CNRS, DGRST, INSERM and Ligue Nationale Française contre le Cancer.

LETTERS TO NATURE

Is our vacuum metastable?

Michael S. Turner

In spontaneously broken gauge theories of particle interactions there are sometimes several local minima of the effective potential. Any of these minima can serve as a vacuum in the sense that we can expand the fields around their values at the minimum, interpret the quantized fluctuations around the minimum as particles, and compare the properties of these particles with experiment. One might think that only the state with absolutely minimum energy could be what we ordinarily call our vacuum, as the other local minima will inevitably decay into this lowest one. However, this is not necessarily the case, because it is possible for the lifetime of a metastable vacuum to be very long, even when compared with the age of the Universe. Furthermore, the energy densities available in present laboratory or astrophysical environments are much less than the barriers which exist in field space between the different local minima, and so we have no direct sensitivity to the presence of a possibly lower vacuum state. (A possible exception to this are magnetic monopoles which do probe the large field region.) If it is not the absolute minimization of the effective potential, what does determine the present vacuum state of the Universe? We argue here that it is determined cosmologically by the dynamical evolution of the Universe from the hot, dense phase which existed shortly after the big bang to the present[1,2].

At finite temperature, the free energy tends to be minimized in phases which contain light particles. Therefore, we expect that in general, at extremely high temperatures the thermodynamically favoured phase is the symmetric one which contains the most massless particles. Assuming that very near the big bang this phase is realized[3-5], one can follow the subsequent dynamical evolution to determine the present state. The present vacuum is properly determined by evolutionary, not merely energetic, considerations. This point is relevant for all proposed models of elementary particle interactions.

In what conditions might we convince ourselves that we live in a metastable vacuum (or, not finding these conditions, assure ourselves that we do not)? Of course, we must demand that the putative vacuum has an extremely long lifetime, and that small fluctuations around it describe known physics. In addition, it should have been realized in the dynamical evolution of the Universe, starting from the symmetric phase at extremely high temperatures.

First, consider the question of metastability. For a ϕ^4 scalar field theory in which the energy difference between the two minima is not too large, the decay rate of the 'false vacuum' (per unit volume per unit time) at zero temperature is[6]

$$\Gamma \simeq A \exp[-(32\pi^2/(3\varepsilon^3\lambda)] \qquad (1)$$

where λ is the quartic self-coupling, ε is the ratio of the energy difference between the two minima to the barrier height between them, and A has dimensions of mass^6 and should be $0(\mu^4)$. Here μ^2 is the bare mass of the scalar field. Taking μ to be of the order of the grand scale ($\sim 10^{14}$ GeV), and the spatial volume to be that of the present observable Universe ($V \sim 10^{84}$ cm^3), the probability that an energetically less favourable minimum has decayed during the age of the Universe is exponentially <1 so long as

$$\varepsilon \ll 0.6\,\lambda^{-1/3} \qquad (2)$$

a condition which is easily satisfied.

We now examine the second and third issues in the context of the simplest unified model of particle interactions, the minimal SU(5) theory[7].

At zero temperature the effective potential can be written as[8,9]:

$$\begin{aligned} V(h,A) = {} & \frac{-\mu^2}{2}\operatorname{tr} A^2 + \frac{a}{4}(\operatorname{tr} A^2)^2 + \frac{b}{2}\operatorname{tr} A^4 \\ & - \frac{\nu^2}{2} h^\dagger h + \frac{\lambda}{4}(h^\dagger h)^2 + \alpha (h^\dagger h)\operatorname{tr} A^2 + \beta h^\dagger A^2 h \end{aligned} \qquad (3)$$

where the discrete symmetry $A \rightarrow -A$ has been imposed, h is an SU(5) vector **5** Higgs field, and A is an SU(5) adjoint **24** Higgs field (traceless hermitian matrix). To reproduce the standard (and thus far very successful) SU(5) phenomenology, there must be a local minimum where A acquires a large vacuum expectation value of the form,

$$\langle A \rangle = \begin{pmatrix} 1 & & & & 0 \\ & 1 & & & \\ & & 1 & & \\ & & & -3/2 & \\ 0 & & & & -3/2 \end{pmatrix} \delta \qquad (4)$$

This vacuum expectation value breaks SU(5) down to SU(3) × SU(2) × U(1).

The second stage of symmetry breaking involves the fifth component of h acquiring a vacuum expectation value much less than δ (the small vacuum expectation value $\langle h \rangle$ will slightly perturb $\langle A \rangle$ from the form given in equation (4); see refs 8–10). In addition, we must also ensure that the colour triplet component of h has a large mass $\simeq 0(\delta)$ as it can mediate proton decay. Both of these requirements are fulfilled if:

$$\beta < 0 \qquad (5a)$$

$$-m_{\text{eff}}^2 \equiv \nu^2 - 3\mu^2(10\alpha + 3\beta)/a' \approx 0 \qquad (5b)$$

$$(\alpha + \beta/2) > -[\lambda(a+b)]^{1/2}/2 \qquad (5c)$$

$$\mu^2, a', b > 0 \qquad (5d)$$

$$\lambda > 9\beta^2/10b \qquad (5e)$$

where $a' \equiv 15a + 7b$. Condition (5*b*) specifies that the SU(2) doublet component of h (the ordinary Weinberg–Salam doublet) has a small, negative bare mass. Quantitatively, m_{eff} must be about 13 orders of magnitude smaller than $\delta = (2\mu^2/a')^{1/2}$.

For our purpose, the crucial observation is that condition (5*b*), along with the others, can be satisfied with ν^2 large and positive. Looking back at equation (3), it is perhaps not surprising that in this case another very different type of vacuum might be energetically favourable: one in which $\langle h \rangle$ is large. Indeed, if

$$2\alpha\nu^2/\lambda > \mu^2 \qquad (6a)$$

$$2(\alpha + 4\beta/5)\nu^2/\lambda > \mu^2 \qquad (6b)$$

then the potential also has a local minimum at $\langle h_5 \rangle^2 = \nu^2/\lambda$ and $\langle A \rangle = 0$. In this vacuum SU(5) has broken down to SU(4). When we compare the value of the effective potential at this local minimum with the usual one (when both exist), we find that for the following range of parameters:

0028–0836/82/320633—02$01.00

$$\mu^2, \lambda, a', b, -\beta > 0 \quad (7a)$$

$$\lambda > 9\beta^2/10b \quad (7b)$$

$$(\alpha + \beta/2) > -[\lambda(a+b)]^{1/2}/2 \quad (7c)$$

$$(5\alpha + 4\beta)(10\alpha + 3\beta) > 5\lambda a'/6 \quad (7d)$$

$$\nu^2 \approx 3\mu^2(10\alpha + 3\beta)/a' \quad (7e)$$

the usual vacuum corresponds to a local, but not a global, minimum.

From the point of view of microphysics, then, it is quite conceivable that our vacuum is metastable. We must now investigate the dynamical question, whether it is reasonable that during the course of its temperature evolution, the Universe could get 'hung up' in our vacuum in spite of its only being metastable. Basically, we must determine which of the two asymmetric vacua becomes lower than the fully symmetric vacuum first as the Universe cools down from very high temperatures. Although we have not investigated this question in quantitative detail, it seems that a 'hang up' can occur. Finite-temperature modifications to the zero-temperature potential tend to increase the free energy, and those due to the most strongly coupled fields are most important[3-5]. Suppose that the usual vacuum and the SU(4) vacuum discussed above have roughly the same energy at zero temperature. The high temperature state continuously related to the SU(4) vacuum will then be disfavoured if it feels stronger finite-temperature corrections. This will occur, for instance, if all the Higgs self-couplings are small and h, but not A, couples strongly to some fermion field.

It seems distinctly possible in simple unified models, that our present vacuum is only metastable, and that nevertheless, the Universe would have chosen to get 'hung up' in it. If this is the case, then without warning, a bubble of true vacuum could nucleate somewhere in the Universe and move outwards at the speed of light, and before we realized what swept by us our protons would decay away. There is no immediate cause for concern, however, because the lifetime of our metastable vacuum could easily be 10^{30} yr (or only 10^{10} yr for that matter).

A search for evidence of superheavy-element fission in chondritic metal

R. K. Bull*‡ & P. Mold*†

* Department of Physics, University of Birmingham B15 2TT, UK
† West Midlands College of Higher Education, Walsall,
West Midlands, UK

There is evidence for the early melting of the Moon[1,2], and Runcorn[2-4] has concluded from palaeomagnetic data that a fluid core dynamo must have been present for ~10^9 yr and that the decay of a siderophile superheavy element (SHE) with a half life of ~10^8 yr may have been responsible for these phenomena[3-5] Libby and co-workers[6] have suggested that SHE-decay could have produced certain trace-element abundance patterns in iron meteorites. Several searches[7-9] have failed to detect evidence for SHE decay in iron meteorites. We describe here a search for SHE in metal fragments within ordinary chondrites. The absence of excesses of tracks along the boundaries between olivines and metal grains allows upper limits to the SHE content of the metal of ~2.5×10^{-13} to ~2.5×10^{-15} kg per kg to be set at a time ~4×10^9 yr ago, determined from the ^{244}Pu fission track densities in chondritic phosphates.

Our experimental methods are essentially similar to those described previously[7]. Slices and coarse fragments from three chondrites, Estacado (type H6), Wold Cottage (L6) and Alta'ameem (LL5), were ground and polished. They were then etched in WN solution at pH 8 and 50% of the usual concentration to reveal tracks in olivine crystals[10]. The etched samples were then examined under an optical microscope at a magnification of approximately ×630 and under a scanning electron microscope at about ×5,000 magnification. Abundant cosmic ray tracks (identification as cosmic ray tracks was based on the anisotropic angular distribution of the tracks and a length distribution peaking at short track lengths) were observed throughout the olivine grains from Alta'ameem but track densities were observed to be much lower in Wold Cottage and Estacado (see Table 1). The boundaries between the olivine crystals and metal grains were carefully examined using both scanning electron microscopy and optical microscopy, and no significant excesses of tracks were detected in these regions in any of the three meteorites. For the purposes of calculation it is assumed that the contribution of fission tracks from the metal is, in each case, equal to the cosmic ray track density. These track densities (column 4 of Table 1) allow upper limits to the SHE content of the metal to be calculated and these are displayed in column 5 of Table 1. In obtaining these estimates it is assumed that the SHE have decayed to extinction during the time since tracks began to be retained by the olivine. These limits apply to the times at which track retention in the olivine began for each of the three meteorites and for any conclusions to be drawn from these data it is necessary to establish a time scale for track retention by the olivine.

An estimate of the track retention time for these meteorites can be made by examining the fission track densities in apatite and merrillite crystals from each meteorite. These phosphate crystals are usually found to contain tracks produced by the fission of ^{238}U and ^{244}Pu. Since the latter has a half life of ~10^8 yr, the identification of ^{244}Pu tracks in these phases would provide strong evidence that track retention in the olivine occurred relatively close to the time of formation of the meteorites, because olivine is believed to retain tracks at higher temperatures than apatite and merrillite[11].

Phosphates were concentrated in non-magnetic fractions of density between 2.8 and 3.3 g cm^{-3} and grain size between 63 and 106 μm. These were then etched in aqueous HNO_3 solutions at room temperature. The precise etching conditions used in each case are shown in Table 2. The track densities were obtained from scanning electron microscopy photographs at a magnification of about ×5,000. The uranium concentrations in the phosphates were determined by irradiating them with thermal neutrons (fluences of about 10^{18} neutrons cm^{-2}) in the Herald reactor at Aldermaston. Induced-fission fragments were detected in adjacent sheets of uranium-poor mica. The neutron fluence was monitored by irradiating standard reference glasses along with the meteorite samples.

Fission track density and uranium content data are shown in Table 2. The track density figures for Alta'ameem have been

Table 1 Track densities in olivines

Meteorite (class)	Central track density in olivines* (cm^{-2})	Track density along boundary with metal† (cm^{-2})	Upper limit to contribution from fission in metal (cm^{-2})	Upper limit to SHE concentration at time of track retention by olivine (kg per kg)
Wold Cottage (L6)	$<10^4$	$<10^4$	10^4	2.5×10^{-15}
Alta'ameem (LL5)	$(0.9\text{–}1.3)\times10^6$	$\sim10^6$	10^6	2.5×10^{-13}
Estacado (H6)	$<10^4$	$<10^4$	10^4	2.5×10^{-15}

* Mainly due to heavy cosmic ray primaries.
† Measured within a strip of olivine 10 μm wide immediately adjacent to metal grains.

Table 2 Summary of track data for phosphates

Meteorite	Mineral	Etching conditions	Track density† (10^6 cm^{-2})	U content (10^{-6} kg per kg)	Approximate average ratio of ^{244}Pu fission tracks to ^{238}U fission tracks
Wold Cottage	Merrillite*	75s, 0.25% HNO_3, 20 °C	67–82 (6)	0.08–0.19	165
	Apatite		16–25 (2)	1.8–3.7	2
Alta'ameem	Merrillite	20s, 1% HNO_3, 20 °C	34 (1)	0.1	100
	Apatite		7–16 (20)	0.3–1.7	4
Estacado (This work)	Merrillite	50s, 1% HNO_3, 20 °C	33 (18)	0.1	120
(Pellas and Storzer[15])	Merrillite		37.5 (15)	0.19	75
	Apatite		8.2 (15)	3.26	<1

* In many earlier papers on meteoritic phosphates, this mineral is referred to as whitlookite.
† Number of crystals shown in parentheses.

corrected for a cosmic ray track background of $\sim10^6$ cm^{-2}. The contribution to the total track density from the spontaneous fission of ^{238}U can be calculated from the measured uranium content of each phase. The excess fission tracks are assumed to be due to the spontaneous fission of ^{244}Pu and the last column of Table 2 gives the ratio of ^{244}Pu to ^{238}U fission tracks. The assumption of a ^{244}Pu source for these tracks rests on numerous determinations of ^{244}Pu fission Xe in merrillites[12–14] (formerly known as whitlockites) and in apatites[13] from chondritic meteorites. In particular, Kirsten and co-workers[13] have measured the fissiogenic Xe content of Estacado. The fission track data for Estacado obtained by Pellas and Storzer[15] is included in Table 2.

Merrillites from all three of the meteorites that we studied show large excesses of ^{244}Pu fission tracks and notwithstanding uncertainties in the initial Pu content of these crystals, it seems unlikely that these three meteorites could have cooled to the track retention temperature of merrillite (and therefore of olivine) much later than $\sim4\times10^9$ yr ago. The upper limits to SHE concentrations given in Table 1 therefore apply to approxomately this time. Runcorn[4] requires a SHE concentration in the lunar core of $\sim10^{-7}$ kg per kg at $\sim4.1\times10^9$ yr ago. The concentration would have fallen to $\sim6\times10^{-9}$ kg per kg at $\sim3.7\times10^9$ yr ago, assuming a SHE half life of $\sim10^8$ yr. Our results indicate that the SHE content of chondritic metal was lower by at least 4–6 orders of magnitude at that time.

These results, taken together with the failure to find evidence for SHE in the metal from iron meteorites[7–9], indicate that the abundance of SHE in meteoritic metal was very low $\sim4\times10^9$ yr ago and unless the metal of the lunar core was very much enriched in siderophiles relative to meteorites, SHE could not have played an important role in the early heating of the Moon.

We thank Drs P. F. Green and S. A. Durrani for useful comments and the staff of the Herald reactor at the Atomic Weapons Research Establishment, Aldermaston, for carrying out the neutron irradiations. Meteorite samples were provided by Dr R. Hutchison (British Museum) and by Dr Y. Al-Rawi (College of Science, Baghdad, Iraq). The financial support of the SERC is gratefully acknowledged.

Detection of nitrogen at {100} platelets in diamond

S. D. Berger & S. J. Pennycook

Cavendish Laboratory, Madingley Road, Cambridge CB3 0HE, UK

Platelets in type Ia diamond were first directly observed with transmission electron microscopy by Evans and Phaal[1] in 1962. Considerable controversy still exists over their structure and chemical composition. One of the earliest models of the platelet structure was that proposed by Lang[2] in which nitrogen, the major impurity in type Ia diamonds, is segregated into plate-like structures, only two atoms thick, lying on the cube planes. Later evidence seemed to favour interstitial carbon as the major component of the platelets[3–5], although more recent evidence from the production of platelets in synthetic diamond[6] again points to nitrogen as forming an important constituent. High resolution electron microscopy also supports this view[7,8]. Here we report for the first time the direct observation of nitrogen at platelets using the technique of electron energy loss spectroscopy (EELS).

A type Ia diamond was cut and thinned parallel to an (001) plane. The platelets were studied using a VG Microscopes' HB5 scanning transmission electron microscope (STEM). In the STEM transmitted electron images showing diffraction or phase contrast can be obtained similar in all respects to those obtained in a conventional TEM, but in addition elemental analysis and diffraction patterns can be obtained at very high

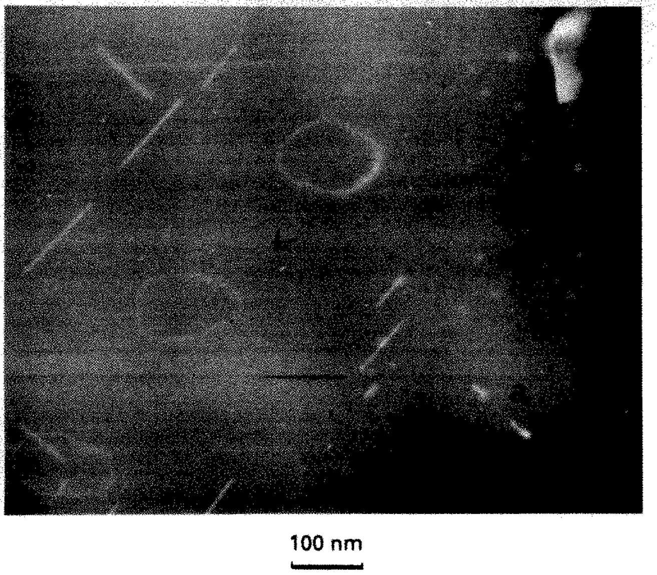

Fig. 1 Weak beam image of platelets in type Ia diamond. The dark marks are burns in the phosphor of the display tube.

spatial resolution (see ref. 9 for a full discussion of the techniques). Figure 1 shows an edge of the diamond flake containing several platelets. The image is obtained using an annular dark field detector, which detects electrons scattered out of the main beam. The diamond is orientated with the electron beam incident exactly along the [001] direction, so that the image is formed mainly from the four 220 Bragg reflections, weakly excited. Three sets of platelets are visible. Those lying on the (100) and (010) planes are seen as two sets of straight lines perpendicular to each other, while those lying on the (001) plane within the foil have a roughly circular shape, made visible by the partial dislocation around the circumference of the platelet. In thinner regions of the diamond, platelets lying parallel to the beam may extend through the thickness of the specimen (platelet a in Fig. 1 for example). In such regions the diffraction contrast along the length of the platelet is lost but it is still visible at the ends where the defect terminates inside the crystal. The central region of such platelets can be imaged by phase contrast microscopy giving images similar to those shown by Bursill *et al.*[8], although the resolution is limited to about 0.7 nm, in our case, due to stray magnetic fields around the field emission gun.

A previous attempt[10] to find nitrogen by EELS failed due to insufficient sensitivity to nitrogen in the experimental conditions used. Several factors must be optimized to achieve the highest sensitivity when analysing a platelet with a fine electron probe. First, steps must be taken to prevent the build-up of carbon contamination on the area analysed. This can be a severe limitation to microanalysis at the highest spatial resolution, but was completely eliminated by baking both the microscope and specimen at 120 °C for 10 h before analysis. Second, the specimen geometry was optimized by choosing platelets parallel to the beam running right through the thickness of the diamond. The highest sensitivity to the elemental composition is then achieved by passing the smallest electron probe down the centre of the platelet. The third factor is the correction for electron beam or specimen drift. As type Ia diamond is an insulating material, drift tends to occur as the specimen charges up and it is important to keep the electron probe over the platelet throughout the analysis. By scanning the smallest possible area (~1 nm^2) an image is available on the annular dark field detector while the electrons in the bright field beam are analysed by the spectrometer. In this way drift can be continuously compensated for using electrical beam shift controls. To facilitate this correction, improved contrast in the annular detector image was obtained by tilting the diamond slightly off the [001] direction into a two-beam condition, typical images being shown in Fig. 2.

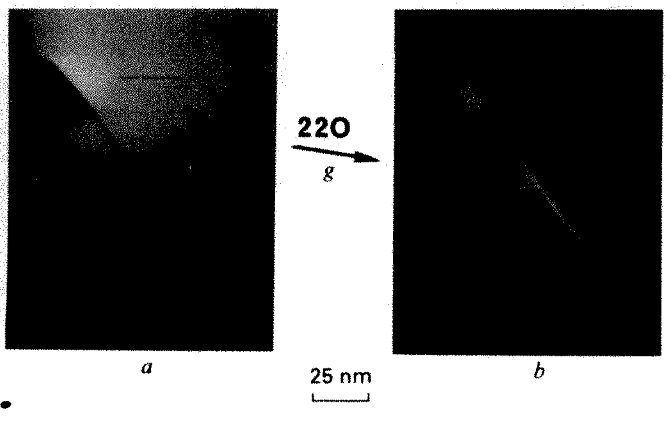

Fig. 2 Typical two-beam bright field (*a*) and annular dark field (*b*) images of platelets suitable for microanalysis.

The fourth and possibly most important factor is to achieve the most accurate background subtraction under the nitrogen edge in the energy loss spectrum. This would normally be done by extrapolation from the region of the spectrum just before the edge. However, due to strong intensity modulations following the carbon K-edge this technique would be inaccurate in this case. The spectrum from the normal diamond lattice shows the same modulations and hence provides a much more accurate background for subtraction.

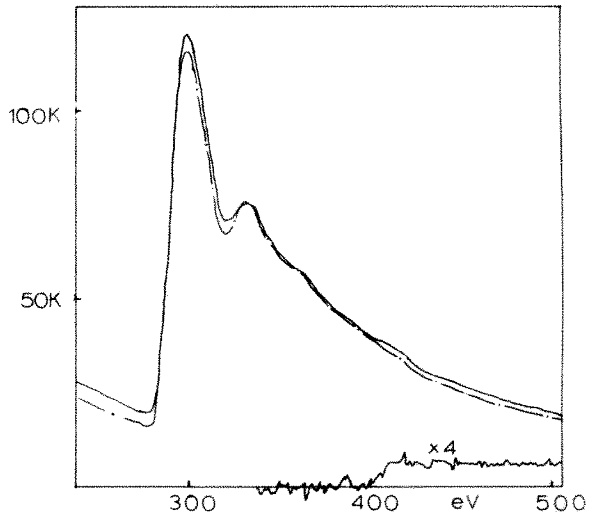

Fig. 3 Electron energy loss spectra from the centre of a platelet (solid line) and from just off the platelet (broken line). Also shown is the difference (×4) which shows the nitrogen-*K* edge at ≈406 eV from the platelet.

The spectra were obtained by scanning an isolated drift tube to give an absolute energy calibration[11] with digital data acquisition using a Link Systems 860 analyser. The incident beam semi-angle $\alpha = 8.3$ mrad and spectrometer acceptance semi-angle $\beta = 3$ mrad were chosen to give good spatial resolution together with a high count rate in the spectrometer with an energy resolution of about 12 eV.

The spectrum from the platelet acquired in this way is shown in Fig. 3 and is compared with the spectrum taken from the diamond just adjacent to the platelet. As well as the carbon *K*-edge at ≈290 eV an edge is clearly visible at ≈406 eV from the platelet which corresponds to the nitrogen K loss (both edges are shifted by ~7 eV from their expected positions[12] due to band structure effects[13]). The mismatch between the spectra in the region of the carbon edge is due to a slight change in specimen thickness between the two areas analysed. The area of normal lattice analysed was slightly thicker due, possibly, to preferential etching of the platelet during preparation. Generally, the effect of taking a matrix spectrum from a thicker region would be to decrease the slope of the decaying carbon edge as a result of multiple scattering. This would manifest

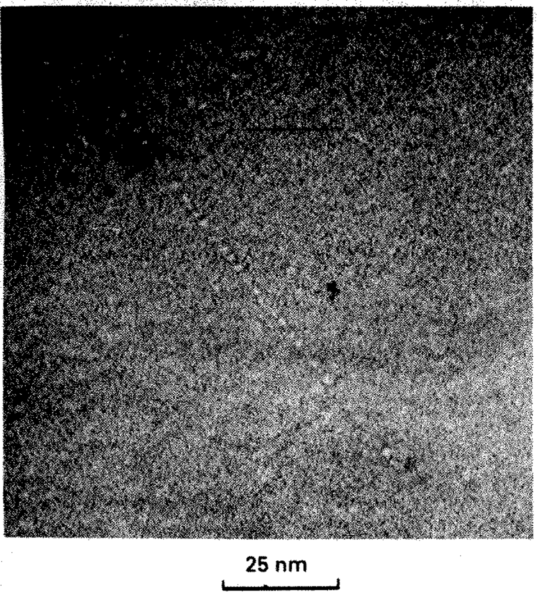

Fig. 4 Bright field image of an inhomogeneous platelet, or 'voidite' (noisy image is due to a shorter exposure time than in Figs 1 and 2).

itself, after subtraction from the platelet spectrum, in a slow modulation on the difference curve. In our case the change in thickness is ~3% and, as can be seen, produces negligible modulation of the difference between the spectra. The feature at ~406 eV rises over ~12 eV, corresponding to the spectrometer resolution, continues for the rest of the spectrum and can only be due to a nitrogen *K*-absorption edge. It has been shown[14] that most of the nitrogen in type Ia diamonds is in a dispersed form. Any signal due to this nitrogen will appear in both the background spectrum and the spectrum from the platelet. Thus when the two spectra are subtracted, only the nitrogen signal associated with the platelet will remain. However, the concent ations of the dispersed forms of nitrogen are so low that it is unlikely that they will be detected at all by this technique. The result of subtracting the two spectra is shown on an increased vertical scale and the nitrogen edge is very clearly visible.

So far, five platelets have been analysed, of which four contained nitrogen to a significant extent, while one contained no detectable nitrogen (<10% of the amounts found in the other platelets). By scanning an accurately known area and integrating the counts under the carbon and nitrogen edges in the spectrum, it is possible to obtain the percentage of nitrogen present in the volume analysed, and this can be compared with the expected percentage of nitrogen present if the platelet followed the Lang model. We found that the percentage of nitrogen detected varied significantly and no platelet contained as much nitrogen as the model predicts. Sequential spectra were then taken from the same platelet and it was found that nitrogen was being gradually lost from the defects. Although this would appear to account for the variation in nitrogen content already seen, early results indicate that some platelets are more susceptible to damage than others and further experiments are being carried out to clarify this point.

One platelet was found which showed a particularly interesting form of inhomogeneous contrast and is shown in Fig. 4. Analysis showed the bright regions of Fig. 4 contained at least three times as much nitrogen as the dark regions. The contrast seen from this platelet is very similar to that seen from 'voidites' (T. Evans and J. Macguire, and J. L. Hutchinson, personal communications) which appear to be a form of collapsed or semi-collapsed platelet. If the bright regions of Fig. 4 do not extend through a significant fraction of the thickness then they must contain a very high concentration of nitrogen.

The results from this work show directly that nitrogen is associated with platelet defects in type 1a diamond. The fact that some platelets are susceptible to beam damage at an energy of 80 keV indicates perhaps that the nitrogen is not bonded into the lattice in the covalent manner that the Lang model suggests. Also, if beam damage is unable to account for the variable nitrogen content seen, then again a modification to the simple models is called for.

We thank Professor T. Evans and Miss J. Maguire for providing the thinned specimen and for many useful discussions, together with Drs L. M. Brown and A. Howie. We are grateful to the SERC for financial support.

Reconstruction of past ice conditions in a Hudson Bay estuary using tree rings

Gordon C. Jacoby & Linda D. Ulan

Lamont-Doherty Geological Observatory, Columbia University,
Palisades, New York 10964, USA

Descriptions of ice conditions, ranging from lake and sea ice to glacial advances and retreats, form an important portion of the climatic record. Ice formation, deterioration and changing areal extent are of increasing interest in climatology, sea transportation, petroleum exploration and the fishing industry. With few exceptions, quantitative information on ice conditions is generally brief, with many records in the US and Canada beginning only in the 1950s[1]. Tree-ring data from long-lived trees can be used as quantitative proxy data for past climatically related parameters. The record of first complete freezing of the Churchill River estuary on Hudson Bay is reconstructed here for 298 yr (1680–1977) by means of tree-ring analysis.

Both high-latitude tree growth and ice are influenced by many factors but can be significantly related to temperature[2–5]. In areas where ice conditions are influenced by a complex set of factors, a simple or direct relationship with climate may be difficult to establish. However, ice conditions in some areas show a more direct relationship to particular climate parameters (P. M. Kelly, personal communication). It is in these latter areas that we are investigating the possibility of using selected tree-ring data as a proxy series for past ice conditions.

A promising location to test the feasibility of reconstruction is near Churchill, Manitoba, Canada (see Fig. 1). Both a recent record of ice conditions and an independent, historical record are available, and we have developed a tree-ring chronology from the same location. The historical record of ice conditions is now used to calibrate the tree-ring time series which is in turn used to reconstruct the ice conditions for almost three centuries. The reconstruction is verified by modern data.

The tree-ring chronology is based on annual ring-width measurements of 15 increment cores from 7 white spruce (*Picea glauca* [Moench] Voss) from flat, poorly drained muskeg overlying permafrost. Ten of the 15 cores extend back to 1686 or

0028–0836/82/320637—03$01.00

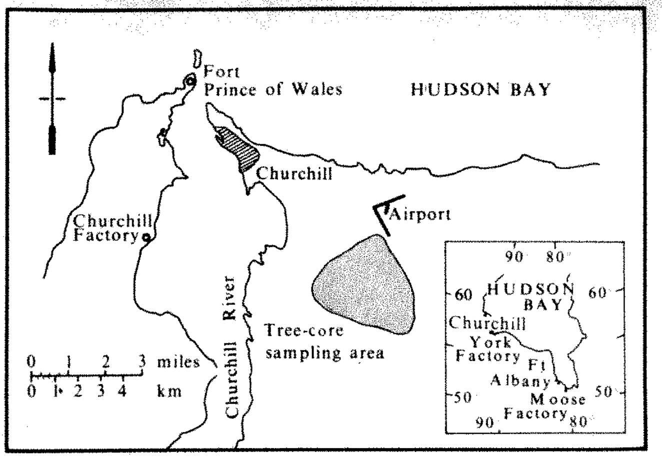

Fig. 1 Map of the Churchill area showing tree-core sampling site, Fort Prince of Wales, airport (meteorological station) and modern Churchill. Although total collection at this site was 39 cores from 15 trees, we feel that objective screening out of cores with abnormal anatomy (mainly reaction wood—eccentric growth due to leaning) and use of principal component analysis (PCA) to determine the most homogeneous subgroup produces a chronology with a better climatic signal-to-noise ratio. The PCA procedures are used before and independently of comparisons between the tree-ring data and meteorological information. The purpose is to determine a subgroup of tree cores with maximum common variance, which presumably is dominated by climate. The PCA results in ref. 20 show that, even from one site, smaller, homogeneous subgroups of cores can produce equally good or better climatically sensitive time series than larger numbers of cores. Cross-spectral analysis has also been used in selecting coherent subsets of cores from sites in Switzerland to maximize the signal-to-noise ratio of the resulting chronologies (J. Guiot, personal communication). Because we calibrated with historical data from 1741 to 1764, we also deleted cores younger than 1741 so that the sample size would not change between the calibration and verification periods. The deletions proceeded as follows: 17 cores due to abnormal growth or extreme youth of tree, 3 cores (all from one tree) shown by PCA to be heterogeneous with respect to the common variance of the rest of the cores, and 4 cores younger than 1740. Due to heterogeneous low-frequency variations in ring widths, conventional standardization methods did not produce a usable time series of ring-width indices for these tree cores. The s.d. of mean indices for individual years were above acceptable levels. The cubic-spline technique has been very useful in some of our analyses of trees from the subarctic and from the closed-canopy forests of the eastern US[6]. This group of trees does not exhibit the coherent, common, low-frequency trends that have been observed in some other subarctic trees[2–4]. This could be attributed in part to the standardization method but, additionally, inspection of the cores and the raw data do not show such trends to be as evident as they are in cores from other subarctic sites sampled.

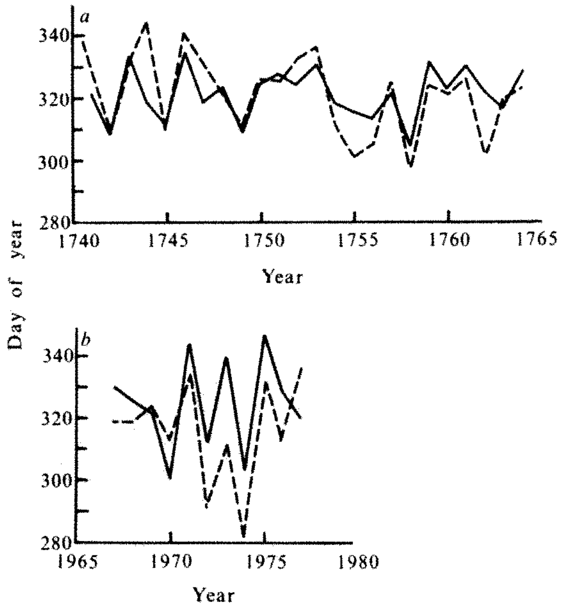

Fig. 2 *a*, Calibration data (dashed line) and reconstructed data (solid line) for first complete freeze of the Churchill Estuary. *b*, Verification data (dashed line) and reconstructed data (solid line) for first complete freeze.

earlier (see Fig. 1 legend). In an attempt to remove much of the nonclimatic variation, the raw ring-width data were standardized using cubic smoothing splines[6] which removed much of the variance with periods of 100 yr or more in length. The mean sensitivity of the standardized ring-width indices[7] for this chronology is 0.15, standard deviation (s.d.) is 0.17 and serial correlation is 0.44. Average values for these parameters for subarctic chronologies are 0.16, 0.25 and 0.62 respectively[4]. Based on a common period of 182 yr (1718–1899), the first principal component of the normalized ring-width indices for the cores accounts for 34% of the total variance.

One of the serious problems in reconstructing climate-related phenomena in the subarctic is the shortness of records and the lack of data for verification. The ice record for Churchill is unusual in that there are both recent and historical data. The older records result from an exhaustive analysis of old Hudson Bay Company records by Moodie and Catchpole[8] who were able to construct time series of quantitative data on ice conditions for several sites near old Hudson Bay Company factories along the south and south-west coast of Hudson Bay.

The historical ice data contain the following parameters for the nearby estuaries: days of first breaking, first partial freezing and first complete freezing. Not all the ice parameters have a clear relationship with climate nor are they equally reliable. The Churchill record is considered most reliable with respect to the records at York Factory, Fort Albany and Moose Factory[8] (see Fig. 1). The ice parameters at Churchill are, in order of increasing reliability: first partial freezing, first complete freezing and first breaking[8]. A fourth parameter, first ice free, shows very low reliability.

Table 1 Mean and standard deviation of first-full-freeze time series used or reconstructed

	Mean	s.d.
Prince of Wales—all data	321	11.96
Prince of Wales—calibration period (1751–64)	322	11.95
Modern Churchill—all data	317	15.10
Modern Churchill—verification period (1967–77)	317	15.08
Reconstruction (1680–1977)	323	10.31

The first-breaking data are judged to be most reliable from the standpoint of observational accuracy but for the following reasons may be less reliable as a simple climatic parameter. Ice breakup in many north-flowing, high-latitude rivers results from a combination of climatic and hydrological factors. In relatively low-relief regions such as Manitoba, the southern, headwater areas thaw sooner than the northern, outflow areas. The flow of water from the south causes hydraulic pressure and can either overflow or rupture the ice in the more northerly portions of rivers. These hydrodynamic effects of spring meltwater on breakup produce a more complex response to climate than the freeze response.

Modern Churchill River ice data are recorded by the Canadian Meteorological Service and extend from 1957 to 1980[9]. Precise definitions of specific ice events and observer judgement are crucial to the quality of ice record[1]. Due to changes in freeze-up definition[8], an 'approximate only' value for 1965 and a missing value for 1966, we used only the past 14 yr of reliable record for our analyses.

The meteorological data used are from the Churchill A station at the Churchill airport, ~7 km east of the estuary and 1 km north of the tree-core sampling area. This record of mean monthly temperatures and total monthly precipitation starts in January 1943. First subfreezing temperatures occur in September and, in the historical and modern ice records, complete freezing of ice takes place during October or November, usually the latter. Temperature data for these 3 months successfully passed tests for homogeneity[10,11].

We concluded that, for this study, any proxy time series should be based on tree-ring samples from the same locality

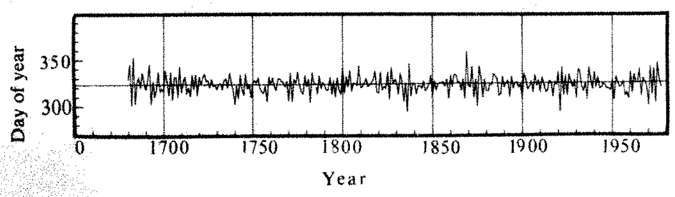

Fig. 3 Day of first complete freeze of the Churchill Estuary, Manitoba, Canada, reconstructed using rree rings, 1680–1978.

as the particular set of ice data because (1) plots of ice-condition time series and tree-ring series from distant locations showed little correspondence; and (2) similarly, the graphical relationships and correlations between the historical ice records at different stations were generally low.

Comparison of graphical plots of tree-ring and ice-condition data from Churchill indicated a correspondence between complete-freeze day and tree growth the next year. Response-function analysis[12] indicated a significant positive relationship between July temperature and ring-width indices as is common in most high-latitude forest–ecotone chronologies[4]. More importantly, a significantly positive ring-width response to warm October and November of the earlier year was shown. Although increased tree growth after a warm autumn the previous year has shown up in other dendroclimatic analyses of subarctic chronologies, generally only one autumn month, November, shows a significant positive relation to radial growth of the next year[2,3].

The freezing of the estuary at Churchill may be influenced by river flow and wind effects but, based on correlations with monthly meterological data, the major apparent influence is autumn temperature. The simple correlation coefficients between complete freeze day and monthly mean air temperatures for September, October and November are 0.67, 0.73 and −0.02, respectively, for the period of reliable modern ice data 1967–79. The first two coefficients are significant at the 95% level, the third obviously not. One can infer that most of the heat loss from the estuarine waters takes place in September and October, although the mean modern full-freeze day is 12 November for this same period.

Two sets of historical ice data comprise the Churchill record, one for Churchill Factory and the other for Fort Prince of Wales (see Fig. 1)[8]. Although the first-complete-freeze subset of data includes more values for Churchill Factory, more of these values have been inferred during the continuous period used for calibration[8]. Therefore, we based our calibration and reconstruction on the Fort Prince of Wales record.

Based on the graphical comparisons, response–function results and the correlations between fall temperatures and freeze-up, we performed multiple linear regression (MLR) using tree growth of the next year and current year as predictors of complete freeze day for the longest continuous freeze-up record, 1741–64. The multiple correlation coefficient (R) is 0.69, variance explained (R^2) is 0.47 and R^2 adjusted for loss of degrees of freedon due to the regression is 0.42 (ref. 13). The standard error of estimate is 9.00 and the F-ratio after the second step is 9.44. The latter is significant beyond the 99% level. The first variable entered is the ring-width index for the following year. This relationship concurs with the response–function result showing a positive relationship between tree growth and a warm autumn the previous year. The negative relationship with current year's growth is due to the difference between autoregressive properties of the tree-ring series and the ice data. The calibration equation resulting from the MLR is

$$\text{Full freeze day} \hat{=} 301.7 + 68.5 I_{t+1} - 46.6 I_t$$

where I_{t+1} = ring width index, following year, and I_t = ring width index, current year.

A regression between Churchill Factory first-complete-freeze data and the tree-ring data is not significantly different from the regression between Fort Prince of Wales record and the tree-ring data for the calibration period (1741–64). MLRs between the other ice parameters from Fort Prince of Wales and Churchill Factory and tree-ring data are not as strong as the first-complete-freeze data results.

Figure 2 compares the reconstructed first-complete-freeze record to the calibration period and the verification period. The entire reconstruction record from 1680 to 1978 is shown in Fig. 3. The reliable portion of the modern record from 1967 onwards, verifies the reconstruction with a correlation coefficient for the common period of 0.62 and a coefficient of determination of 0.38; both are significant at the 95% level. The more rigorous reduction of error statistic (*Re*) (ref. 14) is +0.14, also verifying some skill at estimating first-full-freeze day. The *Re* statistic should be viewed with caution in this case as it is unstable for small ($N \leq 20$) data sets[14].

Although 38% explanation of variance is not too impressive, the reconstruction passes the two verification tests. This reconstruction is calibrated by data developed from 200-yr-old descriptive accounts, is based on trees that respond to other factors besides those affecting the full-freeze conditions, and is verified by modern observation. Both the historical and modern ice data involve subjective observer decisions[1] and thus can be sources of error. In view of these difficulties, the graphical comparisons in Fig. 2 and the verification tests are good indications of the validity of the reconstruction.

Temporal and spatial ice variations in the Arctic have an important interactive role with climate[15]. Increase and decrease in areal extent of ice responds to climate[16] and also causes feedback into climatic change[17]. Very few long-term quantitative records of ice are available. This reconstruction of almost 300 yr demonstrates the feasibility of reconstructing ice data in one location. For this first effort we deliberately chose a favourable estuarine area. Other studies have related tree rings to atmospheric pressure variations[18] and pressure to ice variations[5,19]. From these earlier studies and the significant relationships indicated by this study, we are confident that additional reconstructions of ice conditions over wider areas can be achieved using tree-ring information.

We thank E. R. Cook and J. M. Duncanson for advice and assistance and P. M. Kelly, K. R. Briffa and P. D. Jones for helpful comments. A. J. W. Catchpole of the University of Manitoba and the Canadian Atmospheric Environment Service in Downsview, Ontario and Winnipeg, Manitoba provided essential information and data. This material is based on work supported by the NSF under grants ATM79-19223 and ATM81-16184.

Isotope evidence for Pleistocene climatic changes in Kashmir, India

R. V. Krishnamurthy* **& Michael J. DeNiro**

Department of Earth and Space Sciences, University of California,
Los Angeles, California 90024, USA

R. K. Pant

Physical Research Laboratory, Ahmedabad 380 009, India

Stable carbon isotope ratios of organic carbon from palaeosols in loess, and oxygen isotope ratios of pedogenic and lacustrine carbonates reveal significant Pleistocene climatic changes in the Kashmir basin. The extreme $\delta^{13}C$ values of −16 and −25‰ reported here indicate a shift from arid to sub-humid conditions. The $\delta^{18}O$ values of pedogenic carbonates is ~2‰ higher than that of the underlying lacustrine carbonates, suggesting that they were deposited in different climatic conditions.

The Plio-Pleistocene infillings in the intermontane Kashmir basin preserve a sequence of climatic events in the form of the Karewa sediments which have an estimated thickness of ~1,000 m and have been identified as glacio-fluvio-lacustrine, capped by a mantle of loess. At various localities in the valley, these sediments have been exposed by tectonic events[1,2]. Preliminary palaeomagnetic measurements suggest that the upper part of the Karewas are within the Brunhes normal epoch and therefore should preserve a large segment of the Pleistocene climatic record[3]. Figure 1 shows a schematic section at Burzahom (34°10′ N, 74°53′ E), ~25 km north-east of Srinagar. Member 1 represents a lacustrine regime with $CaCO_3$-rich marl layer said to represent periodic drying of the lake. Member 2 is a structureless mud facies representing swampy conditions after the draining out of this lake. Member 3 is a loess deposit of 15 m with three palaeosols and member 4 is the top archaeological deposit. Dilpur (33°56′ N, 74°57′ E) section follows the same sequence of events except that member 2 here is a gravelly deposit. Member 3 is ~22m thick while member 4 is absent.

Loess constitutes the top of the Karewas[4]. Loess, a silt-sized sediment, is generally wind-deposited in periglacial environments and represents cold, arid conditions. Palaeosols, or buried soils, in the loess are indicative of warmer/wetter phases. Extensive studies on loess and palaeosols have revealed their value as continental palaeoclimatic indicators[5–7].

We have studied the carbon and oxygen isotope variations in the palaeosols and pedogenic carbonates respectively from Burzahom (member 3, Fig. 1). The palaeosols are relatively rich in organic carbon and the pedogenic carbonates occur in dense, nodular forms, deposited through secondary dissolution—reprecipitation cycles. Oxygen isotope ratios of the lacustrine carbonates from Burzahom (member 1, Fig. 1) pedogenic and lacustrine carbonates from Dilpur have also been studied.

Buried soils in the loess indicate phases of vegetation growth due to climatic amelioration. The organic fraction of the buried soils is derived largely from the terrestrial plant community which fall into two major categories, C3 and C4, characterized by distinct $\delta^{13}C$ values and ecological preferences[8]. The C3 plants have an average $\delta^{13}C$ value of −27‰ and the C4 plants −14‰ on the PDB scale. The C4 plants are mostly distributed in deserts and salt marshes. Carbon isotope measurements indicate that while there are differences in isotope ratios among individual metabolates, the total organic matter in a sediment is a reliable indicator of the source ratio[9]. "Most studies of carbon isotopic composition in plants have made use of unfractionated organic matter. Gross differences in metabolism (C3 compared with C4) can be readily distinguished from such experiments"[10]. The $\delta^{13}C$ values of the organic fraction of a buried soil should therefore document the type of vegetation it supported and hence the ambient climate.

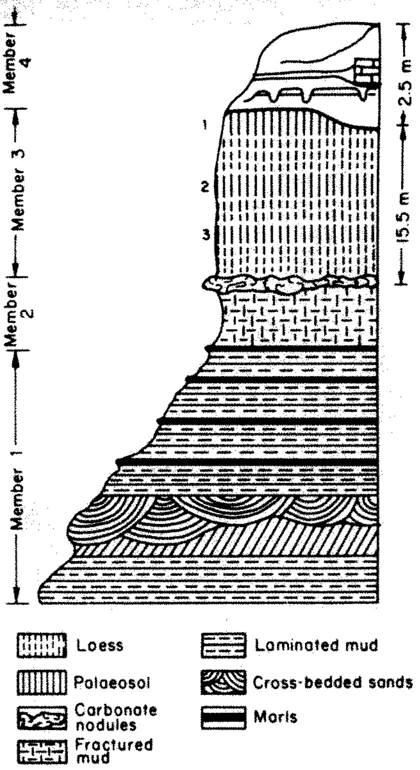

Fig. 1 Schematic section at Burzahom, near Srinagar. Member 1 comprises laminated muds, cross-bedded sands and marls, representing lacustrine and fluvial conditions. Member 2 represents swampy conditions when the lake drained out. Member 3 is the loessic deposit intercalated with three palaeosols (1, 2, 3); the top (member 4) 2.5 m is an archaeological deposit (~4,500 yr BP) (not to scale).

The results of the stable isotope measurements on the organic fraction are shown in Table 1. For organic carbon, samples were first demineralized by 20% HCl, freeze-dried and combusted to give CO_2 using a method described by Stump and Frazer[11]. Carbonate samples were treated with 'Chlorox' to remove any organics present and reacted with 100% H_3PO_4 at 25 °C. (All the measurements were carried out at the University of California, Los Angeles.)

The $\delta^{13}C$ values of the organic fractions range from −16.2 to −25‰ and indicate a clear dominance of the C4 type of plants in palaeosol 2. A gradual increase in the contribution of the C4 type vegetation towards the top of palaeosol 2 indicates an increasing aridity, which merges with the arid, unweathered loessic phase. In this the bottommost layer marks a transition from the laminated member to loess. If the loess deposition there commenced at the termination of a lacustrine regime, therefore, marking the onset of glacial aridity, our isotope measurements point to episodic soil formations through climatic

Table 1 Stable carbon isotope ratios of organic fraction of palaeosols

Site	Depth (cm)	Material	$\delta^{13}C$* (‰)	^{14}C date ($t_{\frac{1}{2}} = 5{,}568$yr) (yr BP)

Table 2 Stable oxygen isotope ratios of pedogenic and lacustrine carbonates

Site	Material	$\delta^{18}O$(‰)	No. of samples analysed
Burzahom	Pedogenic carbonates	−7 ± 0.3	12
	Lacustrine carbonates	−8.8 ± 0.2	15
Dilpur	Pedogenic carbonates	−7 ± 0.3	10
	Lacustrine carbonates	−8.4 ± 0.2	8

* Reproducibility on a single sample is 0.2‰.

amelioration, but not so dramatic as represented by palaeosol 1 when the region had a less arid climate, and a C3 type of vegetation reflected in the $\delta^{13}C$ value of −25‰. Note that palaeosol 1 is dated to ~18 kyr BP (ref. 12), which represents a relatively more humid climate. The relatively wetter-warmer conditions seem to have continued up to 15 kyr BP at higher altitudes of ~3,000 m as reflected by the pollen profile at Toshmaidan in Kashmir[13].

In many areas the period 18 kyr BP coincides with the last glacial maximum[14–17]. Peninsular Rajasthan also shows an intense sand dune building at this period[18]. This anti-correlation between Kashmir and Rajasthan could be explained either by an early deglaciation in certain parts of the world[19], or better still, by the strengthening of the northeastern monsoon and heavier winter precipitations during this period of weaker southwestern monsoon as indicated by Duplessey[20]. During the past 3 Myr the rise of the Pir Panjal range (≃5,000m) has effectively shielded off the Kashmir valley from the Indian southwestern monsoon (D. P. Agrawal, personal communication). Present-day rainfall pattern in the region is dominated by heavier winter rains as opposed to the southwestern monsoon in most of Peninsular India.

Oxygen isotope ratios of carbonates, precipitated in equilibrium conditions, are determined by the oxygen isotope composition of the water from which they form (ice-volume effect) and the temperature of precipitation (temperature effect)[21]. For lacustrine and pedogenic carbonates, conditions of isotopic equilibrium are generally assumed but not proved. Interpretation of the isotopic record of continental carbonates require also that the 'meteoric effect'[22] and possible changes in the local hydrological conditions be taken into account. The meteoric effect makes the carbonates heavier with increasing temperature as opposed to the temperature and ice volume effects, which make the carbonates lighter with increasing temperature. The role played by changing local hydrological conditions are often of an unknown magnitude but could be indirectly climate-controlled. Studies on speleothems have indicated that the meteoric effect may be insignificant thus carbonate isotope record interpretation can be made less complicated[23].

The carbonates that we studied are massive and laminated or large-sized nodules, sandwiched between impervious clay members, and therefore represent sealed environments. Moreover, we have analysed a population of carbonates from various layers to check on possible post-depositional exchanges. The rather negligible scatter within a population suggests minimal such exchanges as any secondary exchange is more likely to produce a wide scatter.

The lacustrine carbonates and the pedogenic carbonates from the loess fall into two oxygen isotope groups, the latter being heavier by 2‰ (Table 2). This depletion in the lacustrine carbonates could point to a warmer period during the lake phase. Sedimentologically, the carbonates are associated with finer particles typical of melt water load, therefore snow melt contribution to the lake, making carbonates lighter, is a distinct possibility. Such an effect also points indirectly to a warmer phase. Therefore, despite the 2‰ variation being small and following the observations by Cerling *et al.*[24] and Magaritz *et al.*[25], it appears from our preliminary measurements that these sedimentary carbonates may provide useful palaeoclimatic evidence. Analysis of many more carbonates from the basin, together with present day meteoric and lake waters should provide a firmer interpretation of the carbonate isotopic data.

These, the first isotope measurements from the continental sediments of Kashmir, have proved to be useful markers of climatic change. For detailed and definitive palaeoclimatic inferences, much wider data are needed—these are being obtained as part of a 5-yr project.

This work was carried out as part of the Kashmir Palaeoclimate Project funded by the Department of Science and Technology, Government of India. We thank Drs D. P. Agrawal, Ravi Korisettar and S. K. Tandon for discussions and Dr D. Winter for technical assistance. Partial financial assistance from Dr R. Berger of the Institute of Geophysics and Planetary Physics at UCLA, the Academic Senate Committee on Research at UCLA and NSF grants BNS 79-24756 and ATM-79-24581 are acknowledged.

The major impact that man is likely to have on climate comes from the artificial increase of the atmospheric CO_2 level, caused by the combustion of fossil fuels[1,2]. To predict its magnitude, the future rise of the global atmospheric CO_2 level must be calculated using carbon reservoir models. Because fossil fuel CO_2 lacks ^{14}C and has a $^{13}C/^{12}C$ ratio which is 18‰ lower than the present average atmospheric $^{13}C/^{12}C$ ratio, the validity of such geochemical models can be tested using past temporal variations in the atmospheric concentration of these isotopes. However, the past variation of the $^{13}C/^{12}C$ ratio in global

reservoirs is very difficult to infer[3]. Using $\Delta^{14}C$ data of tree rings Suess measured a depletion in the atmospheric ^{14}C concentration over the past century of <10‰ (ref. 4). Some years later more accurate data gave a value for this 'Suess effect' of 15–25‰ (ref. 5). As the models have been improved considerably over the past few years[6–8] the availability of $\Delta^{14}C$ data with an accuracy of better than 1.5‰ was thought to be essential to test these[9,10]. The present results indicate a good correlation with model predictions taking into account natural ^{14}C variations. However, deviations between American and European tree ring data after AD 1920 suggest a European continental CO_2 effect.

As the Netherlands are bordered by the most industrialized regions in Europe, it was suspected that the ^{14}C level of the local air masses was depressed below the average ^{14}C level[9]. We therefore selected two oaks grown in southern Germany near Unterfahlheim (48°24′ N, 10°10′ E) and Sindelfingen (48°43′ N, 9°0′ E). Comparison with the absolute master chronology showed that no rings were missing. To avoid the influence of radial transport of material with nuclear-bomb produced ^{14}C, cellulose was extracted from those tree rings which were part of the estimated sap–wood section when the nuclear bomb tests began[10–12]. All other tree rings were pretreated according to the AAA method[13]. In several cases a combination of material from several tree rings was required to obtain the 100–200 g of wood necessary for a ^{14}C analysis with a standard deviation of 1.2‰. The system stability and counting corrections for the set of seven proportional counters used have been described elsewhere[12,14].

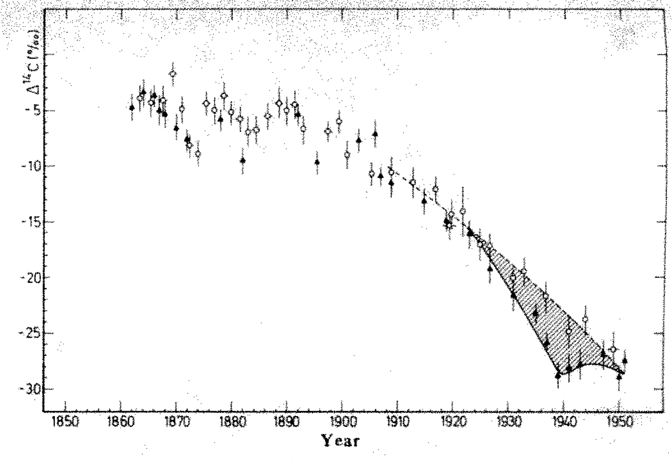

Fig. 1 A compilation of the $\Delta^{14}C$ results for both the Dutch (▲) and German (○) material. The dashed area indicates the local fuel contamination at the Dutch sampling site.

1863–64	9919	−24.93	−3.9 ± 1.3

* Cellulose pretreatment; the other samples were pretreated according to the standard AAA extraction procedure[13].

The results obtained for the south German oaks are presented in Fig. 1 and are listed in Table 1 as the age ($t_{\frac{1}{2}}$ = 5,730 yr) and fractionation corrected deviation from A_{ox}, the standard 0.95× NBS oxalic acid activity:

$$\Delta^{14}C = \left(\frac{A - A_{ox}}{A_{ox}}\right) \times 1,000 \quad (‰)$$

where A_{ox} is corrected to 1950 and −19‰, and A to the year of growth and −25‰, respectively.

For the period before AD 1900, when the dilution of the atmospheric ^{14}C level was still negligible, our results are in good agreement with the results previously obtained for the Dutch oaks[9]. We suggest that the fine structure superimposed on the rather constant ^{14}C level during the nineteenth century is caused by solar-cycle induced changes in the natural ^{14}C production.

For the period AD 1920–40, however, there is an increasing divergence between the two data sets (Fig. 2). This effect is confirmed by the results obtained for three additional tree ring samples from the Dutch tree (*Quercus rubra*, Sleen) (Fig. 2 and Table 2). The maximum local depression of the atmospheric ^{14}C level at the Dutch sampling site appears to be 26%, with an average of slightly less. This must be caused by a regional contamination. However, after AD 1940 the divergence decreases and disappears around AD 1950. An explanation for this can be found in either a decreased regional effect at the Dutch site or an increased local effect at the German sampling site. To investigate this, our results are compared with ^{14}C data from the US West Coast with a comparable accuracy, covering

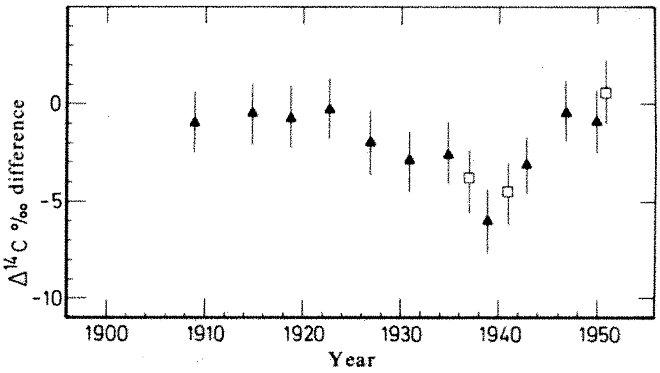

Fig. 2 The calculated difference between the $\Delta^{14}C$ results for the Dutch oak (*Quercus rubra*, Sleen[9]) and a curve calculated through the ^{14}C results for the German trees. Additional samples (□) confirm the existence of a local fossil fuel effect.

the same time interval. These data were obtained from material from two American Douglass firs[10]. These trees grew in oceanic air at the Olympic Peninsula (47°46′ N, 124°06′ W). Due to a lack of reliable data between AD 1895 and 1915, a comparison could not be made for the entire period (Fig. 3) but three points of interest can be noticed:

(1) During the nineteenth century the average $\Delta^{14}C$ level between both European and American data sets is almost identical. However, the correlation in fine structure as observed to exist between the Dutch and south German $\Delta^{14}C$ data sets is absent.

(2) The south German $\Delta^{14}C$ data also seem to be 2–3‰ lower than the American data during the period AD 1920–40. This would reflect a 10% local depression at the German sampling site.

(3) Also for the German material the divergence seems to decrease after AD 1940. The observation that the Dutch, south German as well as the American data indicate an almost identical ^{14}C level in 1950 must mean than this change can hardly be attributed to a natural variation in the ^{14}C production. This effect would be identical for all three sites and the divergence would be maintained.

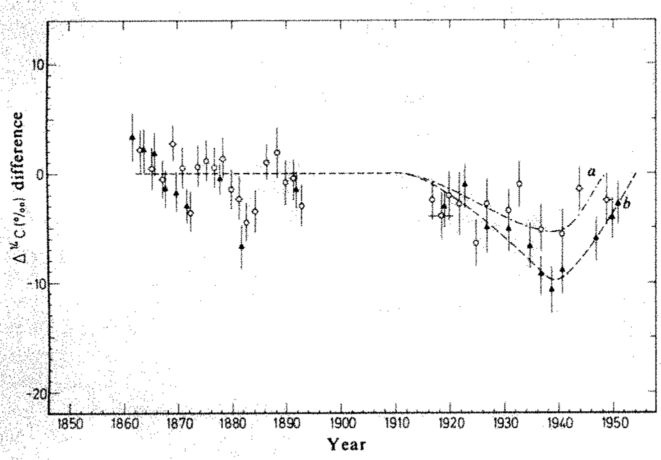

Fig. 3 The calculated difference between the $\Delta^{14}C$ results for the American Douglass firs and: *a*, the south German oaks (○); *b*, the Dutch oak (▲) allowed some curves to be drawn by hand. During the nineteenth century the correlation between $\Delta^{14}C$ results for the Dutch and German oaks does not exist for the American Douglass fir.

We suggest that this has been caused by changes in the relative rates of local influence. As the American data are believed to be a true representation of the atmospheric ^{14}C concentration above the ocean and therefore more widely representative, the effect most probably indicates that the decrease in fossil fuel consumption during the Second World War was more dramatic in the industrialized part of Western Europe than in the rest of the world.

We conclude that until AD 1920 the time variation in the dilution of the atmospheric ^{14}C level for northwestern and central Europe on the average seems to be identical with the ^{14}C level above the ocean. The results for the period after AD 1920, however, suggest a variable European continental ^{14}C effect. Large air masses may have a ^{14}C level which differs by 10–30% from the ^{14}C level of the oceanic air masses. If this is confirmed by more measurements for material from both the European and American continent, the true global time variation of the atmospheric ^{14}C concentration during the past 150 yr cannot easily be established. If the $\Delta^{14}C$ data of the Suess effect are obtained from a single tree, this will reduce its use for testing the accuracy of global carbon reservoir models. Only a global sample network, including the Southern Hemisphere, can thus give more information about the size and distribution of the diluted continental air masses in the past.

Although these ^{14}C results are probably only representative of the variations in ^{14}C concentrations of the European air masses, we have made a comparison with a recent global reservoir model calculation (Fig. 4)[10] carried out using a box diffusion model[7,15]. Values of the annual production during the period AD 1860–1950 were taken from ref. 16. In this calculation the varying background ^{14}C level has also been taken into account. Both the long-term geomagnetically- and medium-term solar-induced ^{14}C variations were calculated, respectively, using the relation derived by Houtermans[17] and an empirical relation between the average 11-yr solar cycle sunspot number and the ^{14}C production rate as determined for the pre-industrial interval AD 1723–1885 [18]. A short-term annual variation has been introduced superimposed on the medium-term contribution, as established from neutron flux observations[18,19].

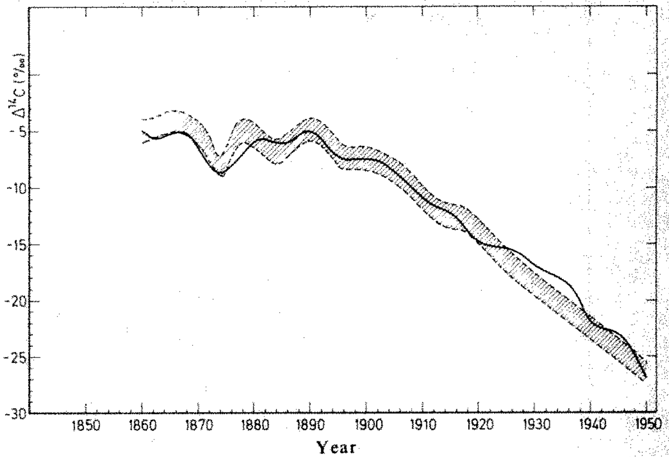

Fig. 4 A comparison of the changes in the atmospheric ^{14}C concentration calculated by model C in ref. 10 (solid curve) with a smoothed spline function with its standard deviation, calculated using the tree ring measurements (dashed area)[20]. The data from both Dutch and German oaks were used. For the period after AD 1920 the Dutch results were neglected.

Table 2 Radiocarbon content in tree rings of a Dutch oak (*Quercus rubra*, Sleen, 52°45′ N, 6°45′ E)

Year of growth	Laboratory no. GrN-	$\delta^{13}C_{PDB}$ (‰)	$\Delta^{14}C$ (‰)
1951	9293	−25.45	−27.6 ± 1.2
1941	9480*	−23.90	−28.1 ± 1.3
1937	9479*	−24.65	−25.9 ± 0.9

Radiocarbon content is calculated with the half life 5,730 yr and corrected for isotopic fractionation. More results from this tree have been published previously[9].

* Cellulose pretreatment; the other sample was pretreated according to the standard AAA extraction procedure[13].

If we now compare our ^{14}C results with these model calculations then apart from the local dilution effect after AD 1920, the fine structure during the nineteenth century is in rather good agreement. Because during that period there was only a minor effect of fossil fuel combustion, the influence on the variation in the model-calculated ^{14}C level is minimal. Therefore, the influence of changes in the solar activity on the ^{14}C production within an 11-yr solar cycle, as given in the model, seems to explain quite acceptably our measured short-term ^{14}C variations. However, especially for this fine structure, which can hardly be influenced by regional effects during this period, a better correlation between trees grown at different sites in the Northern Hemisphere is thought to be essential to establish a ^{14}C variation modulated by the 11-yr solar cycle.

We thank Dr B. Becker for providing samples of oaks grown in southern Germany.

Triassic bedded cherts in central Japan are not pelagic

Ryuichi Sugisaki, Koshi Yamamoto & Mamoru Adachi

Department of Earth Sciences, Nagoya University, Nagoya, Japan

Although the origin of bedded radiolarian cherts in orogenic belts has been widely debated[1-15], their geochemistry is still poorly understood. Triassic bedded radiolarian cherts occur extensively in the Japanese Islands and are generally not associated with ophiolitic rocks but rather with clastic rocks. We present here chemical data on the Triassic bedded cherts of Kamiaso in central Japan. The relationship of SiO_2 with Al_2O_3, TiO_2 and Zr shows that the bedded cherts have been formed by a simple mixing of biogenic silica derived from radiolarians and sponge spicules with lithogenic materials. The ratios of several elements relative to TiO_2 strongly suggest that the shale partings and lithogenic portions of the cherts are consanguineous. Sedimentary structures as well as the geochemical evidence suggest that most Kamiaso cherts are turbidity current deposits. Our geochemical and geological data compared with those of recent marine sediments from various environments, demonstrate that the Triassic cherts and associated shale partings are not deep pelagic in origin but formed in an offshore or marginal sea environment.

Samples were collected from an extensive continuous outcrop of a Triassic chert formation[16-18] along the Hida river, Kamiaso, Gifu Prefecture, central Japan (Fig. 1). The chert formation, ~100 m thick, is conformably overlain by a series of Lower(?)–Middle Jurassic strata[19] of chert, siliceous shale and turbidite and is underlain by Triassic siliceous shale with chert layers. No ophiolitic rocks occur spatially associated with the cherts. The bedded chert consists of rhythmically interbedded chert and thinner shale (Fig. 1*a*); chert layers are from 1 to 30 cm thick, mostly 2–7 cm, and shale layers from paper-thin to 1.5 cm thick. The chert has a wide colour range: green, grey, dark red-brown, red, white and black. Some dark red-brown chert has a less vitreous appearance and yields best-preserved Triassic radiolarians. Bedding surfaces are generally smooth, but where shale partings become thicker they tend to be knobby and pinch-and-swell structures and load casts are common. The chert layers occasionally show parallel lamination, whereas graded bedding is rare and inconspicuous because detrital grains of quartz, feldspar or lithic fragments are not present in the cherts. Locally, graded bedding is displayed either by the upwards increase of clay content or by the upwards size grading of siliceous remains within one lamina. The chert is made up largely of cryptocrystalline quartz with a small amount of illite, chlorite and opaques; radiolarian tests and sponge spicules filled with cryptocrystalline quartz or length-fast chalcedony are ubiquitous (Fig. 1*b*). Some radiolarians are cut by vertical microstylolites. Secondary minerals such as quartz, chlorite, carbonate and opaques are generally present in trace amounts except for white chert which is invariably veined by microcrystalline quartz and chalcedony.

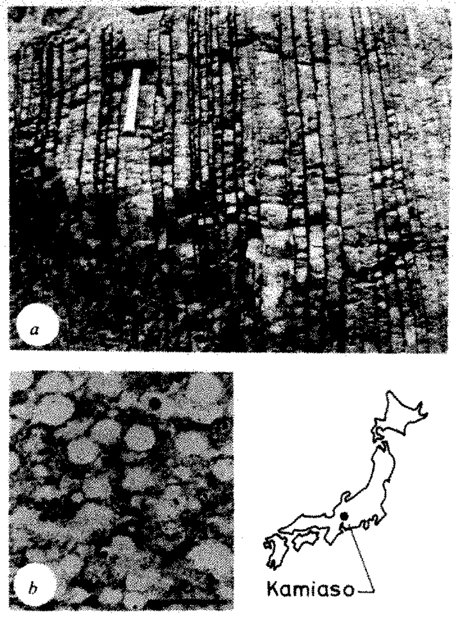

Fig. 1 Triassic bedded radiolarian chert at Kamiaso, Gifu Prefecture, central Japan. *a*, Rhythmically interbedded chert and thinner shale (hammer head, 20 cm); *b*, photomicrograph of black chert containing abundant silica-filled tests of radiolaria (scale bar, 0.2 mm).

The shale partings are very fissile and soft compared with cherts, have the same colour as associated cherts, and are composed essentially of a fine aggregate of illite, quartz, chlorite and opaques with or without radiolarian remains. Some partings have a conspicuous fracture cleavage with flattened radiolarians and well-oriented clay minerals.

Sixty-nine chert samples and 37 shale partings collected from the outcrop were analysed with an automatic X-ray fluorescence spectrometer (Table 1). Figure 2 shows the SiO_2 content in cherts and shale partings plotted against Al_2O_3, TiO_2 and Zr. That the composition of the chert samples trends to $SiO_2 = 100\%$ indicates that pure silica from a separate source is diluting other components during sedimentation. We thus conclude that the SiO_2 of the bedded cherts can be regarded as biogenic; the biogenic silica in each sample experienced different degrees of mixing with other elements which are considered mostly as lithogenic.

To examine the depositional environment of the Triassic cherts, the analytical data were compared with those of about 750 marine argillaceous sediments, which were collected during

[*] Samples of marine sediments are mostly collected from piston cores and deep sea drilling cores. 'Distance from land' and 'water depth' are expressed as values in averaged locations of a core group.

[†] The low Al_2O_3/TiO_2 ratio can be attributed to basalts of the Ogasawara Islands.

[‡] Some samples of this group show high ratios of Al_2O_3/TiO_2 and high content of SiO_2 (ref. 23); these contain much acidic tuff.

[§] The low Al_2O_3/TiO_2 ratio can be attributed to basalts from the Manihiki Plateau.

[‖] The high Al_2O_3/TiO_2 ratio is due to zeolites which are derived from acidic tuff.

cruises of the Geological Survey of Japan and Deep Sea Drilling Project (DSDP) and analysed in our laboratory with the same method used for cherts[20–28]. Si, Al, Ti and Zr tend to remain in the resistates and hydrozates during the sedimentation process: accordingly, the mutual abundances of these elements generally remain stationary during weathering and transportation. We examined the relative abundances of these 'conservative' elements by using TiO_2 concentration as a standard. For example, the Al_2O_3/TiO_2 ratio of sediment hardly changes, even if the sediment is diluted by biogenic silica. Thus, several oxides were normalized to TiO_2 for the marine argillaceous sediments in several regions (Table 2, Fig. 3). We noticed that the ratios of Al_2O_3/TiO_2 and total Fe_2O_3/TiO_2 fall in a narrow range in each region with a few exceptions; the ratios are from 22 to 24 and from 8 to 11, respectively. It is particularly interesting that the ratios are similar to mean values of those of granites and basalts (Fig. 3) because this suggests that the lithogenic part of the marine argillaceous sediments is derived mostly from the continental crust. The exceptions can be attributed to the contribution from oceanic island basalt, acidic tuff and others as noted in Table 2.

The chemical features of the shale partings in the bedded cherts can be compared with those of marine argillaceous sediments to examine the environment of formation for the cherts. The average ratios of Al_2O_3/TiO_2 and total Fe_2O_3/TiO_2 fall into the general range for the marine argillaceous sediments (Table 2, Fig. 3). The partings, however, are especially lacking in CaO and Na_2O (Table 1). This feature is usually observed in fault clay and gouge[29], suggesting that elements other than the 'conservative' elements would be soluble through weathering. As the shale partings are very fissile compared with cherts, meteoric waters will selectively soak into the partings and wash out mobile elements, as is the case with shear zones of faults. Accordingly, the elements other than the 'conservative' elements in the shale are of no use for comparison.

On the other hand, the average ratio of Al_2O_3/TiO_2 in the cherts (22.1) is remarkably close to that of the shale partings (22.0) in spite of errors in sampling and analysis. The ratios of total Fe_2O_3/TiO_2 in the chert and in the shale are also similar to each other, although Fe cannot be regarded as conservative. This similarity strongly suggests that the shale partings and lithogenic portions of the cherts are consanguineous. This is

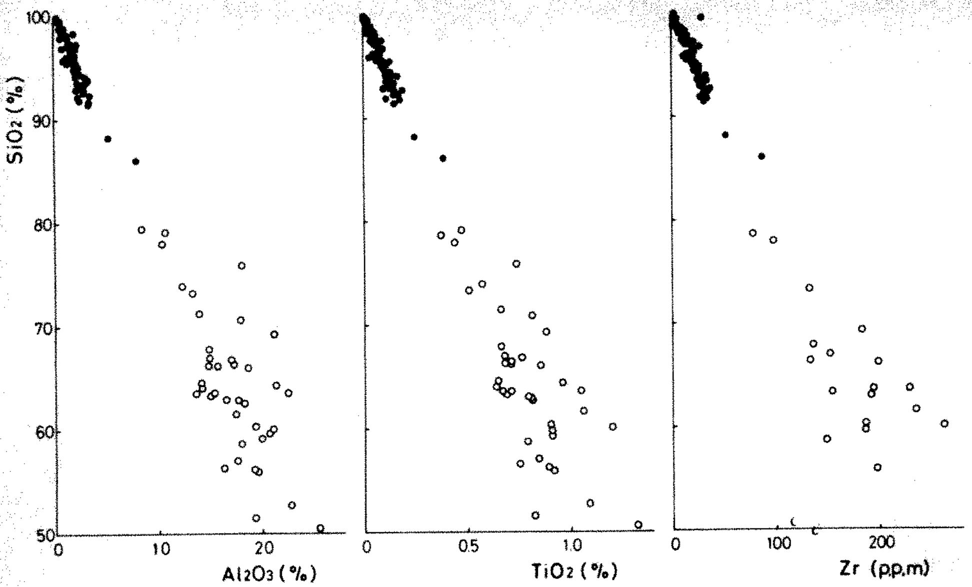

Fig. 2 Relation between SiO_2 and Al_2O_3, TiO_2 and Zr. ●, Cherts; ○, shale partings.

also implicitly shown in Fig. 2 where points for cherts and those for partings are approximately aligned. Cherts, which resist weathering, are expected to have kept their original composition: most TiO_2 normalized compositions, except for SiO_2/TiO_2 in the cherts, therefore, show the chemical feature of the lithogenic portion deposited with biogenic silica. From this, we can deduce the sedimentation environment of the lithogenic portion and ultimately that of the whole chert.

Most cherts are the same colour as associated shales; some cherts display parallel lamination and/or graded bedding, and some appear to grade upwards into overlying shales. These data strongly suggest that the Triassic bedded cherts of Kamiaso are turbidites[2,6,7,9,14], derived mostly from a previously gathered accumulation of biogenic silica, shale partings being deposited as the tail of the currents. This conclusion is compatible with the chemical inference that the shale partings are consanguineous to the lithogenic portions of cherts.

Support for a turbidite origin of Kamiaso cherts also comes from microfossil evidence: both late Triassic conodonts and early Jurassic radiolarians occur together in some green cherts of the uppermost part of the chert formation[18]. A similar reworking of conodonts is also known in the bedded cherts of Inuyama[30], ~20 km south of Kamiaso, which are stratigraphically almost in the same horizon as of Kamiaso. Presumably the conodonts would have been reworked at times when the original silica-rich material was transported from shallow sites to deeper depositional basins by turbidity currents. Because detrital grains other than fine clayey materials are not contained in both the cherts and shales, the depositional sites must have been sea basins where little or no coarser terrigenous sediments reached. Where did such basins occur during Triassic time, and where can we find such basins in the modern ocean?

A useful criterion for discriminating depositional environments of marine sediments is the MnO/TiO_2 ratio. This ratio in nearshore sediments remains generally low and does not fluctuate much because granites and basalts regarded as a main source of the sediments have a uniform and low ratio (Fig. 3). As the distance from land and the water depth increase, terrigenous materials decrease while Mn precipitates nearly uniformly from ocean water (Table 2, Fig. 3). The ratio shows almost two orders of magnitude of variation from the nearshore area to the abyssal area. The MnO/TiO_2 ratio of the Triassic cherts under consideration is 0.254 ± 0.196 and is close to those of the argillaceous sediments from the Central Sea of Japan and the continental shelf and slope off South-west Japan. The distance from land to both areas is at most 300 km. The fact that the ratio of the Triassic bedded cherts is quite different from that of deep ocean sediments implies that the cherts are not deep pelagic but would have formed in an offshore or shallow marginal sea within ~300 km from land. Furthermore, our preliminary analyses of 37 cherts from DSDP Leg 32 give 6.28 for the average MnO/TiO_2 ratio, which is much larger than that of the Triassic cherts. The study of rare-earth elements on DSDP and on-land cherts suggests that some Triassic radiolarian cherts of Kamiaso formed in coastal areas, marginal seas or land-enclosed seas[11]. All these facts confirm our view that the Triassic bedded cherts in central Japan are not pelagic in origin.

Another factor enhancing the MnO/TiO_2 ratio is the contribution of hydrothermal components resulting from submarine volcanism[31]. For example, Jurassic cherts overlying ophiolites

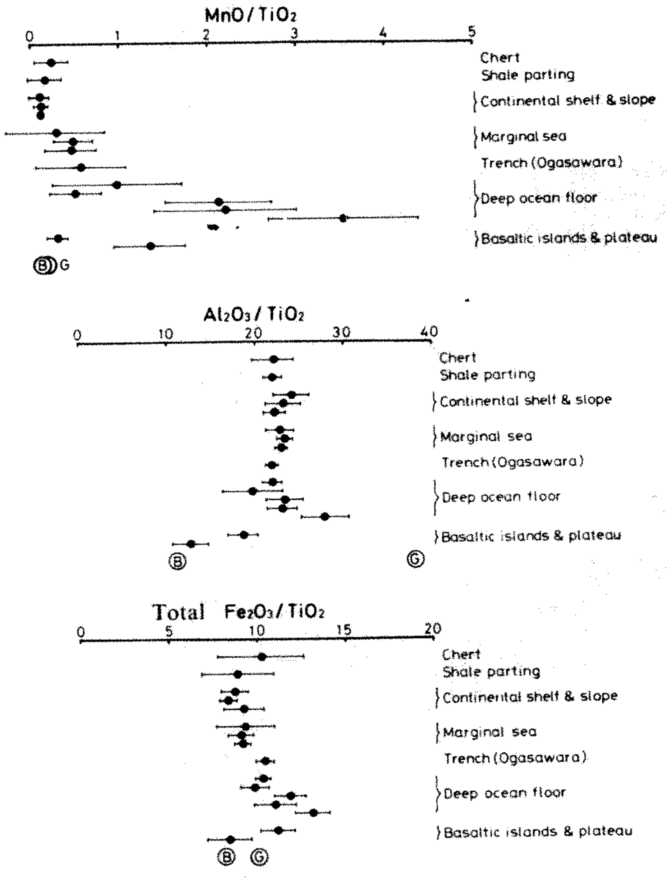

Fig. 3 Comparison of TiO_2 normalized values of marine argillaceous sediments in various environments and Triassic cherts and shale partings. The detailed description is listed in Table 2. The horizontal line indicates $\pm 1\sigma$. G and B represent the averaged values of granites and basalts, respectively[34].

in Italy show a higher range of the ratio (0.53–1.40) (refs 4, 32) and they contain much Ni, Co and Cu. The features of these elemental abundance and Pb isotopic compositions[33] have been ascribed to hydrothermal activity during submarine volcanism which gave rise to ophiolites. The MnO/TiO_2 ratio and the concentration of Co, Ni and Cu in the Japanese Triassic bedded cherts (Tables 1, 2) are significantly lower than those in the Italian cherts. This suggests that bedded cherts in close association with ophiolites as in Steinmann Trinity[1] are different in genesis from those intercalated within sedimentary sequences treated here. Clearly the study of bedded cherts from geochemical aspects in various orogenic belts will provide an important key to understanding the environment of ancient geosynclines.

We thank Setsuo Yogo and Miss Yumiko Isobe for technical assistance.

Mid-Palaeozoic travels of Arctic–Alaska

J. F. Sweeney*

Earth Physics Branch, Department of Energy, Mines and Resources, Ottawa, Canada K1A 0Y3

One of the most persistent proposals[1] for the origin of the Arctic sea floor is that Alaska, or parts thereof, broke away from polar Canada and rotated as much as 70° anticlockwise relative to the North American craton. Subsequent modifications[2–8] reduced the size of the rotated block (Fig. 1) and put the date of rotation at latest Jurassic–early Cretaceous (refs 4, 6, 7, 9, 10, and A. Grantz and S. May in preparation). Although restoration of the block provides a good geological fit between northern Alaska and the Arctic islands for late Palaeozoic and younger pre-rift age rocks,[8] the character of Devonian and older Palaeozoic rocks across the restored boundary is anomalous, with deformed and thermally altered rocks of northern Alaska lying against unaltered sediments on Banks Island (Fig. 2*b*). Here I compare the known geology of mid-and early Palaeozoic rocks along the margins of the restored rift and explain the anomalous Arctic–Alaska terrane as a block that was displaced southwestwards in mid-Palaeozoic time by as much as 2,000 km from its initial orogenic site to the north and east of Ellesmere Island.

Devonian and older rocks outcrop in northern Greenland[11], northern Axel Heiberg and Ellesmere islands[12] and northern Alaska[13] and are found in the subsurface along the modern polar margin on Ellef Ringnes and Brock islands[14], Banks Island[15], beneath the Mackenzie Delta[16], in northernmost Alaska, Chukotsk Peninsula and the adjacent continental shelf[17]. Across northern Greenland and adjacent parts of Canada, shallow-dipping Cambrian platform rocks pass northward from the craton into dominantly carbonate shelf facies which in turn grade northward into a dominantly clastic filled ensialic trough that on Ellesmere Island was two-sided and bounded on the north by a volcanic arc[11,12,18]. Trough sediments on Ellesmere Island were derived from both margins although the source to the north declined steadily during the Cambrian interval[18]. At this time in northern Greenland, detritus was derived from cratonic sources to the south[19].

In early and middle Ordovician time, felsic to intermediate volcanism prevailed on northernmost Ellesmere Island and was followed by local deformation and rapid deposition of flysch derived, at least in part, from Cambrian or older low-grade metamorphic rocks[12,18] within a major new or rejuvenated source terrane to the north (Fig. 2*c*). This terrane also delivered clastic debris to northern Greenland beginning in Ordovician time[19]. Clastic deposition advanced southward in both regions during the Silurian and early Devonian periods[12,18,19] and on Ellesmere Island both the volume and grade of deposited material increased to the north-east[18].

To the west of Mackenzie Delta across northeastern Alaska outcrop and borehole data indicate that in Cambrian and Ordovician time shallow-water carbonate arches graded northward into shale–chert basinal sequences that contained substantial volcanic deposits[13,16,17,20]. In later Ordovician and Silurian time this setting was interrupted by major uplift (Fig. 2*c*) within the shale–chert zone and was accompanied by deformation, emplacement of a felsic pluton at 431 ± 13 Myr (K/Ar hornblende date)[20,21] and erosion that exposed Cambrian and older low-grade metamorphic assemblages along the uplift axis[13]. The grain size of early and (?) middle Devonian clastic debris in northernmost Alaska increased towards what is now the west along the present coast[13].

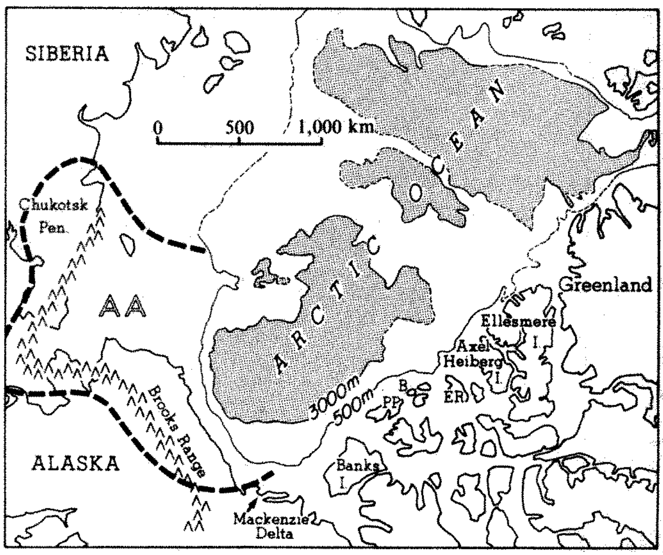

Fig. 1 Boundaries of the terrane[26,31], designated Arctic–Alaska[6] (AA), presumed to have rotated. B, Brock Island; ER, Ellef Ringnes Island; PP, Prince Patrick Island.

Plutonic rocks occur mainly along the southern Brooks Range in a relatively narrow belt (Fig. 2*a*) that extends northeastwards into the Mackenzie Delta region[21]. A second belt of small intrusions is found along northernmost Axel Heiberg and Ellesmere islands[12]. Intrusive rocks in each belt are dominantly felsic and most were emplaced during middle and late Devonian time[12,21]. Several small ultramafic to felsic bodies of late Silurian or early Devonian age are present within the Axel Heiberg–Ellesmere belt[12,18]. In both regions, shallow marine conditions at the time of emplacement suggest that the plutonic rocks may represent an ensialic island arc or a continental margin magmatic belt[18,21].

Metamorphic grade declines westward from amphibolite facies in northeastern Greenland[11] to greenschist–subgreenschist facies with local amphibolites on northernmost Ellesmere Island[18,22] to virtually unmetamorphosed rocks at Ellef Ringnes Island and beyond[14] (Fig. 2*a*). West from the Mackenzie Delta thermal effects are variable and reach greenschist grade along the coast but amphibolite grade rocks are associated with the magmatic arc in the southern Brooks Range[17,21,23].

Except for the Banks Island area, these regions experienced one or more early Palaeozoic periods of thermal and structural alteration that generally increased in intensity towards the north and culminated during middle Devonian to early Mississippian time with the deposition of thick southward-tapering clastic sediments that palaeocurrent studies suggest were transported mainly from north-east to south-west in both northern Alaska and the Canadian Arctic Islands[12,13,24,25]. Uplift and clastic wedge formation that began on northern Ellesmere and Axel Heiberg islands in early Middle Devonian time expanded southwestwards at an average rate close to 3 cm yr^{-1} to include Prince Patrick Island by the outset of the Mississippian[24]. A similar orogenic progression is not documented in northern Alaska where, as in Arctic Canada, the mid-Palaeozoic zone of uplift and related clastic deposition extends hundreds of kilometres south of the present continental margin[13,25] (Fig. 2*b*).

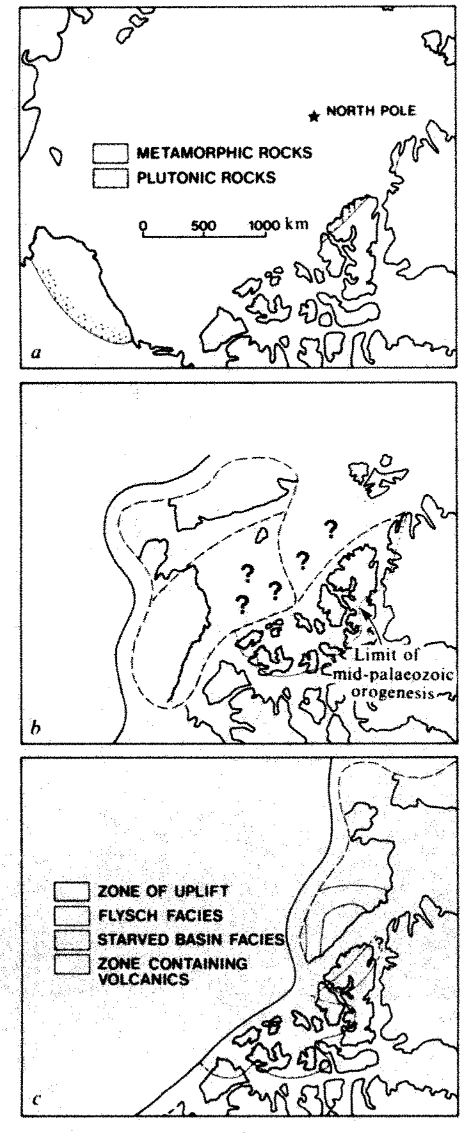

Fig. 2 Early and mid-Palaeozoic orogenic features[12,13,17,18,21] with continental blocks arranged: *a*, as at present; *b*, as they may have appeared before presumed rotation of Arctic–Alaska; *c*, before onset of mid-Palaeozoic tectonism.

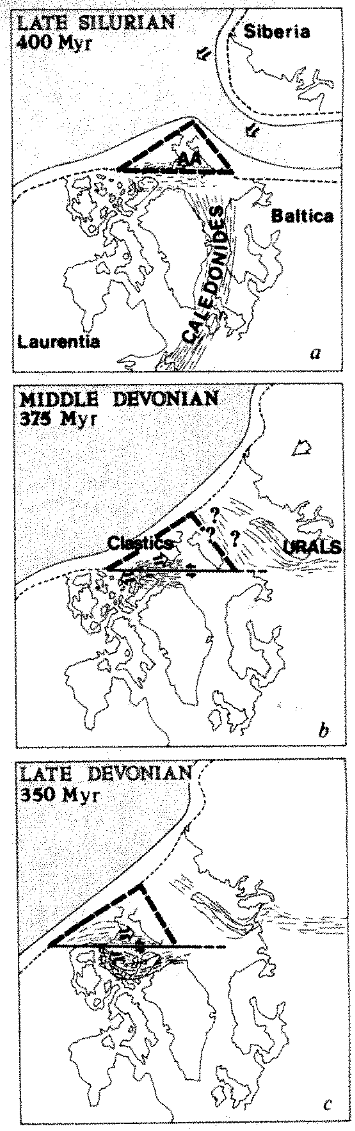

Fig. 3 Possible Devonian tectonic development of the Arctic region. Large arrows in *b* and *c* indicate expected directions of sediment and tectonic transport on opposite sides of the fault zone. *a*, Late Silurian 400 Myr; *b*, middle Devonian 375 Myr; *c*, late Devonian 350 Myr.

In the early 1970s it was proposed that from Greenland to Alaska, the major source of early and mid-Palaeozoic sediments may have been offshore orogenic welts produced by subduction of sea floor beneath the Laurentian continental mass, followed in mid-Palaeozoic time by closure of an ancestral Arctic Ocean and suturing of the opposing cratonic blocks[2,11,12]. The Banks Island area in this view lay opposite an embayment in the approaching landmass and was therefore spared the orogenic effects of continent–continent collision[15]. In a restored rotation, however, no appropriate embayment is evident in palaeogeographical reconstructions of northern Alaska[16]. More recent studies indicate that, in Canada, early and mid-Palaeozoic clastic sources to the north did not extend further south-west than Axel Heiberg Island[18,24] and also that significant left-lateral movements may have been associated with development of the orogen.

The gross similarity in mid- and early Palaeozoic stratigraphy, tectonism and metamorphic grade between Arctic–Alaska and northeastern Laurentia has long been noted[12,17]. Several of these comparative features may be explained if the two terranes were once joined, polar margin to polar margin (Figs 2*c*, 3*a*). The ensialic trough and associated volcanism noted for the Cambrian in the northern part of each region may indicate the presence of an adjacent consuming margin that ceased activity when the opposing Arctic–Alaska block collided with northeastern Laurentia in middle Ordovician time[18,19]. Uplift, metamorphism, deformation and plutonism in northern Alaska at about this time is matched by contemporary metamorphism, deformation and volcanism on northernmost Ellesmere Island. Uplift in Arctic–Alaska may thereby have become the source region for Ordovician through early Devonian clastics derived from the north in the Greenland–Ellesmere region (Fig. 2*c*). The crystalline fraction of detritus delivered to the latter region and rocks within the core of the eroded zone in Alaska are similar in age and metamorphic grade. Further, with Arctic–Alaska so oriented, the present westerly coarsening of early Devonian sediments in coastal Alaska becomes, in mid-Palaeozoic time, a northeasterly coarsening in agreement with the textural trend noted in contemporary clastics on what was then the adjacent landmass of Ellesmere Island. For middle Devonian to early Mississippian syntectonic deposits, however, the proposed reconstruction places major sediment transport directions within adjacent terranes in opposition, northeasterly in Arctic–Alaska, southwesterly in Arctic Canada[26].

Preliminary palaeomagnetic reconstructions[27,28] show that the Siberian Shield may have approached the ancestral polar margin of Laurentia from what is now the east during the early Palaeozoic and that intervening sea floor was probably eliminated during Devonian time (Fig. 3*a*, *b*). The approach of the Siberian block may have ruptured the weld between Arctic–Alaska and northeastern Laurentia and caused the former to move with compression accompanied by significant left-lateral motion against the Laurentian front to produce a broad zone of uplift and erosion within each block. In Laurentia, the affected zone expanded to the south-west as the Arctic–Alaska block proceeded (Fig. 3*b*, *c*). Significant but undated south-west -directed thrusting is also documented on northernmost Ellesmere Island[18]. By early Mississippian time, the migrating Arctic–Alaska terrane presumably came to rest against a zone that included the Banks Island area although, as earlier noted, the deformed belt did not extend beyond Prince Patrick Island. Final late- to post-orogenic movements in the region may not have been attended by significant disruption along the zone of contact between the two plates.

This reconstruction implies that Arctic–Alaska also moved against oceanic lithosphere as it advanced to the south-west (Fig. 3). Underthrusting or subduction of the latter beneath the encroaching continental block in middle and late Devonian time may be indicated by the belt of plutonic rocks along the southern Brooks Range (Fig. 2*a*), which would have been close to the leading edge of the Arctic–Alaska block during this interval (Fig. 3*b*, *c*). Contemporary magmatism in northernmost Ellesmere Island may be related to the initial stages of this event. Late Silurian–early Devonian intrusions within the Ellesmere belt may mark the line of separation between Laurentia and Arctic–Alaska or they could be the intrusive equivalents of nearby Ordovician volcanics[18] (Fig. 2*c*).

A key feature of this concept is that compression combined with left-lateral translation between adjacent continental blocks produces a region of uplift and clastic deposition that advances in each terrane as the zone of contact between them progresses. In Laurentia, the contact zone is seen to move to the south-west as does the region of middle and late Devonian uplift and clastic deposition[24] (Fig. 3*b*, *c*). In Arctic–Alaska, the opposing Laurentian block will appear to move to the north-east. Mid-Palaeozoic uplift and sediment transport in Arctic–Alaska should therefore proceed also towards the north-east. That is, the relative motions should produce overall directions of orogenic expansion and sediment transport in each block that, when compared, will be diametrically opposed. As indicated earlier, this is the case for mid-Palaeozoic palaeocurrent directions when Arctic–Alaska is placed in its pre-rotated position against polar Canada[25,26]. However, there is little evidence of corresponding northeastward orogenic expansion at this time in northern Alaska, perhaps because the entire facing side of the smaller Arctic–Alaska block was already in contact with the larger Laurentian block at the start of the tectonic episode (Fig. 3*a*).

This scheme was anticipated as early as 1965 by Harland[29] who proposed left-lateral shearing north of Greenland and Ellesmere Island as an extension of major sinistral faulting in late Devonian time within the Caledonian foldbelt. Recent palaeomagnetic evidence[30] assigns a Carboniferous age to the latter displacement which implies that Devonian shearing along the polar margin was an earlier and therefore separate event as suggested here.

The present scenario is attractive in that it explains early Palaeozoic and Devonian geological and tectonic similarities between what are now widely separated regions and, in a restored rotation, it accounts for dissimilarities between pre-Carboniferous sequences in the Banks Island area and in northern Alaska. The location as well as the linearity of the present polar margin from Greenland to the Mackenzie Delta are also explained as having been the site of a major mid-Palaeozoic shear.

At the end of Jurassic time, some 200 Myr after its Palaeozoic travels came to an end, Arctic–Alaska moved again, this time in anticlockwise rotation to begin the process of opening the modern Arctic Ocean basin.

A mutation in *Drosophila* alters normal connectivity between two identified neurones

John B. Thomas & Robert J. Wyman

Department of Biology, Yale University, Box 6666, New Haven, Connecticut 06511, USA

The mechanisms involved in producing the vast number of specific connections in the nervous system are unknown. As nerve cells grow during development and seek out their targets there must be some sort of molecular cues for axonal guidance and final target recognition. One strategy for identifying such factors is to locate the genes which code for or control the expression of the molecules. To identify these genes, we have chosen a simple network of eight neurones in *Drosophila melanogaster*, comprising the giant fibre (GF) system[1-3], in which we can detect the effect of mutations on connectivity. We report here the isolation of an X-linked, recessive mutation, *bendless* (*ben*), which deletes one process of the GF while leaving other portions functionally unaltered.

The GF network is activated by a light-off visual stimulus and mediates the early events of an escape response consisting of a jump and subsequent flight[4]. To isolate potential connectivity mutants we used standard mutagenesis techniques and a behavioural screen to select flies failing to jump to the light-off stimulus. Males 1 or 2 days old were fed the mutagen ethyl methane sulphonate (EMS)[5] and mated to $C(1)M3/Y$ females[6]; the F_1 male progeny from this cross inherit the mutagenized paternal X chromosome. We screened 50,000 F_1 males. The screening device consists of a flask inverted in a beaker. Flies are placed inside the flask and are free to walk along its inner surface. A light-off stimulus causes them to jump, but because activation of the flight muscle does not always result in maintained flight, the flies fall a small distance. After several stimuli, jumpers fall into the beaker where they are unable to re-enter the testing area; non-jumpers remain in the flask. White-eyed flies, which lack the visual screening pigments, show greater reliability than wild type in jumping to the light-off stimulus. Therefore, white-eyed flies of the *brown*; *scarlet* (*bw*; *st*) genotype were used. Both the morphology of the GF and its motor output in *bw*; *st* flies are indistinguishable from wild type.

Non-jumping lines were established from individuals selected in the screen. Males from these mutant lines were then tested physiologically for defects in the GF system by stimulating the GFs extracellularly in the brain and recording from thoracic muscles known to be driven by them[3]. Underlying structural abnormalities in the GF were revealed by intracellularly injecting the GF with the fluorescent dye Lucifer yellow. From these experiments several X-linked mutations have been isolated which disrupt the normal physiology and morphology of GF system neurones. The *bendless* mutation is one of these and maps between *vermilion* and *forked*.

The GFs themselves are a pair of large interneurones having cell bodies located ipsilaterally in the brain[2]. Each sends an axon along the dorsal midline of the cervical connective to the thoracic ganglion where it courses ventrally. Within the mesothoracic neuromere the GF axon makes a lateral bend and ends abruptly[1,2] (Fig. 1*a*, *b*). Just before this lateral bend, the GF makes an electrical synapse with the peripherally synapsing interneurone (PSI)[1], which crosses the ganglion and chemically synapses onto the five motoneurones of the contralateral dorsal longitudinal flight muscle (DLM). At the terminus of its bend, the GF makes another electrical synapse with a large motoneurone innervating the tergotrochanteral muscle (TTM, or jump muscle)[1].

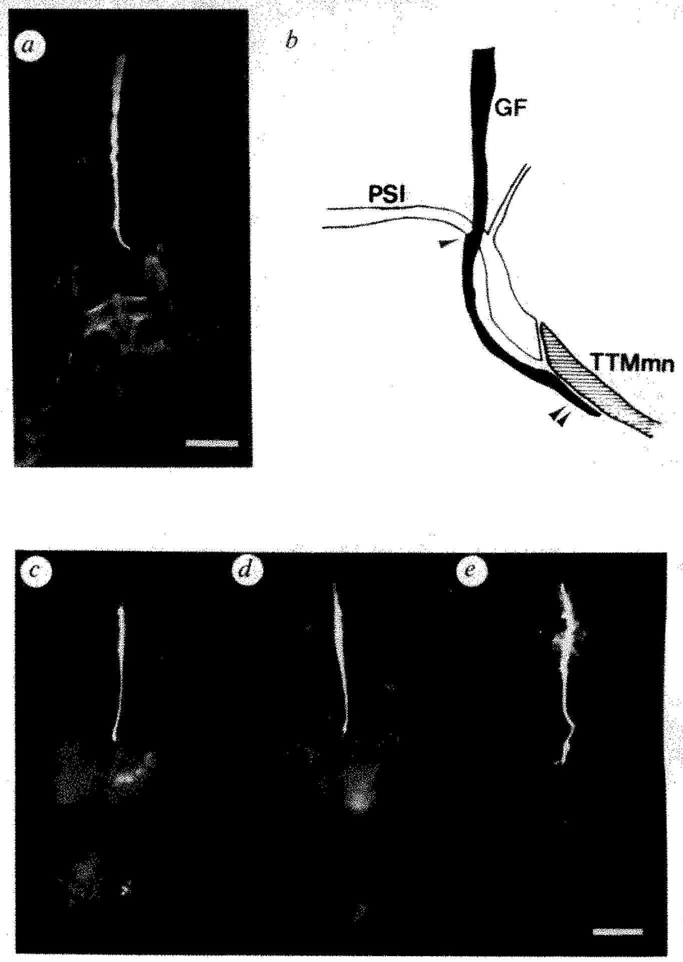

Fig. 1 *a*, *c*–*e*, Whole mounted thoracic ganglia, viewed with fluorescence optics, from a wild-type (*a*) and three *bendless* (*c*–*e*) individuals. In each the GF has been injected with Lucifer yellow. Techniques of dye injection are as described by Koto *et al.*[2]. *a*, *c*, *d*, Dorsal views; *e*, a dorso-lateral view in which the normal ventral bend and abnormal branches are visible. Anterior is up; scale bar, 100 μm. *b*, Schematic diagram of the GF bend region from an electron micrograph reconstruction[1] showing the location of synapses between the GF and PSI (single arrowhead) and between the GF and TTM motoneurone (double arrowhead).

In mutant flies ($n = 10$) the GF cell body position and dendritic morphology are indistinguishable from wild type (data not shown) and the GF axon descends unbranched to the thoracic ganglion. However, within the ganglion the GF fails to make the lateral bend characteristic of wild type and terminates before making the bend (Fig. 1*c*, *d*). Extending from the tip are numerous fine processes ~3–5 μm long. Occasionally, this branching is more extensive ($n = 2$), consisting of processes up to 30 μm long (Fig. 1*e*). In neither case does the GF extend to the region where it normally makes synaptic contact with the TTM motoneurone. The TTM motoneurone itself is present and drives the TTM normally. Preliminary experiments using retrograde labelling with horseradish peroxidase indicate that the TTM motoneurone morphology is normal in *ben* flies (M. Koto, personal communication).

Physiological experiments show that in the mutant the GF drives the DLM normally, but the TTM is driven abnormally. In wild type a spike in the GF drives the TTM and DLM with short and constant latencies. Figure 2*a* shows the response recorded in the TTM and DLM to intracellular stimulation of the GF in a wild-type individual. The TTM, whose motoneurone is driven monosynaptically by the GF, has a response latency

0028-0836/82/320650—02$01.00

of 0.8 ms; the DLM, whose motoneurones are driven disynaptically via the PSI, has a response latency of 1.2 ms. Figure 2*b* shows the GF output to the TTM and DLM of a *ben* individual. It can be seen that the DLM response latency of the mutant is indistinguishable from that of wild type. However, the TTM latency is abnormally long at 2.2 ms. All *ben* flies examined physiologically ($n = 40$) had abnormal TTM response latencies of 2.2–3.0 ms. Whether the giant fibre in the mutant actually does make synaptic contact with the TTM motoneurone, albeit in an abnormal region, is not known. However, as the TTM latency is 1.4–2.2 ms greater than wild type, and a normal synaptic delay is of the order of 0.5 ms, it is unlikely that there is direct functional contact between the GF and the TTM motoneurone. Instead, it is likely that the GF is driving the TTM via an as yet unidentified polysynaptic pathway.

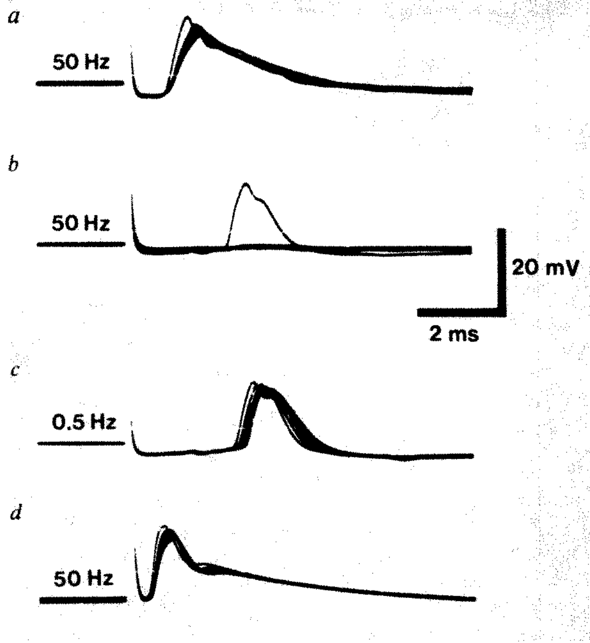

Fig. 3 *a*, GF stimulation at 50 Hz while recording the response in the TTM of a wild-type individual. *b*, Same as *a* but in the mutant *ben*. *c*, GF stimulation at 0.5 Hz while recording the response in the TTM of a *ben* individual. *d*, TTM motoneurone stimulation at 50 Hz in *ben*. In each trace 10 effective stimuli were delivered. Insulated tungsten electrodes were used for stimulating and recording in all experiments.

Evidence from following frequency experiments supports the conclusion that the normal GF–TTM motoneurone synapse is absent. The TTM of wild-type flies can be driven by GF stimulation at frequencies >100 Hz (ref. 3), but in the mutant, the TTM can be driven 1 : 1 only at frequencies <1 Hz. In contrast, the normal DLM following frequency to GF stimulation is unaffected in the mutant. Figure 3*a* shows the response in the TTM of wild type to extracellular stimulation of the GF at 50 Hz. The pathway can respond to each of the stimuli with its characteristically short and constant latency. Figure 3*b* shows the response in the TTM of a *ben* individual to GF stimulation at 50 Hz. The pathway can only follow the first stimulus. As the DLM responded normally to all stimuli in the train, each stimulus was effective in eliciting a spike in the GF. Figure 3*c* shows that the TTM pathway of *ben* flies is capable of following low frequencies of GF stimulation without failure. In this experiment the GF was stimulated at a frequency of 0.5 Hz; the TTM followed 1 : 1. To exclude the possibility of a defect in motoneurone spike conduction, neuromuscular transmission or the muscle membrane, the TTM motoneurone was stimulated extracellularly in the ganglion while recording from the TTM itself. Figure 3*d* shows the TTM response to stimulation of its motoneurone at 50 Hz; the muscle follows the train of stimuli without a failure. This indicates that the site of lability in the pathway mediating the abnormal TTM response lies centrally, between the GF and TTM motoneurone.

One of the more interesting possibilities for the mutation's mechanism of action is that some molecule necessary for the recognition between the GF and the TTM motoneurone is either missing or defective in the mutant. During normal development, insect neurones often send out many branches and retract them at approximately the time synaptic contact is made with their targets[7]. In this case, the presence of abnormal branches in *ben* may be the result of the GF failing to make normal synaptic contact with the TTM motoneurone. Further genetic analysis of mutations such as *ben* may lead to the identification of genes encoding developmentally important molecules involved in connectivity. Ultimately, the molecules themselves may be identified using the techniques of molecular biology.

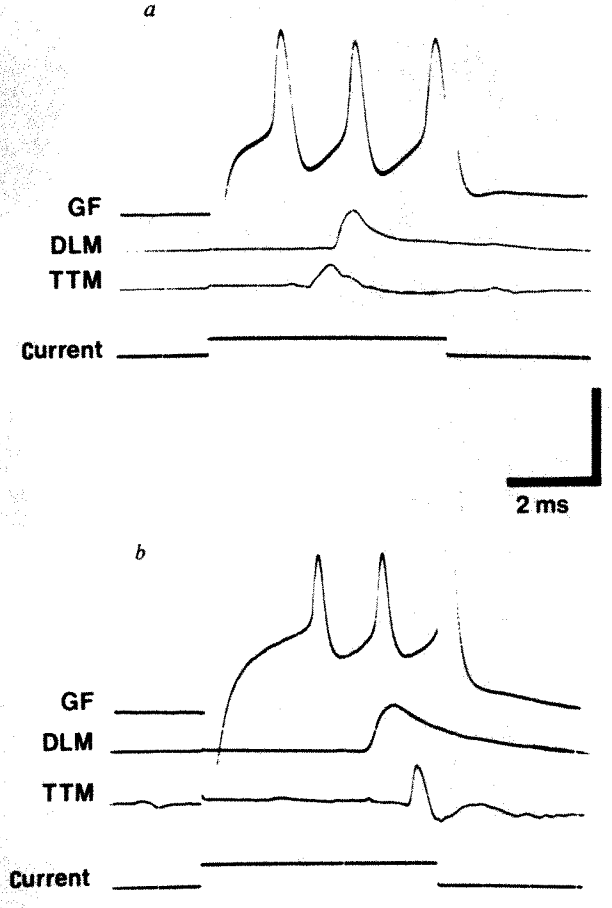

Fig. 2 Response in TTM and DLM to intracellular stimulation of the GF in wild-type (*a*) and *ben* (*b*). Top traces are the intracellular records of the GF. Current is shown in the lower traces. Muscle responses shown in the middle trace are driven by the first GF spike. Vertical calibration is 40 mV for the GF and DLM, 20 mV for the TTM; 10 nA for the current.

Cross-species neural grafting in a rat model of Parkinson's disease

Anders Björklund, Ulf Stenevi, Stephen B. Dunnett & Fred H. Gage

Department of Histology, University of Lund, Lund, Sweden

Previous studies[1-7] have shown that intracerebral implants of embryonic mesencephalic dopamine (DA) neurones, grafted between individuals of the same inbred rat strain, can reverse some of the functional deficits caused by damage to the nigrostriatal DA pathway. These observations have raised the possibility that the intracerebral neural grafting technique may eventually find a clinical application in the treatment of neurodegenerative disorders, particularly Parkinson's disease. One obvious obstacle to any such attempts is the immunological rejection mechanisms associated with allogeneic or xenogeneic grafting. Thus, neural tissue (sensory and sympathetic ganglia), transplanted across immunological barriers to sites outside the central nervous system (CNS), are known to be rejected[8,9]. The brain has, however, been described as an immunologically 'privileged' site, partly perhaps because of its protective blood–brain barrier[10-12]. This may be the case for grafts of embryonic tissue, in particular. Thus, Zalewski *et al.*[13] have reported rejection of allografts of adult ganglionic neurones transplanted o the spinal cord, while Low *et al.*[14] found prolonged survival of embryonic brain tissue in the hippocampal region, grafted between rats of different strains. We report here long-lasting functional cross-species transplantation of mesencephalic DA neurones, taken from mouse embryos, to the dopaminergically denervated neostriatum of adult recipient rats.

Grafts were taken from the ventral mesencephalon (containing the developing substantia nigra–ventral tegmental area DA cell group) of 16–17-day-old mouse embryos (NMRI-strain, Anticimex, Stockholm). The recipients were 18 young adult female rats (Sprague–Dawley strain, Anticimex AB) subjected to a unilateral 6-hydroxydopamine (6-OHDA) lesion of the right nigrostriatal DA pathway 1 month before transplantation. The lesion was performed by local injection of 8 μg 6-OHDA-HCl (Hässle) into the nigrostriatal pathway[15]. The lesion of the nigrostriatal DA pathway was complete in all recipients as assessed by the intensity of the amphetamine-induced turning response. The criterion rate >6 full ipsilateral turns per min over 90 min in response to 5 mg per kg metamphetamine (intraperitoneally) has previously been shown to correspond to a permanent reduction of neostriatal DA of more than 97% (refs 3, 16). The rotation tests were made in automated rotometer bowls according to Ungerstedt and Arbuthnott[17]. The grafts were placed on the dorsal surface of the denervated neostriatum, within a cavity made by aspiration through the anterior parietal cortex and the corpus callosum, as described elsewhere[1,3]. Further rotation tests were conducted $1\frac{1}{2}$, $3\frac{1}{2}$ and $5\frac{1}{2}$ months after transplantation. Turning in response to a low dose of apomorphine (0.05 mg per kg, subcutaneously) was tested twice, at 4 and 5 months after transplantation. All animals were killed at 6 months after transplantation and the brains processed for catecholamine fluorescence histochemistry according to the ALFA method[18]. Alternate sections were stained with cresyl violet.

In 10 of the 18 rats the fluorescence histochemistry revealed surviving DA neurones and reinnervation of the denervated neostriatum. In the remaining 8 animals the transplantation cavities were empty (except for some connective tissue and residual Gelfoam remnants) and there was no trace of surviving DA neurones, suggesting that the grafts in these cases had been totally resorbed (Fig. 1*b*). In the 10 positive cases the actual transplant piece, within the cavity, had also been largely resorbed. The surviving DA-containing neurones occurred either in small, apparently non-vascularized cell clusters at the surface of the caudate-putamen, or scattered within the dorsal part of the caudate-putamen (Fig. 1*a*). These DA neurones were mostly small and rounded, and exhibited a DA fluorescence of widely varying intensity. The cresyl violet stain suggested the presence also of some non-DA neurones in the cell clusters, but there were no obvious signs of lymphocytic infiltration within these clusters, or within the caudate-putamen of the host.

The most striking microscopic finding was the newly formed DA-fluorescent terminal network within the caudate-putamen of the positive cases. In 8 of the 10 specimens this reinnervation was rich and covered large areas of the head of the host caudate-putamen (Fig. 1*a*). In several cases the DA fibres occurred in patches which were seemingly derived from single DA-containing cell bodies in their vicinity. In two of the positive cases the ingrowth of DA fibres was poor and confined to a few small patches close to the transplantation cavity.

For behavioural analysis the rats were allocated in a blind manner to one of three groups: rich ingrowth, poor ingrowth or no ingrowth. The amphetamine and apomorphine rotation tests revealed a striking relationship between graft ingrowth and compensation of the turning response in the lesioned rats (Fig. 2). Thus, whereas the rats with no DA neurone survival (open circles in Fig. 2*a*) increased their amphetamine-induced turning response, from an average of 8.1 turns per min before grafting, to an average of 15 turns per min by $5\frac{1}{2}$ months, the rats with DA neurone survival and rich ingrowth into the caudate-putamen (filled circles in Fig. 2*a*) reduced their turning response from 9.6 turns per min to 1.0 turns per min. The compensation of the turning response developed over the first $3\frac{1}{2}$ months and remained stable between $3\frac{1}{2}$ and $5\frac{1}{2}$ months after transplantation. Both the magnitude and the time course of compensation of the turning response in the xenografted animals are very similar to those previously observed in rats with homologous nigral grafts[3]. In the rats with poor DA ingrowth into the caudate-putamen, the compensation of the amphetamine-induced turning followed a different time course and became evident only between $3\frac{1}{2}$ and $5\frac{1}{2}$ months after transplantation (open triangles in Fig. 2*a*). The differences between the groups are statistically significant (Fig. 2).

The contralateral turning response to a low dose of the DA receptor agonist, apomorphine (0.05 mg per kg), which can be taken as a measure of the degree of DA receptor supersensitivity in the denervated neostriatum[19], was on the average reduced by 65–75% in the richly reinnervated rats compared with the rats with no or poor DA ingrowth (Fig. 2*b*). This reduction is statistically significant and similar to that previously recorded from rats with homologous grafts[5].

The present results demonstrate that long-term survival of cross-species grafts of embryonic DA neurones can be achieved in the adult rat CNS in the absence of any immunosuppressive treatment. It is interesting that the surviving DA neurones were found on the surface and in the depth of the host caudate-putamen, whereas the bulk of the discrete transplant had been almost totally resorbed. This suggests that the migratory capacity of the embryonic neurones or neuroblasts in the graft is of critical importance for their ability to escape rejection. Although a blood–brain barrier is known to develop within grafts of embryonic CNS tissue, it is likely that it is established by vessels derived from the graft itself rather than from the host[20,21]. Thus, if the blood–brain barrier is important for long-term survival of immunologically imcompatible grafts in the CNS, our results would support the idea that grafted neurones can escape rejection by migration into the protected environment behind the barrier of the host. This would also explain the ability of the xenogeneic DA neurones to reinnervate and establish a new, long-lasting terminal network within the host caudate-putamen.

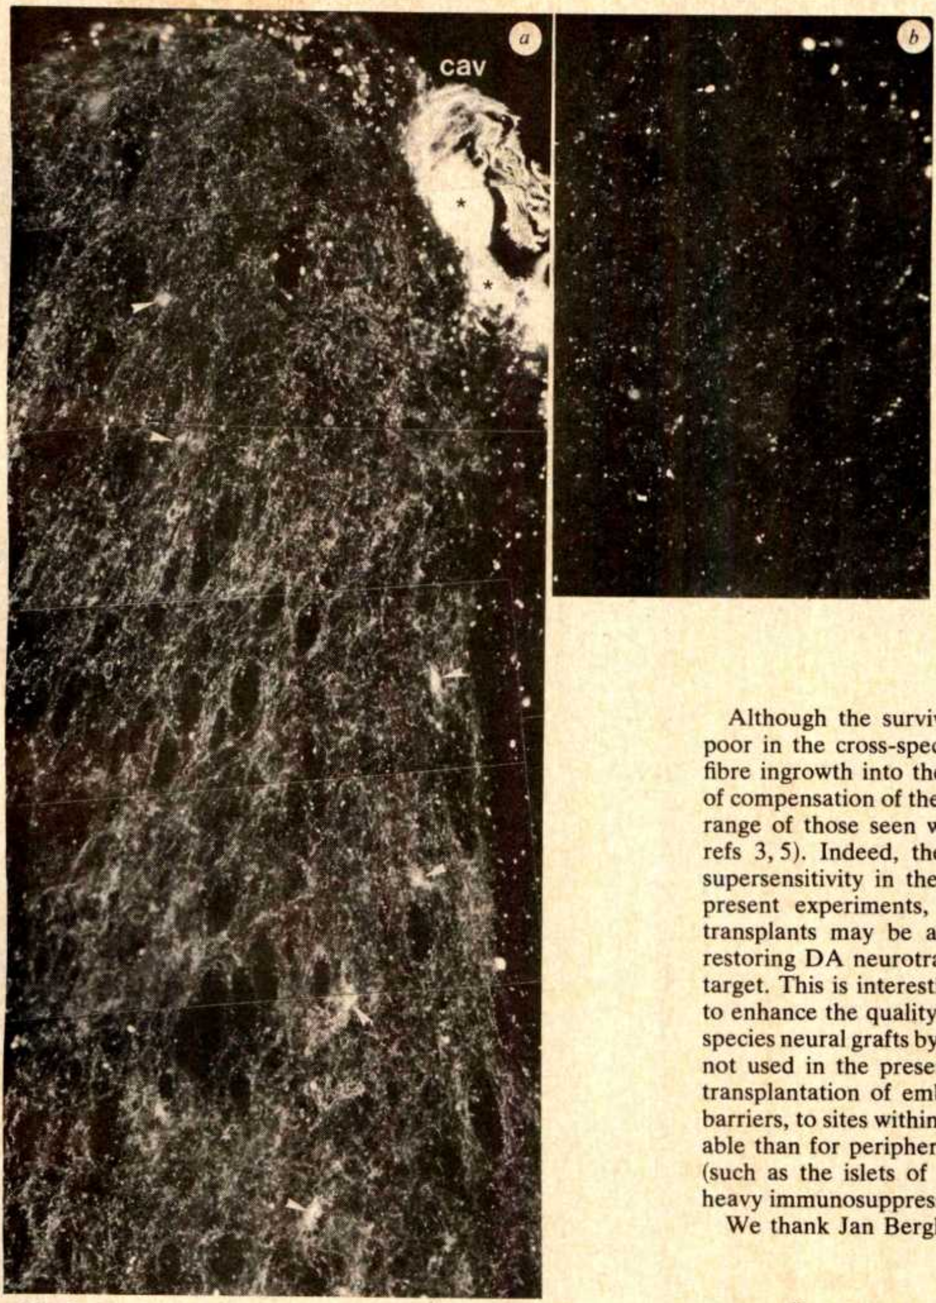

Fig. 1 The dorsal part of the caudate-putamen: *a*, in a case with surviving grafted DA neurones and a rich dopaminergic reinnervation of the dorsal caudate-putamen, and *b*, in a case with no surviving graft and a persisting total dopaminergic denervation of the caudate-putamen. Both rats were killed 6 months after transplantation. Asterisks in *a* denote clusters of intensely fluorescent DA-containing neurones at the bottom of the transplantation cavity (cav). Some fluorescent DA-containing cells within the caudate-putamen of the host are marked with arrow heads. (×160.)

Although the survival of the discrete grafts was generally poor in the cross-species experiments, the magnitude of DA fibre ingrowth into the host caudate-putamen and the degree of compensation of the turning asymmetry were well within the range of those seen with homologous nigral grafts (compare refs 3, 5). Indeed, the degree of reduction in DA receptor supersensitivity in the reinnervated neostriatum, seen in the present experiments, suggests that the cross-species nigral transplants may be as effective as the homotypic grafts in restoring DA neurotransmission in the previously denervated target. This is interesting not least because it may be possible to enhance the quality and magnitude of survival of the cross-species neural grafts by applying immunosuppressive treatment, not used in the present study. The conditions for functional transplantation of embryonic neurones across immunological barriers, to sites within the brain, thus seem to be more favourable than for peripheral grafts of neurones or endocrine cells (such as the islets of Langerhans) which are rejected unless heavy immunosuppressive treatments are applied[8,9,22–24].

We thank Jan Berglund, Ulla Jarl and Gertrude Stridsberg

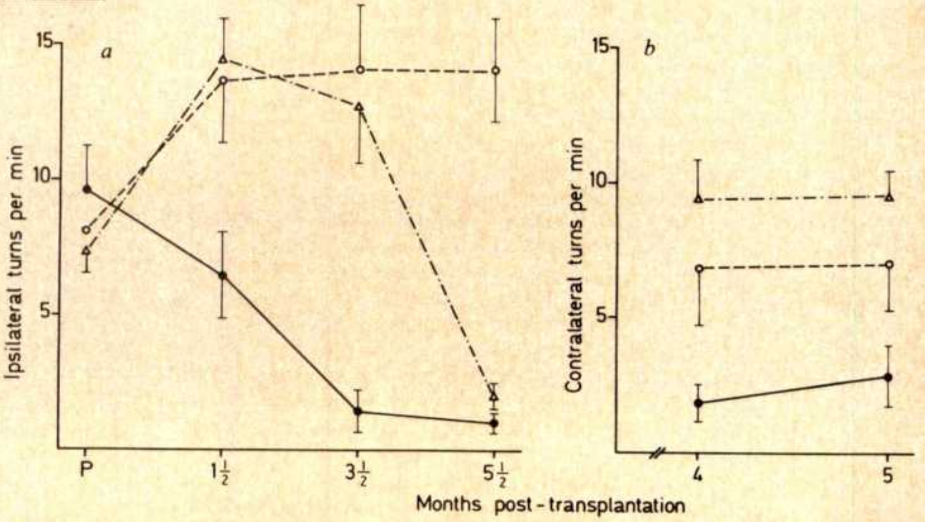

Fig. 2 Drug-induced rotation in rats with unilateral 6-OHDA lesions of the nigrostriatal pathway, followed 1 month later by grafts of DA-rich embryonic mouse mesencephalon to the neostriatum on the same side as the initial lesion. Rats were allocated to three groups on the basis of subsequent blind histological analysis: ∘- - -∘, no detectable surviving fluorescent DA cells or fibre ingrowth ($n = 8$); △- · -· △, poor fibre ingrowth in small patches in the host rat caudate-putamen ($n = 2$); •—•, rich surviving fluorescent fibre ingrowth in dorsal portions of the host caudate-putamen ($n = 8$). Values plotted are means ±s.e.m. *a*, Ipsilateral rotation over 90 min following intraperitoneal injection of 5.0 mg per kg metamphetamine, before (*P*) and at regular intervals following transplantation. Difference between groups: $F(2, 15) = 10.59$, $P < 0.01$; group × time interaction: $F(6, 45) = 9.41$, $P < 0.01$. *b*, Contralateral rotation over 40 min following subcutaneous (s.c.) injection of 0.05 mg per kg apomorphine, 4 and 5 months following transplantation. Difference between groups: $F(2, 15) = 3.97$, $P < 0.05$; group × time interaction: $F(6, 45) = 0.23$, not significant.

Association amacrine cells could mediate directional selectivity in pigeon retina

Andrew P. Mariani

Laboratory of Vision Research, National Eye Institute,
National Institutes of Health, Bethesda, Maryland 20205, USA

Ganglion cell receptive fields in the vertebrate retina are classified as 'simple' if they display mutually antagonistic, concentric on and off responses to stimulation by light[1], or 'complex' if they respond maximally to a stimulus which moves in a certain direction or has a particular orientation[2]. One complex unit frequently reported is directionally selective[3–6]. It is excited by stimuli moving through its receptive field in only one direction, the preferred direction, and is inhibited by motion in the reverse or null direction. In species such as cats and monkeys which have a predominantly simple centre-surround organization of ganglion cell receptive fields, there is a low ratio of conventional (amacrine cell) to ribbon (bipolar cell) synapses in the inner plexiform layer, while in species such as pigeons and frogs which have a large percentage of complex ganglion cell receptive fields, there is a high ratio of conventional to ribbon synapses. It is therefore thought that amacrine cells, which are laterally interconnecting neurones in the inner plexiform layer, form the complex ganglion cell receptive field[7,8]. Although quantitative electron microscopy of the inner plexiform layer has indicated that amacrine cells may form the complex receptive field properties of ganglion cells, it offers no clues to the particular morphology of amacrine cells involved. I have therefore now studied amacrine cells in pigeon retina using Golgi impregnation in both whole-mounted and radially sectioned material to see whether there is a correlation between the morphology of amacrine cells and the receptive fields of ganglion cells. In 30 Golgi-impregnated retinas, I have found many different morphological types of amacrine cell. One of these is so clearly different from all other amacrine cells that it requires the separation of pigeon amacrine cells into two distinct classes, those which lack axons (class I cells) and those which have axons (class II cells).

Class I amacrine cells have dendrites radially organized with respect to their cell bodies when viewed in flat preparations (Fig. 1*b–e*). The cells have diverse morphology, and may include cells with dendritic trees which are multiply stratified, but which nevertheless display a radial symmetry when viewed in flat preparations. In comparison class II amacrine cells of the pigeon retina are not radially organized. In addition to their dendritic processes, they have a short axon with a terminal arborization in the same stratum of the inner plexiform layer as their dendrites. These cells were first described by Cajal[9] in another avian species, and he termed them 'association' amacrines, but their presence has not been reported since that time[10]. They differ from 'ordinary' amacrines (class I cells) as they clearly have an axon.

In the 30 Golgi preparations of the pigeon retina, the association amacrine cells are frequently stained: over a 100 may be found in a single retina, but only 5 have been stained completely through their axon terminal arborization.

Association amacrine cells (Fig. 1*a*) have 13 μm diameter cell bodies, which makes them larger than all other amacrines (6–10 μm), and are situated in the innermost part of the inner nuclear layer where they are exceeded in size only by the Dogiel (displaced ganglion) cells. Four or five dendrites about 2 μm thick arise from the vitreal part of the cell body and branch once or twice. Large 3–4 μm spiny varicosities occur on the dendrites near branch points, and the dendrites then taper to very fine processes and terminate in the outermost stratum of the inner plexiform layer, with a total length of no more than 35 μm. An axon of 1.5 μm diameter arises directly from the cell body or one of the dendrites and courses just beneath the inner nuclear layer for 200–700 μm. Collaterals may arise from the axon, but two axons are rarely observed; if the two axons do exist, both follow the same course. At its terminal arborization in the outermost stratum of the inner plexiform layer the axon thins to 0.5 μm, bears many 1–2 μm terminal and preterminal boutons and spans up to 200 μm. The axons of different cells appear to be non-preferentially oriented: those arising from nearby cells may cross each other at various angles. The association amacrine cells, due to their morphological polarization, might be involved in the organization of directionally selective receptive fields of ganglion cells in pigeon retina.

Directionally selective units in the pigeon retina respond to movement through their receptive fields in the preferred direction with a vigorous discharge of spikes[4,5]. There is virtually no response to a moving stimulus in the opposite or null direction[3] and a small response to a stationary stimulus over the receptive field[4]. The null directional movements, which are inhibitory and determine the null-preferred axes, are oriented in many directions so that different directionally selective units may have different null-preferred axes[6]. Other evidence[3] indicates that there is an inhibitory patch offset from the receptive field centre which determines the null direction, and when examined at this offset patch, the receptive field is non-directional as it is inhibited by moving stimuli in both the null-preferred and orthogonal axes. Similarly, the field centre is non-directional when examined at the preferred side since it may be activated by preferred, null and orthogonal movements[3].

Association amacrine cells could be the anatomical basis for the directionally selective responses recorded in the pigeon retina. Their having an axon which separates morphologically distinct parts of the cell is clearly consistent with a physiological

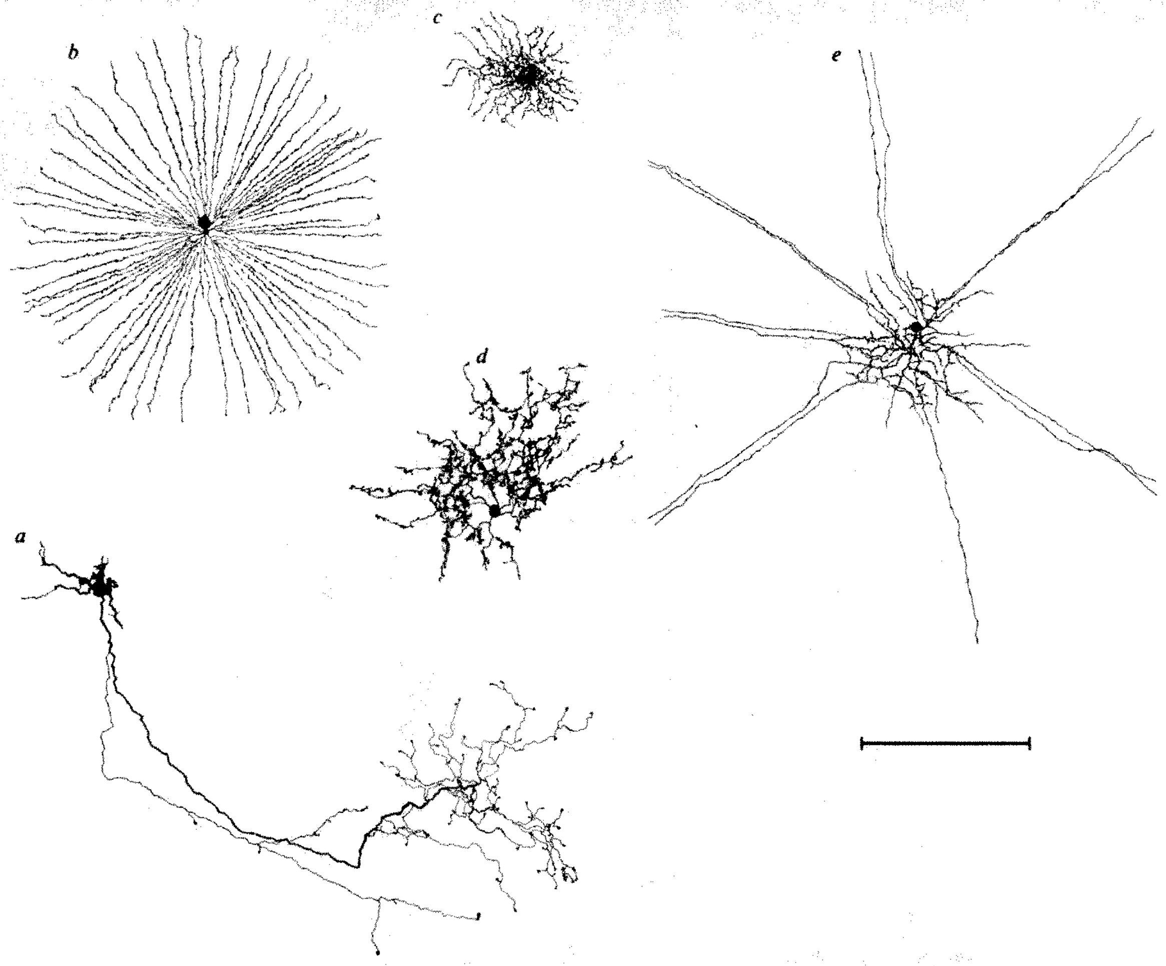

Fig. 1 Camera lucida drawings of Golgi-impregnated amacrine cells in whole, flat-mounted pigeon retina. 'Ordinary' amacrine cells (*b-e*) lack an axon and their dendrites display radial symmetry. 'Association' amacrine cells (*a*) clearly have an intraretinal axon which separates the dendritic end and the axon terminal arborization, and thus are morphologically polarized. This morphological polarization could mediate directional selectivity in pigeon retina. Bar, 100 μm.

concept of asymmetric lateral inhibition extending in only one direction which determines the null-preferred axis[11]. Like different directionally selective units, the axons of association amacrines have different orientations. The axon terminal arborization could be located over the receptive field centre of the ganglion cell. The soma and dendrites of the cell are then offset from the field centre, and activation of the association amacrine by motion in the null direction as a patch offset from the field centre could inhibit the ganglion cell. Thus motion in the preferred direction could excite the ganglion cell. This model can account for the non-directionality of responses at the receptive field centre and the non-directionality of inhibition which appears to be offset from the receptive field centre and determines the null direction[3].

Glycine receptor alteration in the mutant mouse *spastic*

W. F. White* & A. H. Heller†

Department of Neuroscience, Children's Hospital Medical Center
and Departments of *Neuropathology and †Neurology,
Harvard Medical School, Boston, Massachusetts 02115, USA

The mutant mouse *spastic*, which carries a single-locus, recessive mutation[1] on chromosome 3 (refs 2, 3), is characterized by hyperexcitability, rapid tremor, rigidity and prolonged righting reflexes[1]. No anatomical abnormalities have been found in preliminary histological studies of muscle or the central nervous system (CNS)[1]. Electromyographic studies in *spastic* mice demonstrate abnormal electrical bursts during activity and abnormal stereotyped reflexes[4]. Drugs which increase γ-aminobutyric acid (GABA)[5] or enhance GABA synaptic action[6] reduce *spastic* symptoms, suggesting that they result from an imbalance in excitatory and inhibitory influences in the *spastic* CNS. Strychnine antagonizes the synaptic action of glycine[7], and binds to a membrane site with the characteristics of the postsynaptic glycine receptor[8–11]. The behavioural and electrophysiological abnormalities of *spastic* mice are reproduced in normal mice given subconvulsive doses of strychnine[4], suggesting that *spastic* symptoms might result from a deficiency in glycine-mediated inhibition[4]. We describe here evidence that supports this hypothesis: a decrease in ^{3}H-strychnine binding in membrane fractions prepared from *spastic* compared with littermate control mice. We also demonstrate an involvement of the benzodiazepine, and possibly the GABA, binding site in the *spastic* phenotype.

0028-0836/82/320655—03$01.00

Adult mice of both sexes were produced on site from matings between B6C3-a/a-*spa*/+ hybrids (Jackson Laboratory) and homozygous *spa* mice (*spa*/*spa*) were identified by tremor and difficulty in regaining upright posture when turned on their backs. Unaffected littermates (+/?) of the same sex were used as controls in all studies. *Spastic* mutants are significantly smaller than control animals: a sample of adult *spastic* animals ($n = 7$) weighed 81.7±4.4% (mean±s.e.m.) of their littermate controls and the *spa*/*spa* brain regions (spinal cord, brain stem, midbrain and cortex) weighed an average of 88.4±8.4% of comparable +/? regions. There were no significant differences among the *spastic* to control weight ratios for the individual regions.

The binding of ^{3}H-strychnine in *spa*/*spa* and +/? animals is presented in Table 1. In all regions tested, specific ^{3}H-strychnine binding is reduced in *spa*/*spa* compared with +/?. The low level of binding seen in the *spastic* CNS makes accurate quantification difficult.

Because only a small amount of ^{3}H-strychnine binding in *spastic* animals is specific, we used several methods for determining nonspecific binding: excess glycine (10 mM) (Table 1), excess strychnine (100 μM), or heat inactivation (80 °C for 30 min) (data not shown). We find that ^{3}H-strychnine binding is <20% of control in the *spastic* spinal cord, brain stem and midbrain, using any of the measures of nonspecific binding, and <35% of control in cortex using excess glycine to determine nonspecific binding; neither the excess strychnine nor the heat inactivation methods for determining nonspecific binding yielded any specific binding in cortex.

Very different results are obtained in binding studies of the GABA, benzodiazepine and muscarinic acetylcholine receptors (Table 2). Generally, there is more specific ^{3}H-GABA binding in the spinal cord and brain stem of *spastic* compared with control animals. However, because of the low level of specific ^{3}H-GABA binding (10–20%) in these two brain regions, the results were relatively more variable, and the observed difference was not statistically significant ($P > 0.05$). Specific binding of ^{3}H-flunitrazepam is 40% greater in the spinal cord, and 17% greater in the brain stem of *spastic* compared with control animals ($P < 0.05$, both regions); again there are no differences in the midbrain and cortex. These increases in binding to the benzodiazepine binding site and potentially to the GABA binding site are consistent with preliminary studies using ^{3}H-flunitrazepam and ^{3}H-muscimol as ligands for the benzodiazepine and GABA binding sites[12]. In contrast, there are no significant differences in the binding of ^{3}H-QNB (quinuclidinyl benzilate) in any of the regions investigated. The magnitude and regional distribution of the binding of all four ligands in control animals are similar to published values for rodent brain[8,13–15].

Table 1 Specific binding of ^{3}H-strychnine to the CNS of *spastic* and littermate control mice

Region	Genotype	% Specific binding	pmol per mg protein	% Of paired littermate control
Spinal cord	+/?	68	1.26±0.08	
	spa/*spa*	29	0.22±0.06*	16±4*
Brain stem	+/?	87	1.79±0.11	
	spa/*spa*	45	0.34±0.04*	19±2*
Midbrain	+/?	60	0.60±0.04	
	spa/*spa*	28	0.086±0.031*	14±5*
Cortex	+/?	23	0.14±0.02	
	spa/*spa*	5	0.047±0.009*	34±6*

Mice were decapitated and the brains and spinal cords rapidly dissected, weighed, homogenized in a glass–glass homogenizer in ice-cold 200 mM KCl, 50 mM NaKHPO$_4$, pH 7.1, and centrifuged at 100,000*g* for 20 min. The pellet was then washed four times by replacing the supernatant with fresh buffer, sonicating to disperse the pellet and recentrifuging. The final pellet was resuspended at a concentration of 5 mg (original wet wt) per ml for use in the binding assays. In ^{3}H-strychnine binding studies, 500 μl of tissue were added to microcentrifuge tubes (Biorad) containing 500 μl of buffer and 12 nM ^{3}H-strychnine. Nonspecific binding was determined in parallel incubations containing excess glycine (10 mM). Following a 20 min incubation at 4 °C the samples were centrifuged for 10 min in an Eppendorf microcentrifuge. The supernatant was carefully removed and the pellet washed twice with 1 ml of buffer. The pellet was solubilized overnight in 1 ml 1% SDS, 20 mM EDTA, adjusted to pH 8.5 with NaOH, and counted in a Triton X-100, toluene, Omnifluor liquid scintillation cocktail. Parallel studies of ^{3}H-strychnine binding using excess strychnine (100 μM) and heat inactivation (80 °C for 30 min) to determine nonspecific binding values were also performed (data not shown). A small amount of ^{3}H-strychnine was displaced from the assay tube by 100 μM strychnine. Thus, when excess strychnine was used to determine nonspecific binding, nonspecific binding equalled the binding in the presence of excess strychnine plus the binding displaced from the tube. The ^{3}H-strychnine (19.3 Ci mmol^{-1}) was purchased from Amersham. All experiments on a given sample were performed at least in triplicate and samples were obtained from at least four pairs of animals. Specific binding equals total binding minus nonspecific binding. Per cent specific binding equals specific binding divided by total binding times 100. Proteins were assayed by the method of Bradford[25]. Values are the mean±s.e.m. and all values reported are significantly different from 0. Percentage values are the mean±s.e.m. of the percentages derived from comparisons between littermate pairs.

* *Spastic* animals differ from paired littermate control (+/?) at $P \leq 0.05$; Student's *t*-test for paired observations; two-tailed.

Table 2 Specific binding of ^{3}H-GABA, ^{3}H-flunitrazepam and ^{3}H-QNB to the CNS of *spastic* and littermate control mice

A centrifugation assay similar to that used for the strychnine binding assays was used for the GABA binding studies. The tissues used in the GABA binding assay were prepared in Tris-citrate buffer (4 °C, pH 7.1) by washing four times followed by three freeze–thaw–wash cycles. The equivalent of 10 mg of tissue (original wet weight) in 1 ml was used in each tube. The ^{3}H-GABA concentration was 30 nM, and 1 mM GABA was used to determine nonspecific binding. A 10 min centrifugation followed the 10 min incubation. Pellets were washed twice with 1 ml ice-cold Tris-citrate (pH 7.1), solubilized and counted. The binding of both ^{3}H-flunitrazepam and ^{3}H-QNB was investigated using a filtration assay. Briefly, 500 μl of the same tissue suspension used for the strychnine binding studies were added to 500 μl of buffer containing either ^{3}H-flunitrazepam (1 nM) or ^{3}H-QNB (1 nM). Clonazepam (1 μM) or atropine (1 μM) were added to parallel incubations to determine nonspecific binding. Following a 1 h incubation (4 °C flunitrazepam, 24 °C QNB) the bound radioactivity was collected on a 24 mm glass fibre filter (Whatman GF-B) and washed three times with 5 ml of ice-cold 200 mM KCl buffered to pH 7.1 with 50 mM NaKHPO$_4$. The filters were air-dried and counted in liquid scintillation cocktail. The ^{3}H-GABA (34.3 Ci mmol^{-1}), ^{3}H-flunitrazepam (86.4 Ci mmol^{-1}) and ^{3}H-QNB (29.1 Ci mmol^{-1}) were from NEN. See Table 1 legend for further details.

The alterations in the binding of ligands for several neurotransmitters in *spa*/*spa* mice is very provocative. The very low binding of ^{3}H-strychnine in the *spa*/*spa* CNS demonstrates an alteration in the receptor for glycine, the major inhibitory neurotransmitter in spinal cord and brain stem, and a significant inhibitory neurotransmitter in midbrain[7]. This alteration might be expected to decrease the efficacy of glycine-mediated inhibition in these brain areas. On the other hand, the trend towards greater binding of ^{3}H-GABA to the GABA receptor and the greater binding of ^{3}H-flunitrazepam to the benzodiazepine binding site (which is believed to modulate the GABA receptor[16]) in the spinal cord and brain stem would potentially increase the efficacy of inhibition mediated by GABA, the other major inhibitory neurotransmitter in these brain areas[7]. It is tempting to speculate that this alteration in the GABA-benzodiazepine system represents a compensatory response to the decrease in glycine-mediated inhibition. The ability of drugs that enhance GABA-mediated inhibition to reduce the severity of the behavioural[5] and electromyographic[6] symptoms of the *spastic* mutant mouse is consistent with this hypothesis. The localization of the increase in GABA and benzodiazepine binding to the spinal cord and brain stem may result from an inability of the normal GABAergic tone to regulate neuronal excitability in these regions when their normal preponderance of glycine-mediated inhibition is reduced. The absence of this effect in the midbrain and cortex may result from the secondary role of glycine-mediated inhibition in these brain areas and thus the availability of sufficient GABAergic tone to control neuronal excitability. The lack of any difference in the binding of ^{3}H-QNB to the muscarinic acetylcholine receptor in any of the brain regions tested indicates specificity in the alterations produced by the spastic mutation.

Alterations in neurotransmitter receptors have been reported for other murine mutants, and have been attributed to morphological changes in the mutant animal. Both *nervous* and *staggerer* mice, mutants which have a reduced number of Purkinje cells and lack synaptic spines on Purkinje cells respectively, have fewer benzodiazepine binding sites in cerebellum than controls[17-20]. The opposite situation—a greater number of cerebellar benzodiazepine binding sites—has been reported for *weaver* and *reeler* mice, mutants having a reduced number of cerebellar granule cells[17,20]. Fewer GABA receptors have also been reported for all these cerebellar mutants[20,21].

Unlike the cerebellar mutants, the *spastic* mutant shows no obvious anatomical abnormalities in either nervous system or musculature in preliminary histological studies[1]. In addition, the widespread distribution of binding sites for GABA, benzodiazepines and strychnine in the spinal cord, brain stem and midbrain[22-24] makes it seem improbable that the alterations could result from an anatomical abnormality. These preliminary anatomical studies must, however, be confirmed by further, more detailed investigations on the morphological organization of the *spastic* CNS, and in particular of proposed glycinergic and GABAergic inhibitory systems in the affected areas.

These results, together with those from electromyographic studies[4], indicate an alteration in the glycine system in the *spa/spa* mouse which is the probable explanation of the behavioural and electromyographic abnormalities in these mice. They also demonstrate an involvement of the benzodiazepine binding site, and possibly the GABA binding site, in the expression of the *spastic* mutation. The molecular basis of the mutation in the *spastic* mouse which produces these observed alterations in the receptors for neurotransmitters mediating CNS inhibition is unknown. The mutation may result in a direct alteration in one of the receptors, in a component directly associated with one of the receptors, or in some other aspect of one of the affected neurotransmitter systems. On the other hand, the observed effects may be only a few of many widespread secondary effects produced by the mutation. A more complete characterization of both the glycine and GABA-benzodiazepine inhibitory systems in *spa/spa*, proven heterozygous and +/+ animals will further clarify the relationship between these systems and the mutation, and may elucidate the nature of the mutation. The *spastic* mutant mouse should be a valuable system for future investigations on the characteristics of CNS inhibition.

We thank Drs Marc Dichter and Tom Fox for criticism of the manuscript. These studies were supported by NIH grants NS06274, NS00623, NS11237, and the Children's Hospital Mental Retardation Center core grant HD 06276.

Immunocytochemical techniques have increased our ability to identify neurones containing a specific neurotransmitter. These techniques could not, however, be applied to two major neurotransmitter candidates, aspartate and glutamate, until our recent study in which aspartate aminotransferase (L-aspartate:2-oxoglutarate aminotransferase, EC 2.6.1.1, AATase) was proposed as a marker[1]. This enzyme catalyses the reversible reactions of aspartate to oxaloacetate and α-ketoglutarate to glutamate. In the auditory nerve, which is considered to be aspartergic/glutamergic[2-4], AATase was immunocytochemically localized in primary afferent terminals in the cochlear nucleus[1]. These results suggest a presynaptic enrichment of AATase is associated with aspartergic/glutamergic neurotransmitter function. We have now investigated the distribution of AAT-ase-like immunoreactivity in the retina where previous work suggests that glutamate or aspartate is the neurotransmitter of photoreceptors[5-14]. Our results, reported here, show AATase-like immunoreactivity localized in cones and their terminals in the guinea pig retina.

We used 12 female NIH strain guinea pigs, 150–250 g, in this study. Six guinea pigs were pretreated with colchicine: 10 μg in 5 μl were injected into the vitreous of the left eye 24–48 h before perfusion in guinea pigs under ether anaesthesia. Guinea pigs were anaesthetized with chloral hydrate (0.3 g per kg body weight) and perfused through the heart with 25 ml 0.1 M sodium cacodylate buffer followed by 500 ml of fixative containing 4% paraformaldehyde (w/v) in 0.1 M sodium cacodylate buffer, *p*H 7.2 at 4 °C. In some animals, 50 μl of the fixative were injected intravitreally immediately before vascular perfusion. Retinae from both eyes were placed in the same fixative for 1 h on ice and then rinsed in phosphate-buffered saline (PBS) *p*H 7.2, with 6% (w/v) sucrose at 4 °C for 16–48 h. Ten-μm cryostat sections were cut through the central and peripheral retina and the indirect immunofluorescence technique of Coons[15], modified as described previously[1], was applied using antiserum, raised in rabbits, to cytoplasmic AATase[1]. Sections were incubated for 18 h at 4 °C with antiserum diluted 1:400 in PBS with 0.3% Triton X-100. Absorption controls were prepared by adding 20 μg of AATase (Boehringer Mannheim) to 10 μl of antiserum and were used at a 1:400 dilution on adjacent sections as a control for specificity of staining. The second incubation was carried out with fluorescein-labelled swine antiserum to rabbit immunoglobulin (Bio-Rad) diluted 1:10, for 30 min at 37 °C. Sections were viewed with a Zeiss photomicroscope under epifluorescent illumination.

In the retinae of animals without colchicine pretreatment, a band of AATase-like immunofluorescence was seen in the outer plexiform layer (OPL; Fig. 1*a*). In absorption controls, as in the AATase-immunostained preparations, the inner segments of photoreceptors fluoresced non specifically. This was the only fluorescence seen in the retina on absorption control sections (Fig. 1*b*). Colchicine has often been used to concentrate particular antigens in cell bodies[16] and we therefore used colchicine to determine the source of the band of immunoflourescence in the OPL. In retinae pertreated with colchicine, this band could more easily be resolved into individual swellings (Fig. 2*c*). AATase-like immunofluorescence also was seen in cell bodies, in the outer portion of the outer nuclear layer (ONL), giving rise to thin processes ending in large swellings in the OPL (Fig. 2*c*,*d*). This is consistent with the morphological critera of cones and cone pedicles[17].

In retinae with and without colchicine pretreatment, AATase-like immunoreactivity was often seen in a subpopulation of cells along the innermost margin of the inner nuclear layer (INL; Fig. 2*a*–*c*) and in a laminar pattern in the inner plexiform layer (IPL; Figs 1*a*, 2*a*–*d*). These are likely to be a subpopulation of amacrine cells and their fibres.

Immunoreactive cells were also seen in the ganglion cell layer (GCL; Fig. 2*a*), though much less frequently than cells in the IPL. These were easiest to identify in retina prefixed intravitreally due to the better preservation of the ganglion layers. The immunoreactive cells in the GCL might be displaced amacrine cells or may correspond to the class of ganglion cells in which selective uptake of tritiated D-aspartate has been described[11,18].

Several lines of evidence have suggested that aspartate and/or glutamate is a vertebrate photoreceptor transmitter. Physiological studies have shown that glutamate and aspartate mimic the effects of the natural photoreceptor on horizontal and bipolar cells[5-9] and these effects can be eliminated by excitatory amino acid inhibitors[9,10]. Recently Ehinger[11] has demonstrated uptake of D-aspartate into photoreceptors, probably cones, in guinea pig, rabbit and pigeon. Uptake of aspartate and glutamate has also been shown in goldfish photoreceptors[12] where both amino acids were found to be concentrated in red and green cones while only glutamate was concentrated in rods. In rabbit retina, aspartate release has been found to decrease in response to light as would be expected of the natural photoreceptor[13]. Our findings of AATase-like immunoreactivity in cones and cone pedicles provide further evidence that aspartate or glutamate is the neurotransmitter of cones. A recent study showing L-aspartate enhanced excitation of sustained ganglion cells in the cat[19,20] is consistent with our finding of AATase-like immunoreactivity in amacrine cels and suggests aspartate or glutamate as a transmitter for a class of amacrine cells. Ultrastructural immunocytochemical studies are in progress to determine whether AATase is enriched in rod terminals as well as cones and to characterize the immunoreactive cells and fibres in the INL and IPL.

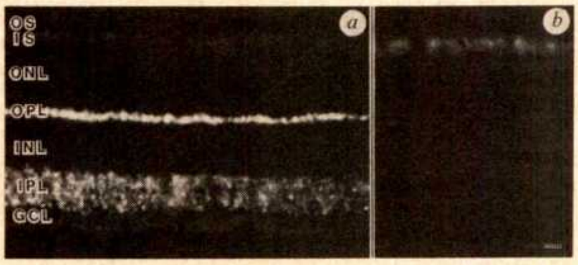

Fig. 1 Fluorescence micrographs of 10 μm cryostat sections of guinea pig retina incubated with antiserum to AATase (*a*) or to AATase preabsorbed with AATase (*b*). *a*, Section showing a band of AATase-like immunofluorescence in the outer plexiform layer and immunofluorescent fibres in the inner plexiform layer. *b*, Absorption control section showing nonspecific fluorescence in inner segments of photoreceptors. OS, outer segments; IS, inner segments; ONL, outer nuclear layer; OPL, outer plexiform layer; INL; inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar, 20 μm.

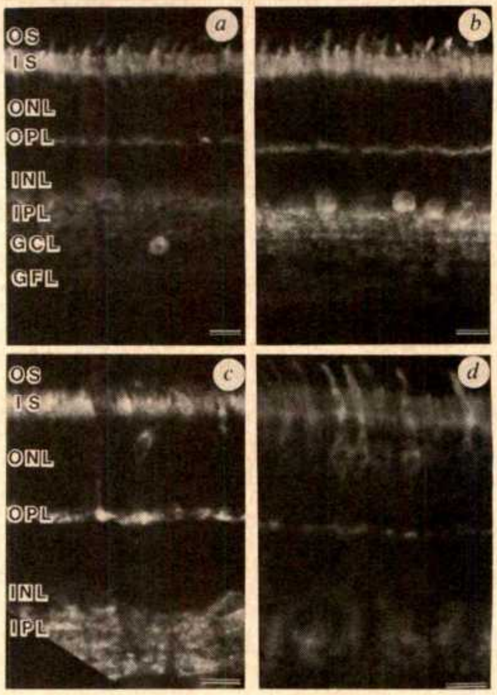

Fig. 2 Fluorescence micrographs of 10 μm cryostat sections of guinea pig retina incubated with antiserum to AATase. *a*, Section through central retina showing AATase-like immunoreactivity in the outer plexiform layer and immunofluorescent cells in the inner nuclear layer and ganglion cell layer. *b*, Section through central retina showing a band of AATase-like immunoreactivity in the outer plexiform layer, immunofluorescent cells in the inner nuclear layer and immunofluorescent fibres in the inner plexiform layer. *c*, Section through retina pretreated with colchicine as described in the text. AATase-like immunoreactivity can be seen in a cone cell body and a cone process and terminal, and immunofluorescent cell bodies and fibres in the inner nuclear and inner plexiform layers. *d*, Section through non-colchicine pretreated retina showing immunofluorescent cones and cone processes. OS, outer segments; IS, inner segments; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer; GFL, ganglion fibre layer. Scale bars, 20 μm.

The present results support our hypotheses that aspartate aminotransferase can serve as a marker for synapses using aspartate or glutamate as a neurotransmitter. While it is a ubiquitous enzyme, aspartate aminotransferase is enriched in terminals of cones where it may be involved in the specialized role of neurotransmitter synthesis.

We thank Drs John E. Dowling, Berndt Ehinger and Jörgen Fex for helpful comments and suggestions and Mary Lou Adams for secretarial assistance.

Origin of lignans in mammals and identification of a precursor from plants

M. Axelson*, J. Sjövall*, B. E. Gustafsson† & K. D. R. Setchell‡

* Department of Physiological Chemistry and † Department of Germfree Research, Karolinska Institutet, S-104 01 Stockholm, Sweden

Lignans are a class of compounds with a dibenzylbutane skeleton[1] which until recently had only been found in higher plants[2,3]. The first lignans to be identified in humans and animals were *trans*-2,3-*bis*(3-hydroxybenzyl)-γ-butyrolactone (enterolactone)[4–6] and 2,3-*bis*(3-hydroxybenzyl)butane-1,4-diol (enterodiol)[4,5]. These structures differ from those of plant lignans by having aromatic rings substituted only in the *meta* position. Enterolactone and enterodiol are excreted in the urine and bile, predominantly as glucuronide conjugates[7,8], and intestinal microflora is required for their formation[8,9]. It is not known, however, whether they are synthesized *de novo* by microorganisms or are formed from dietary precursors. We report here evidence that these mammalian lignans are formed by microbial action on precursor lignans which are present as dietary constituents of plant origin. Precursors are found in seeds of different species, being particularly abundant in linseed. From this source, 2,3-bis(3-methoxy-4-hydroxybenzyl)butane-1,4-diol (secoisolariciresinol) has been identified as a glycoside.

Evidence for dietary precursor(s) was first obtained by changing the diet given to adult rats from commercial pellets to a semisynthetic diet, D7 (ref. 10), which resulted in a marked and rapid decrease in the excretion of mammlian lignans in urine (Fig. 1). When the diet was reverted to commercial pellets, lignans reappeared in the urine.

The minimum concentration of lignan precursors in different food constituents was determined by adding the latter to the semisynthetic diet and measuring the total excretion of lignans in urine. In decreasing order, rye, buckwheat, millet, soya, oat and barley gave from 6 to 2 μg of lignans in urine per g of meal added. Wheat bran gave about 8 μg per g, wheat and corn meal gave less than 1 μg per g, while linseed was by far the richest source of precursor(s), giving about 800 μg per g of meal. The corresponding value for linseed oil was only 17 μg per g.

Preliminary experiments to isolate the precursor(s) from barley, rye, wheat bran and linseed revealed that the compound(s) were polar and could be extracted with 80% aqueous methanol and separated from fibre. After removal of salts and lipids and fractionation on a column of TEAP-LH-20 $[\mathrm{OH}^-]$[7], about 70% of the precursor(s) in linseed was found in the phenolic fraction. Further separation on DEAE-Sephadex[11] yielded more than 80% of the precursor(s) in the diphenolic fraction. Analytical TLC showed a major highly polar component. Mass spectra of the trimethylsilyl (TMS) ether derivative were recorded using a direct probe. Peaks at m/z 451, 361 (base peak), 319, 271, 243, 217 and 204 were indicative of a TMS ether of a hexoside[12]. An intense peak at m/z 209 suggested a benzyl group substituted with a methoxy and a trimethylsiloxy group[13]. This interpretation was supported by the mass spectrum of the perdeuterated TMS ether derivative. Hydrolysis with β-glucosidase (Emulsin, Sigma) yielded a compound the TMS ether of which had the same retention time on SE–30 (1.54 relative to 5α-cholestane) and OV–17 and the same mass spectrum as the TMS ether of a reference sample of secoisolariciresinol. The fragmentation of the latter compound has been discussed previously[13]. The TLC mobilities of the non-derivatized compounds were also identical. When the reference compound (300 μg) was added to the semisynthetic diet for 1 day, approximately 85 μg of lignans of the mammalian type, predominantly enterolactone, were excreted in the urine, confirming that secoisolariciresinol is the major precursor of enterolactone in rats given linseeds.

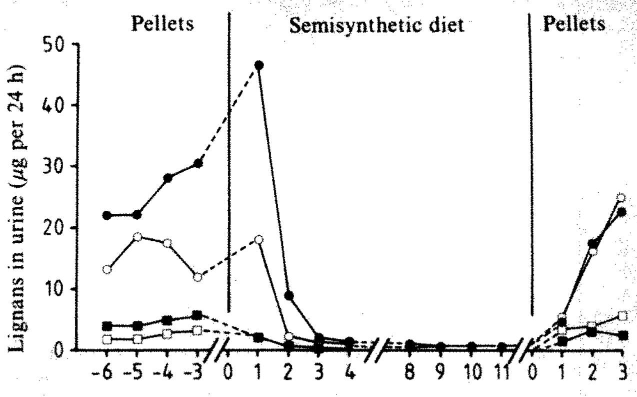

Fig. 1 Daily urinary excretion of enterolactone (circles) and enterodiol (squares) by two adult Long Evans rats (female, body weight 200 g) fed commercial pellets (Astra Ewos, Sweden) or a semisynthetic diet, D7 (ref. 10), composed of wheat starch, casein, arachis oil, salts and vitamins. Lignans were purified and measured by gas chromatography[7,8,11].

Extending these studies to man, the 'normal' diet of adults was supplemented with linseeds and the urinary excretion of enterolactone and enterodiol measured. The response to this diet was analogous to that observed in rats, indicating that the precursor–product relationships are similar in man and rats (Fig. 2).

Our results show that the precursor present in linseeds is a hexoside of 2,3-*bis*(2-methoxy-4-hydroxybenzyl)butane-1,4-diol. The tentative structure proposed in Fig. 3 is based on the previous finding of a diglucoside of a lignan in linseeds[14].

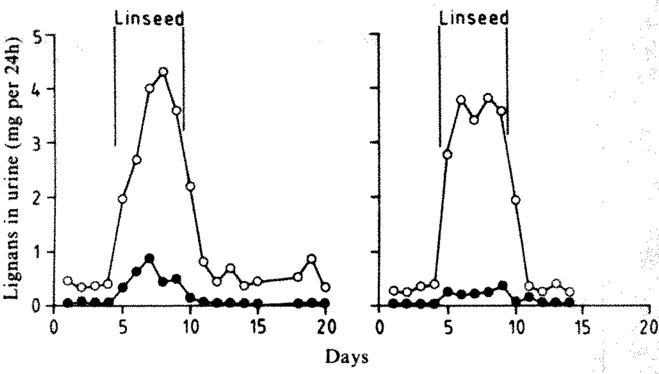

Fig. 2 Daily urinary excretion of enterolactone (○) and enterodiol (●) by two healthy adults before and after the addition of linseeds (10 g per day) to the normal diet over a period of 5 days.

0028–0836/82/320659—02$01.00

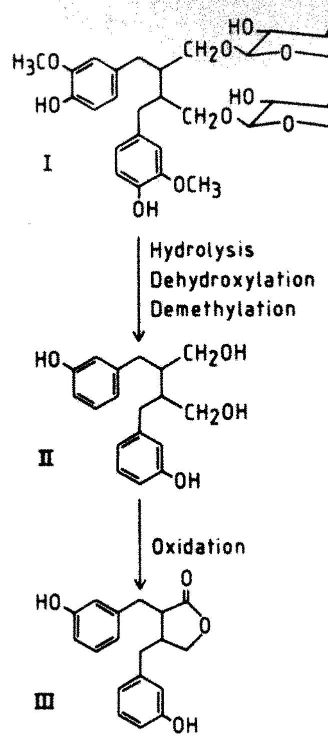

Fig. 3 A simplified scheme for the formation of enterodiol (II) and enterolactone (III) from the dietary precursor secoisolariciresinol glycoside (I). The structure of the sugar moiety is tentative and the exact sequence of reactions is not fully understood.

However, further studies are required to determine the number and position of hexose residues and the stereochemistry of the compound. Other precursors may also exist in plants. Thus, when rats were fed the more abundant plant lignan, matairesinol, enterolactone was excreted in the urine.

Conversion of secoisolariciresinol glycoside to enterodiol requires reactions depicted in Fig. 3. This type of reaction can be carried out by microbial enzymes[15,16]. Extensive formation of enterolactone from enterodiol was demonstrated by feeding 50 μg of the latter[17] to rats in a semisynthetic diet. Enterolactone was not detected when enterodiol was administered orally to germ-free rats, or injected intraperitoneally to bile fistula rats. This indicates that enterolactone can be formed from enterodiol by microbial action.

Lignans have been extensively investigated for their potential anticancer activity, and several have been used as chemotherapeutic agents[3,18]. It is therefore of interest that several common foodstuffs contain lignans. The compounds usually exist in optically pure form; however, enterolactone in human urine is racemic[4-6]. Whether this is due to its formation from precursors of different origin or to isomerization by exchange of a hydrogen vicinal to the carbonyl group of the lactone is unknown. The rate of formation of enterolactone and enterodiol is conceivably influenced by the composition of the microflora, the intestinal transit time and the redox level in the large intestine. Progesterone decreases intestinal motility[19], and this might explain the finding that the excretion of lignans in urine varies during the menstrual cycle[4,6,20,21].

We thank Ms B. Mörk, Mr M. Corrie and Ms E. Conway for technical assistance. Professors T. Norin and D. N. Kirk provided samples of matairesinol, which was reduced to secoisolariciresinol and synthetic enterolactone. Dr R. Ryhage provided mass spectrometric facilities. The work was supported by grants from the Swedish MRC (grants 03X-219 and 16X-206) and Karolinska Institutet.

Fibronectin in adhesion, spreading and cytoskeletal organization of cultured fibroblasts

I. Virtanen*, T. Vartio*†, R. A. Badley‡ & V.-P. Lehto*

Departments of Pathology* and Virology†, University of Helsinki,
Haartmaninkatu 3, SF-00290 Helsinki 29, Finland
‡ Unilever Research, Colworth Laboratory, Sharnbrook,
Bedford MK44 1LQ, UK

The pericellular glycoprotein fibronectin, which has been localized in the pericellular matrix and at the adhesion sites of cells[1-5], has been considered to be important in cell attachment to other cells and to surfaces[1-8]. Using the ionophore monensin, which blocks the secretion of endogenous fibronectin[9,10], we have now shown that human fibroblasts do not require endogenous or exogenous fibronectin for adhesion and spreading, although its absence does prevent formation of the microfilament–vinculin system and the focal adhesion sites.

The indirect immunofluorescence (IIF) technique was used to stain for the presence of fibronectin. Figure 1 shows that trypsinized human embryonal fibroblasts, which adhere to and spread on plastic Petri dishes after plating, develop a typically fuzzy fibronectin-containing plaque after 5 h (Fig. 1*a, b*) and a fibrillar extracellular network of fibronectin after 24 h in culture (Fig. 1*c, d*). No cell-surface-associated fibronectin could be detected on monensin-treated cells (Fig. 1*e, g*) which did, however, adhere and spread in the same way as control cells (Fig. 1*f, h*). Monensin-treated cells do stain for fibronectin in their cytoplasm (Fig. 1*j*), and treatment with the protein synthesis inhibitor puromycin, which causes the cytoplasmic staining of control cells to disappear (Fig. 2*e*), results in an accumulation of fibronectin in the Golgi apparatus (Fig. 2*f*).

The blockage of fibronectin secretion by monensin is further illustrated in Fig. 3, which shows the lack of a polypeptide of molecular weight (M_r) 220,000 (220 K) which corresponds to fibronectin[11], and is the major product in ^{35}S-methionine-labelled control cells, in monensin-treated cells. As shown in Fig. 3*b*, surface labelling of control cells, using the galactose oxidase/sodium borohydride technique[12], also shows up a 220 K polypeptide as a major glycoprotein, lacking in monensin-exposed cells. After 24 h in normal medium, monensin-treated cells recovered the characteristics of normal cells. The surface labelling results also draw attention to the role of cell membrane proteins in cell adhesion and spreading. Interestingly, recent studies have suggested distinct cell-surface glycoproteins[13-16] to be important in cell adhesion. A cell-surface glycoprotein of M_r 140 K could also be shown in this study to be a major cell-surface glycoprotein in cells plated and allowed to spread in the presence of monensin (Fig. 3*b*, asterisk). We have previously shown[14] that the 140 K glycoprotein is the

0028-0836/82/320660—04$01.00

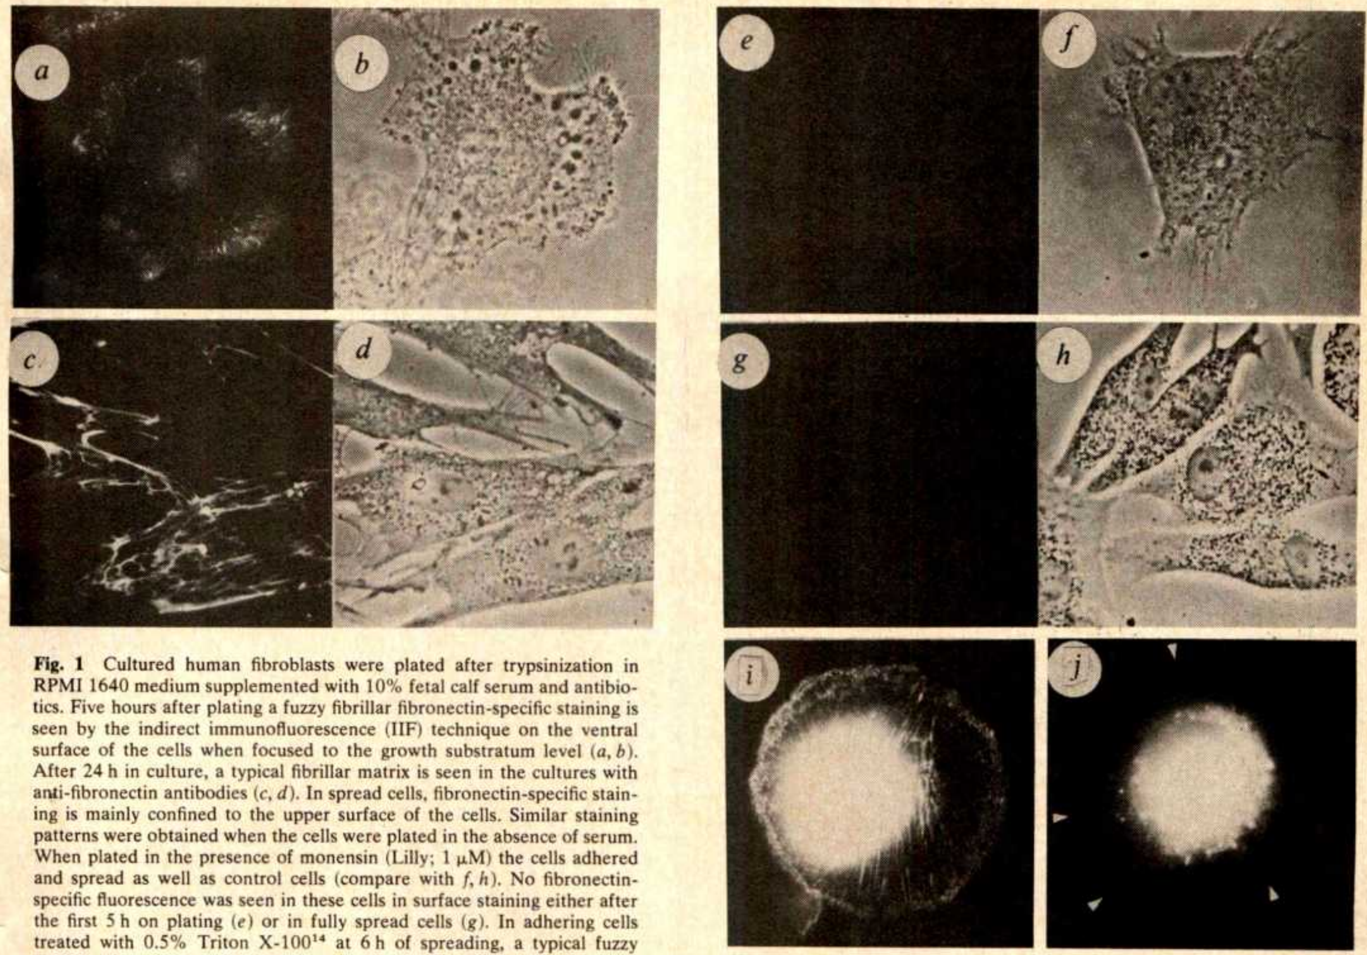

Fig. 1 Cultured human fibroblasts were plated after trypsinization in RPMI 1640 medium supplemented with 10% fetal calf serum and antibiotics. Five hours after plating a fuzzy fibrillar fibronectin-specific staining is seen by the indirect immunofluorescence (IIF) technique on the ventral surface of the cells when focused to the growth substratum level (*a*, *b*). After 24 h in culture, a typical fibrillar matrix is seen in the cultures with anti-fibronectin antibodies (*c*, *d*). In spread cells, fibronectin-specific staining is mainly confined to the upper surface of the cells. Similar staining patterns were obtained when the cells were plated in the absence of serum. When plated in the presence of monensin (Lilly; 1 μM) the cells adhered and spread as well as control cells (compare with *f*, *h*). No fibronectin-specific fluorescence was seen in these cells in surface staining either after the first 5 h on plating (*e*) or in fully spread cells (*g*). In adhering cells treated with 0.5% Triton X-100[14] at 6 h of spreading, a typical fuzzy fibrillar fibronectin-specific fluorescence is seen beneath the control cells, with some diffuse staining in the cytoplasmic domain (*i*) whereas the cells allowed to spread in the presence of monensin only show the remnant cytoplasmic staining following Triton treatment (*j*). In *j* the cell margins are indicated by arrowheads. For surface staining, unfixed cells were exposed to the first antibody washed in phosphate-buffered saline, fixed in 3.5% paraformaldehyde and then exposed to the second antibody, fluorescein isothiocyanate (FITC)-coupled goat anti-rabbit IgG (Cappel). Rabbit antifibronectin antibodies were obtained from Cappel. *a*, *b*, *e*, *f*, *i*, *j*: ×800; *c*, *d*, *g*, *h*: ×400.

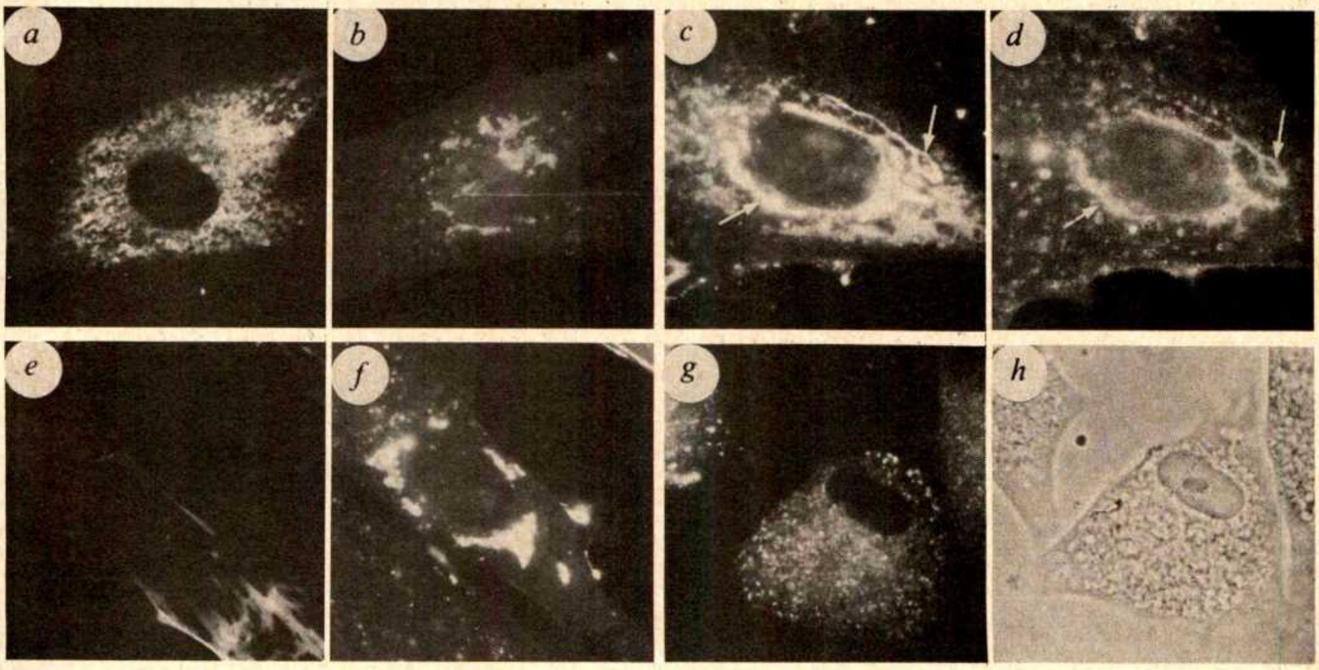

Fig. 2 In control cells fixed in 3.5% paraformaldehyde and permeabilized with 0.1% NP40, a cytoplasmic granular perinuclear staining is seen (*a*). In double-staining with TRITC-wheat germ agglutinin (WGA, Vector Laboratories), used here as a marker for the Golgi apparatus[40], a distinctly different reticular juxtanuclear staining was seen (*b*). Note that no apparent labelling of the Golgi region is seen in *a*. When the cells were exposed to monensin (1 μM) for 1 h, a diffuse cytoplasmic but also a pronounced reticular juxtanuclear fibronectin-specific staining was seen (*c*). The reticular staining (arrows in *c*, *d*) coincided with that obtained with TRITC-WGA (*d*), marking the Golgi apparatus. After exposure to puromycin (2 $\mu g\ ml^{-1}$) for 2 h, no cytoplasmic fluorescence could be detected in control cells (*e*) whereas cells first exposed to monensin (1 μM, 1 h) still showed a bright juxtanuclear fibronectin-specific fluorescence after puromycin treatment (*f*). Cells cultured in the presence of monensin for 24 h, on the other hand, showed a granular cytoplasmic accumulation of fibronectin in IIF but no fibrillar matrix-type fibronectin (*g*, *h*, cells plated in the presence of monensin). ×800.

only surface membrane glycoprotein present in detergent-resistant cytoskeletons of human fibroblasts still anchored to the culture substratum.

With the IIF technique using anti-actin (Fig. 4*a*) and anti-vinculin (Fig. 4*b*) antibodies control cells showed the typical organization of stress fibres and vinculin plaques. Interference reflection microscopy revealed 'black' arrays of focal adhesions in control cells (Fig. 5*a*). In contrast to control cells, IIF of cells plated in the presence of monensin showed only a diffuse actin- and vinculin-specific staining (Fig. 4*c*, *d*). They displayed, however, typical fibrillar arrays of both vimentin-type intermediate filaments and microtubules (Fig. 4*e*, *f*). Monensin-exposed cells did not exhibit focal adhesion sites in interference reflection microscopy but instead showed large grey-coloured areas representing sites of close adhesion (Fig. 5*d*). However, cells first spread in normal medium and then exposed to monensin showed normal arrays of both microfilament bundles (Fig. 4*g*, *h*) and vinculin plaques. A mouse fibroblastoid cell line (3T3), which is known to require exogenous fibronectin for both adhesion and spreading[1], spread on exposure to monensin only if serum was present, but did not develop stress fibres or vinculin plaques (data not shown).

Focal adhesions are specialized cell-surface areas of cell-to-substratum adhesion of cultured cells[17-20] and emerge concomitantly with the formation of bundles of microfilaments[18,19] during cell spreading. Both the vinculin plaques[21,22] and the focal contacts[17,22,23] have been reported to be in close apposition to pericellular fibronectin, and isolated focal adhesions have been reported to contain both actin and fibronectin[17]. During cell spreading, fibronectin seeks to co-align closely with microfilaments[23-25]. Transformed cells, lacking cell-surface-associated fibronectin[4,5], also lack bundles of microfilaments[26,27], but normal arrays of microfilaments are restored on addition of cell-derived fibronectin[28]. However, recent results[29-31] have indicated that fibronectin might be absent or even actively removed from focal adhesions. Based on such an observation, Chen and Singer[29] recently proposed two different molecular mechanisms for microfilament–cell membrane interaction in cultured cells, involving fibronectin differently in cytoskeletal organization and adhesive functions of cultured cells.

Our results with monensin-exposed cells suggest that fibronectin is not needed for fibroblast adhesion to and spreading on culture substrata. On the other hand, endogenous fibronectin seems to be required for the development of focal

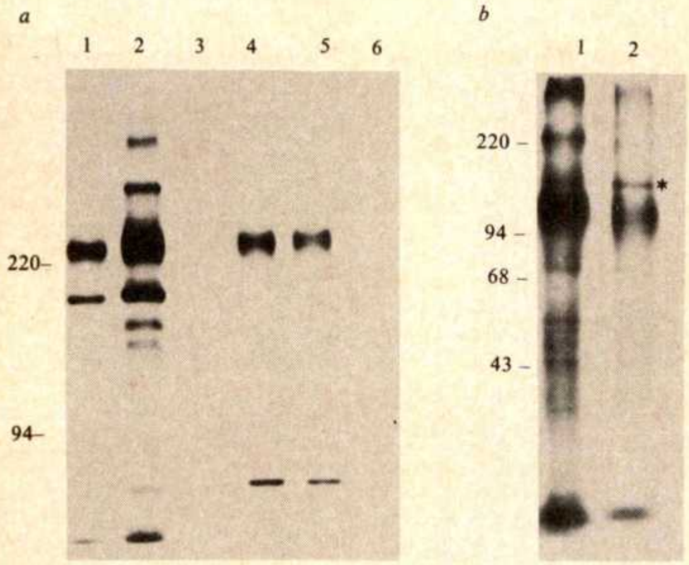

Fig. 3 *a*, Electrophoretic analysis of secreted polypeptides in the culture medium of control cells labelled with L-^{35}S-methionine for 24 h (1,000 Ci mmol^{-1}; 10 μCi ml^{-1}; Radiochemical Centre) showed several polypeptides both after 5 h and 24 h of plating (lanes 1, 2) whereas cultures plated in the presence of monensin and cultured for 24 h did not contain any secreted proteins (lane 3). A prominent 220 K gelatin-binding polypeptide, corresponding to fibronectin[11], was seen in the medium of both spreading (5 h, lane 4) and wholly spread control cultures (24 h, lane 5), but not in cultures plated in the presence of monensin (24 h, lane 6). *b*, Surface labelling experiments using the neuraminidase/galactose oxidase/sodium borohydride method[12] showed a distinct polypeptide with M_r 220 K and several polypeptides of lower molecular weight in control cultures (lane 1). Instead, cells exposed to monensin during plating lacked the 220 K glycoprotein but showed a prominent 140 K glycoprotein (asterisk in lane 2) together with some other polypeptides (lane 2).

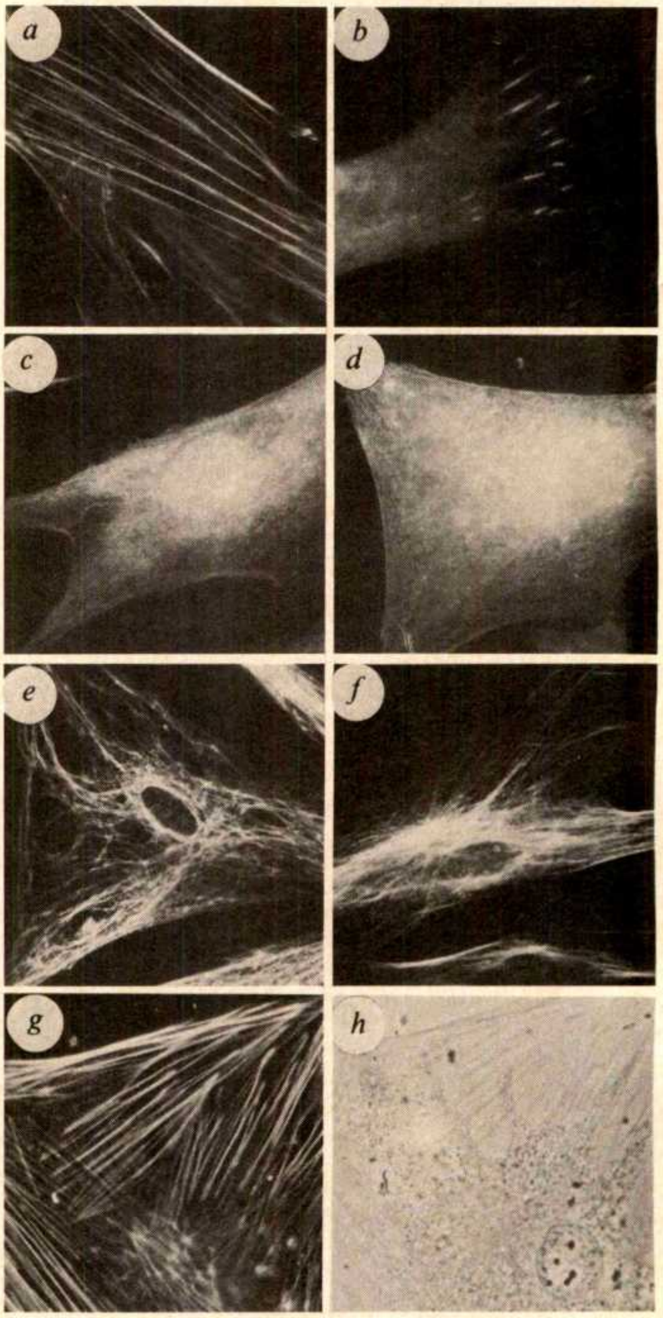

Fig. 4 Control human embryonal fibroblasts showed a stress fibre-type of actin organization in IIF with anti-actin antibodies[17] both when plated with (*a*) or without serum. Typical plaques of vinculin were also seen in these cells in IIF (*b*). Vinculin was isolated from chicken gizzard according to Feramisco and Burridge[41]. Antibodies were raised in rabbits and purified on antigen coupled to Sepharose 4B. Cells exposed to monensin on subcultivation showed only a diffuse actin-specific (*c*) or vinculin-specific (*d*) fluorescene in IIF. Such cells showed, however, typical arrays of both intermediate filaments (*e*), as shown with anti-vimentin antibodies[42], and microtubules (*f*), as revealed with anti-tubulin antibodies[17]. When spread cells were exposed to monensin (1 μM, 24 h), normal arrays of both microfilaments (*g*), phase-dense stress fibres (*h*) and vinculin plaques were still seen. For cytoskeletal antibodies the cells were fixed in −20 °C methanol for 5 min and stained for IIF as in Fig. 1. ×500.

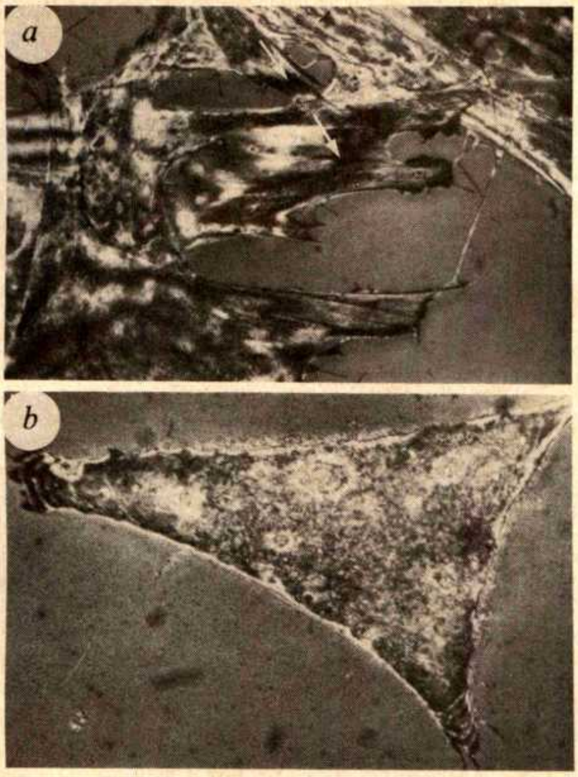

Fig. 5 Interference reflection microscopy[17] of control human fibroblasts (*a*) and of cells exposed to monensin on subcultivation (*b*). Note the black areas of focal adhesion (arrows in *a*) and extensive grey areas of close adhesion in monensin exposed cells (*b*). ×900.

adhesion sites, bundles of microfilaments and plaques of vinculin. This sequence of events corresponds to recent observations distinguishing a cell-independent and a cell-dependent phase in cell-to-substratum adhesion[13,32–35]. We suggest that a prerequisite for cells to enter into the cell-dependent phase of spreading is the deposition of endogenous pericellular fibronectin and subsequent formation of focal adhesion sites and the microfilament–vinculin system which, in turn, are needed to maintain an isometric contraction in cells[36].

Interestingly, human embryonal fibroblasts which were allowed to spread in the presence of monensin, could not acquire the matrix-type of fibronectin even from the culture medium[37]. This might be due to the lack of receptors for exogenous fibronectin in monensin-treated cells, as trypsinized cells are also apparently unable to retain exogenously added fibronectin[38]. A recent study by Atherton and Hynes[39] using monoclonal antibodies has revealed differences in plasma and cellular fibronectins which may be of importance in their apparently different roles in cell adhesion, as suggested by our results.

Evidence for contractile flexing of the gliding bacterium *Flexibacter* FS-1

Robert P. Burchard

Department of Biological Sciences, University of Maryland,
Baltimore County, Catonsville, Maryland 21228, USA

Flexing movements have been described in a variety of gliding bacteria and cyanobacteria (blue-green algae)[1–7]. Flexing of trichomes (chains of cells) of the genera *Oscillatoria* and *Beggiatoa* was attributed[8] to a "certain degree of elasticity"; it was concluded that there is no spontaneous flexibility. In contrast, observations of active flexing of free ends of otherwise immobilized *Oscillatoria* trichomes suggested[9] that active contractions are involved. It has been proposed that flexing and gliding motility are powered by the same mechanism[10]. No organelles have been demonstrated irrefutably to be responsible for these movements, although several mechanistic hypotheses have been proposed[11]. I demonstrate here that flexing movements by the bacterium *Flexibacter* FS-1 require no more than one point of attachment by the cell to its substratum, which suggests that flexing may result from a unilateral, longitudinal contraction. As the same motility mechanism is thought to operate for both flexing and gliding, the latter may be powered by a contractile apparatus, at least in this species.

I and others[6] have observed that flexing, like gliding, requires contact with a surface, such as another cell, a glass slide or an agar gel; in suspension such cells do not move actively. Gliding motility itself could account for flexing: for example, if the two polar regions of a cell or chain of cells were attached to a surface and were gliding in an uncoordinated fashion so as to be moving towards one another, the central portion of the cell(s) would, if not firmly attached to the surface, bow outwards and thus appear to flex. Reversal of the flexion could be explained by reversal of the direction of gliding at both ends. Uncoordinated gliding has been described in trichomes of the cyanobacterium *Oscillatoria*[12,13].

I have investigated this phenomenon by using a simple experimental design. *Flexibacter* FS-1, which grows as long filaments with widely spaced septa[6,14], was cultured in YE/2 medium[10] at ambient temperature or at 30 °C with little or no agitation. Cultures at absorbance (A_{540}) = 0.1, containing filaments ≤200 μm long (capable of active flexing in a wet mount

0028-0836/82/320663—03$01.00

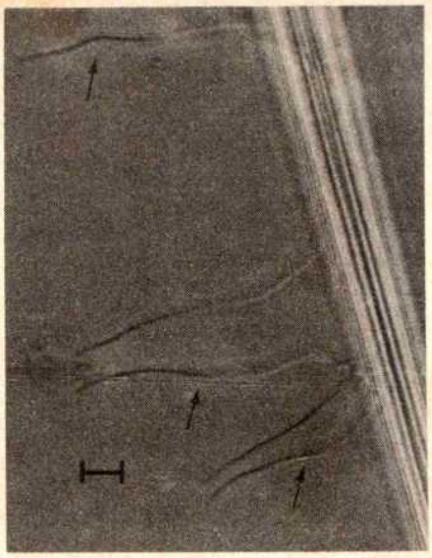

Fig. 1 Flexing *Flexibacter* FS-1 filaments attached to a glass wool fibre. Flexion points are indicated by arrows. Scale bar, 10 μm.

preparation), were diluted in YE/2 to ~10^4 filaments ml^{-1} and loaded into a 1 cm deep chamber mounted on a glass slide. A small tuft of glass wool fibres was submerged in the suspension. The chamber was then covered with a coverslip, and vacuum grease used to prevent leakage. The chamber was inverted and mounted on the stage of an inverted, phase-contrast microscope equipped with a ×10 Zeiss achromat objective (5 mm working distance). It was thus possible to observe individual filaments which readily but reversibly attached at or near one pole (or by their lateral surfaces) to a glass wool fibre and made no contact with any other surface.

Some of these multicellular filaments were observed to flex and relax repeatedly (Figs 1, 2). Flexing assumed various forms, including localized bending and undulating of the filaments. Flexions could be observed to move along a filament towards the unattached end. This end sometimes abruptly flexed so as to form a distinct hook and then very rapidly straightened out, as though the hook were spring-loaded or under some tension. As soon as the filaments detached from the glass wool, flexing ceased. The movements observed were active, as addition of dinitrophenol (5×10^{-4} M final concentration) inhibited flexing, although attachment appeared to have been unaffected. This agent also inhibited flexing in wet mounts and is known to inhibit gliding motility of *Flexibacter* and other gliding bacteria[11].

To ensure further that the observed flexing is an active process rather than one resulting from turbulence in the chamber, I examined the behaviour of strain Ng 7, a UV induced, non-gliding mutant of FS-1. The filaments (≤40 μm long) of this mutant also attached to the glass wool fibres but did not flex in the conditions used nor in wet mounts.

This active flexing by multicellular filaments attached via one pole can most readily be explained by a contractile mechanism which is longitudinally arrayed and unilateral. Similarly, flexional and swinging movements by the free ends of aggregated *Oscillatoria* trichomes[9,15] may also result from contractions. If gliding motility and flexing are indeed powered by the same mechanism, then gliding presumably also involves a contractile mechanism in *Flexibacter* FS-1.

Other theories to account for gliding motility have been proposed. The rotary assembly model[16] is attractive as it provides a unified theory of prokaryotic motility; both flagellated[17,18] and gliding bacteria would be driven by rotary motors. However, it is not clear how the spinning of rotary assemblies could explain the flexing movements described here, especially as flexing was observed in filaments with one end wrapped around a glass wool fibril and in those attached by one point on their lateral surface (Fig. 3). Similarly, 'make and break' interactions within the envelope[19], the elaboration of surfactant gradients[20,21], directed production of extracellular slime[22], and an electrokinetic mechanism[23] cannot account for the observed flexing.

Contractions have been described in a mycoplasma which also demonstrates a form of surface translocation called gliding[24]. However, I am unaware of any previous definitive reports of contractile phenomena among enveloped prokaryotes.

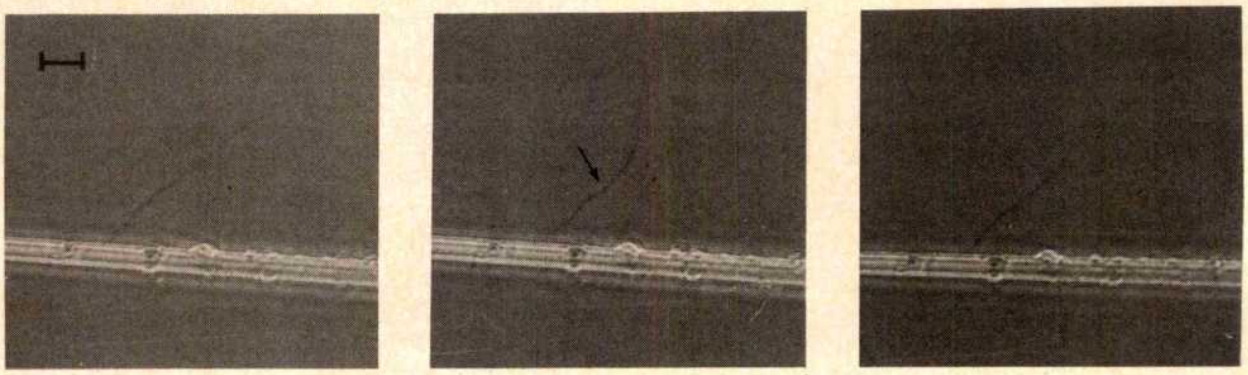

Fig. 2 A *Flexibacter* filament before and during a flexion (arrow). Scale bar, 10 μm.

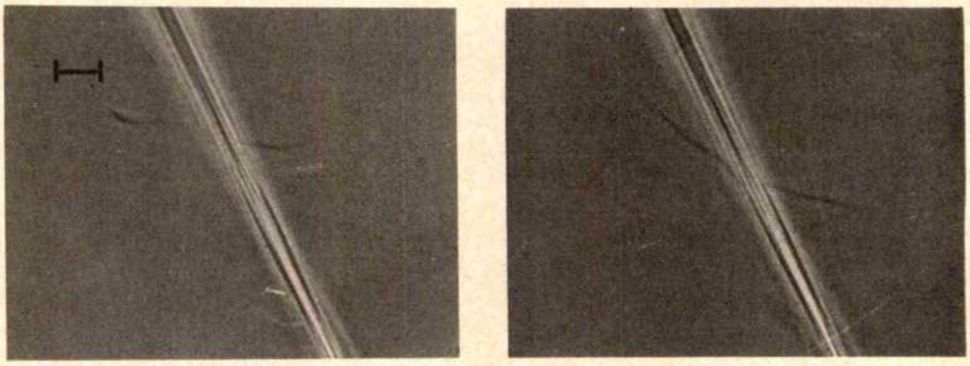

Fig. 3 A flexing *Flexibacter* filament attached to a glass wool fibril along its lateral surface, Scale bar, 10 μm.

There is no known structural basis for contractility in *Flexibacter*. Attempts to isolate eukaryotic-like actin from this bacterium have been unsuccessful (R.P.B. and S. Mockrin, unpublished results). Organelles proposed to have contractile or bending properties and to be mechanistically involved in gliding have been described in *Myxococcus*[25] and in *Oscillatoria*[26]. A contractile mechanism may, in fact, account for all of the forms of movement demonstrated by gliding bacteria[27].

A puzzling question which arises from these observations is why any point of attachment to a substratum should be required for flexing if this movement results from a contractile event. It may be that contact of the cell envelope with a surface is required to initiate such contractions.

X-ray scattering by myosin S-1: implications for the steric blocking model of muscle control

Robert Mendelson

Department of Biochemistry and Biophysics, and Cardiovascular
Research Institute, University of California, San Francisco,
California 94143, USA

Steric blocking and unblocking[1–3] of the myosin interaction sites in muscle thin filaments by tropomyosin provides a simple yet elegant method of regulating contraction in skeletal muscle. Recently, this model was challenged[4] by the finding that tropomyosin is located on the opposite side of the thin filament helix axis from where Moore *et al.* reported that the myosin cross-bridge, S-1, bound[5]. However, new three-dimensional image reconstructions of electron micrographs of thin filaments decorated with S-1 were obtained by Taylor and Amos[6], who proposed that the prior assignment of the S-1 binding site of Moore *et al.*[5] was incorrect, and that consequently tropomyosin and S-1 are located on the same side of the actin helix. These past difficulties and the current lack of agreement[7] on the location of the S-1 binding site suggested that another technique would be useful. We report here that the shape of S-1, derived from reconstructions using the Taylor and Amos actomyosin interpretation, gives a better fit to the X-ray scattering pattern observed from S-1 in solution than alternative interpretations.

The two assignments of S-1 position in the three-dimensional reconstructions are illustrated in Fig. 1. The original assignment by Moore *et al.* was based on the supposition that a radial expansion of the acto-S-1 helix had occurred, as had been found in some isolated F-actin reconstructions. Using minimal dose electron microscopy with improved specimen preparation, Taylor and Amos found additional mass near the helix axis which they assigned to actin. They argued that the filaments of Moore *et al.* had not expanded radially and the mass previously assigned to actin was actually part of S-1. Although their assignment agrees well with the known mean radius of actin, the Moore *et al.* interpretation is difficult to refute with certainty because of the inherent ambiguity in defining a boundary between two complexed molecules whose individual structures are not highly determined. As the S-1 derived from the two proposed locations of the S-1 binding sites have very different shapes, we tested these contrasting models by X-ray scattering from isolated S-1 in solution.

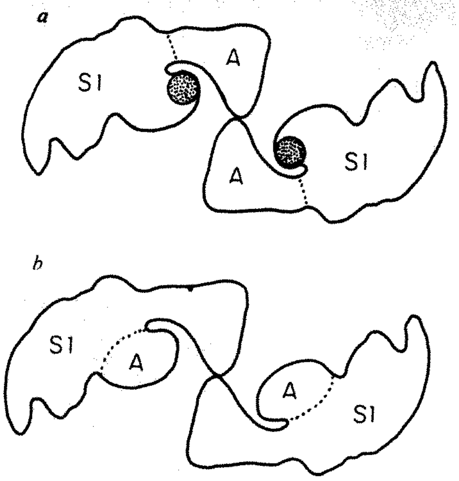

Fig. 1 A projected view (from the three-dimensional reconstructions of ref. 5) looking down the thin filament axis towards the Z-line with the S-1 position drawn according to the interpretation of: *a*, Taylor and Amos, and *b*, Moore *et al.* In the steric blocking model the tropomyosin (shaded in *a*) is thought to unblock the S-1 attachment site as the amount of Ca^{2+} binding to troponin (located at every seventh actin monomer) increases. The position of tropomyosin shown is approximately that given by ref. 4 for the rigor or activated state. If the interpretation of Taylor and Amos is correct, the S-1 binding site is nearer tropomyosin, and the shape of S-1 is more compact than in the Moore *et al.* interpretation. The structure of Moore *et al.* is similar to that shown, except that a significant amount of the mass labelled A is missing at low radii.

Previous X-ray scattering results[8] showed that S-1 shapes derived from three-dimensional helical electron micrograph reconstructions were capable of giving a better fit to scattering data than many simple models that might resemble S-1. Recent high resolution reconstructions, in addition to raising the question of S-1 position, suggest that the shape of S-1 is significantly altered by the presence of the 18,000 molecular weight (M_r) light chain[9]. Previously reported scattering data were from S-1 that contained only a fraction of the 18,000-M_r light chain. Thus, scattering data were accumulated on S-1 both with and without this light chain. The fractional change in the radius of gyration (R_g) was 0.01 ± 0.005 for S-1 with and without the light chain (five double preparations[10,11], seven trials), and the scattering patterns (Fig. 2) and chord distributions were almost identical, indicating that the 18,000-M_r light chain is not a significant determinant of S-1 shape. Thus, the present results validate the results of previous modelling studies[8] for S-1s that have varying amounts of light chain.

If the addition of light chain causes an isotropic increase in size, it would be expected that $\Delta R_g/R_g = 1/3\ (\Delta M_r/M_r) = 0.05$, when using the molecular weights of Margossian *et al.*[12]. Thus, S-1 with 18,000-M_r light chain is slightly more symmetrical than S-1 without it. The disagreement of the present result with those computed from reconstructions of decoration of actin by scallop S-1 ($\Delta R_g/R_g = 0.15$)[9] may be only apparent; our studies

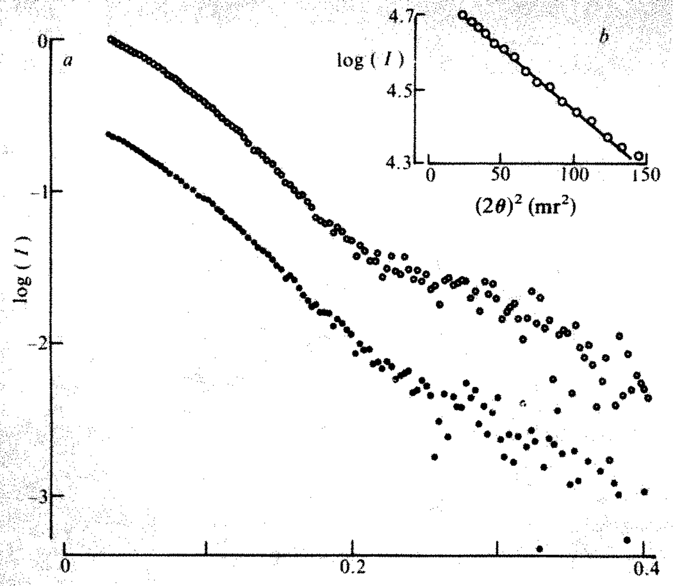

Fig. 2 *a*, Typical scattering patterns from S-1 with (●) and without (○) the 18,000-M_r light chain. Rabbit S-1 with this light chain was prepared and purified as described in ref. 10 except that the S-1 yield was kept below 20% so as to minimize heavy chain degradation. S-1 without the light chain was prepared as in ref. 11 except that purification was by S-200 gel filtration, which did not separate S-1 isoenzymes. The buffer contained 150 mM KCl; 20 mM tri[hydroxymethyl]methylaminoethane sulphonic acid; 0.1 mM NaN_3; 1 mM dithiothreitol, *p*H 7 at $T = 4°C$; [S-1] = 7 mg ml^{-1}. *b*, A Guinier plot from the lowest angle portion of the scattering curve, where *I* is the scattering intensity, and 2θ is the scattering angle. Guinier plots and chord distributions appeared virtually identical with and without light chain. Data were accumulated from $s = 1/38$ nm^{-1} to about $s = 1/2.5$ nm^{-1} (where $s = 2\sin\theta/\lambda$) using a Kratky camera with a position-sensitive proportional counter. The sample-to-registration-plane distance was 214 mm. The range of S-1 concentrations was 7–32 mg ml^{-1}. mr = milliradians.

were performed on rabbit skeletal S-1, which shows a less barbed structure than scallop S-1 in acto–S-1 micrographs[13]. In addition, the R_g and chord distribution (not shown) of scallop S-1 without 18,000-M_r light chain were in good agreement with the data; thus, an intact, flexible, light chain could be oriented most frequently along the surface of the S-1 heavy chain to give on average a compact S-1 structure in solution, while the electron microscopy stain could cause it to be visualized only in an extended orientation which would make the overall structure appear more elongate.

Comparison of the S-1 shapes derived from the two different interpretations is shown in Table 1 and Fig. 3. The radius of gyration (R_g), which is derived from the lowest resolution portion (smallest angle) of the scattering curve, most directly reflects the overall shape of the protein. As shown in Table 1, the R_g's showed a consistent preference for the Taylor and Amos interpretation in the micrographs of both Moore *et al.* and Taylor and Amos. The interpretations of the Wakabayashi and Toyoshima[7] reconstruction in terms of the two aforementioned S-1 positions are not fully consistent with the findings of other workers; their assignment of the Moore *et al.* actin position has a lower radius than that of their Taylor and Amos actin position. Further, their proposed actin structure, in both interpretations, has a smaller volume, relative to S-1, than actin in the reconstruction of Taylor and Amos. However, even this study favours a Taylor and Amos type of S-1 binding position. The mean and the maximum chord can be extracted from the chord distributions[14] and directly compared with these parameters from the reconstructions. As the mean chord (and R_g) is an average that depends on the entire structure of the molecule, it is a better parameter for experimental comparison than the maximum chord. The mean chord and relative goodness of fit factors to the chord distributions obtained in this study also favour the Taylor and Amos interpretation, although the maximum chord was inconclusive.

The choice of different micrograph contour levels had little effect on the overall shape of S-1; the difference in R_g using two plausible extreme contours of the model in ref. 5 (provided by K. Taylor) was only 0.05 nm when the contours were scaled to give the correct S-1 volume. In the previous X-ray scattering study[8], a good fit was obtained using a different reconstruction (J. Seymour and E. J. O'Brien, unpublished). Although the actin and tropomyosin were not fully resolved from S-1 in this reconstruction, their subtraction was consistent with that of Taylor and Amos (J. Seymour, personal communication). Indeed, alignment of this reconstruction with that of Taylor and Amos indicated that the shape and location of S-1 were very similar to those of Taylor and Amos. The results of X-ray scattering by S-1 in solution substantiate the shape of S-1 derived when it is attached to actin in the manner proposed by Taylor and Amos rather than in the position of Moore *et al.* Although we cannot formally exclude the possibility that the

Table 1 Structural parameters of S-1 from electron microscopy and X-ray scattering

Author and S-1 position	R_g (nm)	Mean chord (nm)	Max chord (nm)	*R*(Moore)/*R*(Taylor)*
Moore *et al.* (*x, y, z*)				
Moore *et al.* S-1	3.83	4.80	15.1	11

No LC2 (M_r = 110 K)	3.27 (0.1)	4.25 (0.15)	12 (1)	
Part LC2 (M_r = 122 K)	3.28 (0.06)	4.25 (0.15)	12 (1)	
Full LC2 (M_r = 130 K)	3.3 (0.1)	4.25 (0.15)	12 (1)	

Letters in parentheses denote the method of scaling suggested by each author. Wakabayashi and Toyoshima's maps were also scaled on *x, y, z* to illustrate the effect of a different scaling method on the parameters. K, molecular weight 1,000.

$$* \; R \equiv \frac{\{\Sigma_i[p_0(r_i) - p_c(r_i)]\}^2}{\{\Sigma_i\, p_0(r_i)\}^2}$$

where $p_0(r)$ is the observed and $p_c(r)$ is the calculated chord distribution function.

† All maps are to be compared with 'no LC2' except those of Moore *et al.*, which is to be compared with 'part LC2'. Any error in the findings that true molecular weight scales with LC2 content will improve the agreement with the Taylor and Amos interpretation.

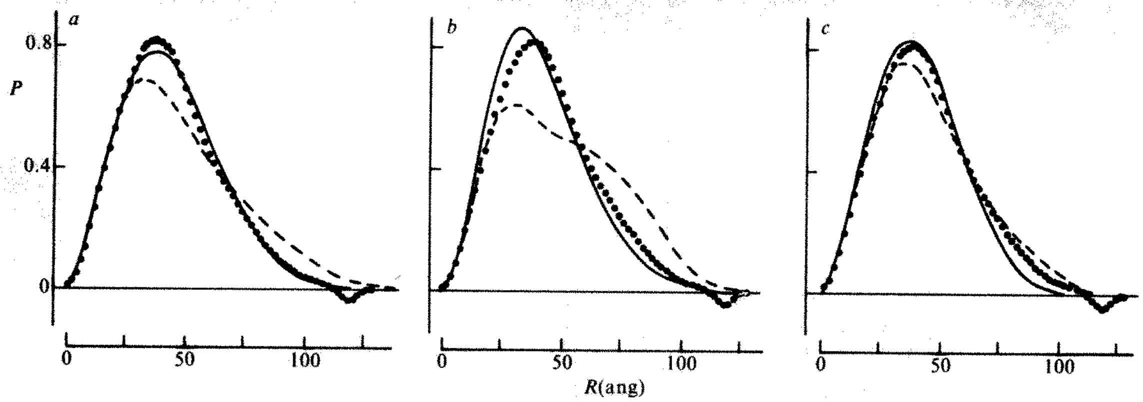

Fig. 3 A comparison of the S-1 experimental (●) chord distribution with the predictions from electron microscopy using the Taylor and Amos interpretation (solid lines) and the Moore *et al.* interpretation (dashed lines). The electron density maps were from: *a*, Moore *et al.*; *b*, Taylor and Amos; *c*, Wakabayashi and Toyoshima. The maps were furnished with the actin–S-1 interfaces delimited by their authors except in the case of the Moore *et al.* map, where the interface was delimited by L. Amos. The maps were scaled to the correct volume. This was done by scaling each *x* and *y* coordinate or each *x*, *y* and *z* (helix axis) coordinate as recommended by the author. Typically, the scaling changed these dimensions by only 10–20%. Tests showed that the method of scaling had only a small effect on the predicted chord distributions and on the overall molecular shape (see Table 1). Chord distributions were obtained by Fourier transforming the experimental and model scattering curves using the method of Glatter[14].

S-1 solution could have a shape similar to that found by Taylor and Amos and yet makes a conformational change to the shape described by Moore on binding to actin[7], such a large change seems improbable because the accompanying R_g change would be of an unprecendented magnitude. Thus, the present results are consistent with the notion that regulation of muscle contraction occurs by the steric blocking of the actin–S-1 interaction.

Insulin forms a complex with its receptors on the plasma membrane of cells and initiates a series of biochemical events which lead to the hormone's recognized effects[1,2]. The exact mechanism that initiates these events is unknown. We previously reported that insulin stimulates the phosphorylation of the 95,000 molecular weight (M_r) (β) subunit of its own receptor in intact cells and proposed that this phosphorylation reaction could be a very early step in insulin action[3]. To clarify the molecular basis of this reaction, we have now investigated the phosphorylation of insulin receptor in a cell-free system. Using [γ-^{32}P]ATP in solubilized and partially purified receptor preparations from rat liver plasma membrane, we find that both the α and β subunits of the insulin receptor are phosphorylated. Furthermore, insulin stimulates the incorporation of ^{32}P into both receptor subunits in a specific and dose-dependent manner. Phosphoamino acid determination of the β subunit after insulin stimulation reveals only phosphotyrosine. These findings suggest that the elements required for phosphorylation are associated with the plasma membrane of the cell and that specific phosphorylation of the insulin receptor on tyrosine residues can be activated in a solubilized preparation.

Rat liver plasma membranes were prepared by the procedure of Neville[4] and phosphorylation studied using [γ-^{32}P]ATP as described in Fig. 1 legend. Insulin receptors in this rat liver membrane fraction and solubilized insulin receptors prepared from these membranes have been well characterized[5,6]. Further, as previously shown lectin chromatography allows a 20-fold purification with nearly 100% recovery of insulin receptors as determined by ^{125}I-insulin binding[7]. The insulin receptor subunits were identified by immunoprecipitation with antibodies against insulin receptor followed by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and autoradiography[3,8].

When the immunoprecipitates were analysed in SDS-PAGE in reducing conditions (100 mM dithiothreitol; DTT), one major band of M_r 95,000 and a minor band of M_r 135,000 were specifically phosphorylated in basal state (Fig. 1*A*, lane *b*). These 135,000- and 95,000-M_r phosphoproteins have been tentatively identified as the α and β subunits of insulin receptor, respectively, by their immunoprecipitation by anti-receptor antibody and by the fact that they migrate in the same position in SDS-PAGE as α and β subunits of insulin receptor labelled either biosynthetically or externally[3,8]. After incubation of the solubilized fraction with insulin (10^{-6} M), the incorporation of ^{32}P into these two proteins was increased approximately fivefold as determined by scanning densitometry (Fig. 1*A*, lane *d*). A phosphoprotein band corresponding to M_r ~50,000 is also observed; this may represent phosphorylation of the heavy chain of IgG.

In the native insulin receptor, the receptor subunits are thought to be linked by disulphide bonds to form high molecular weight oligomers[9,10]. When the same samples were analysed without reduction of disulphide bonds, five bands were observed (Fig. 1*B*, lane *b*). Two bands had molecular weights higher than 300,000. In addition, there were phosphoproteins of M_rs 240,000, 130,000 and 90,000 in basal state (Fig. 1*B*, lane *b*); these bands are identical to those found when the receptor

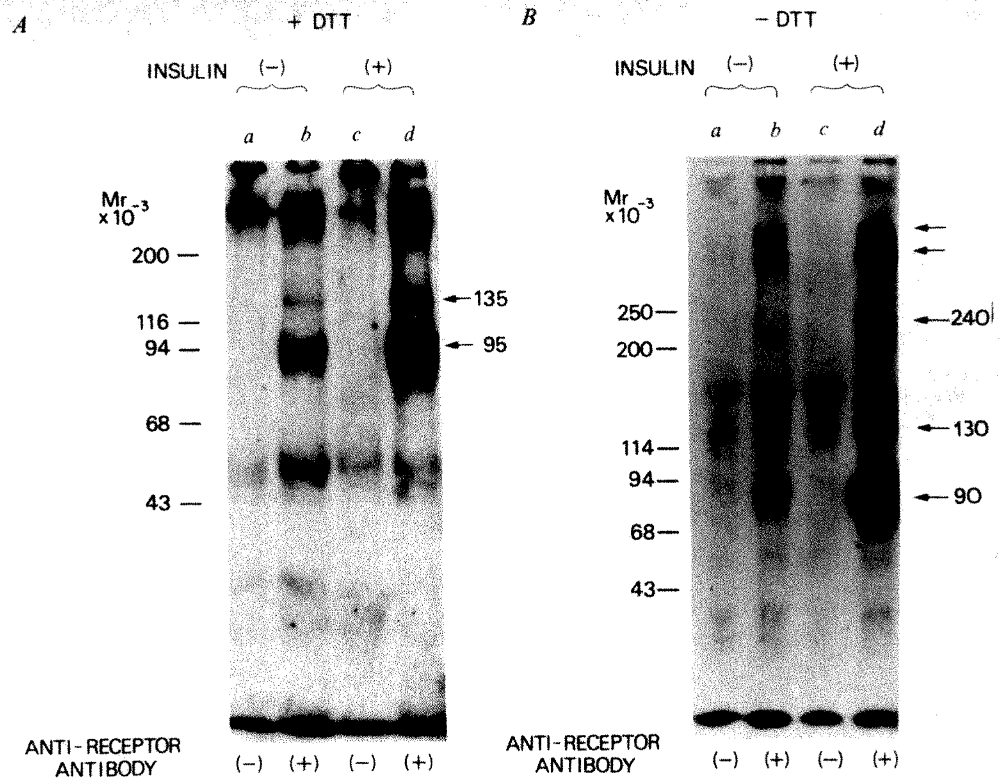

Fig. 1 Autoradiogram showing the incorporation of the ^{32}P from [γ-^{32}P]ATP into solubilized insulin receptor from rat liver plasma membrane. Rat liver plasma membranes were prepared by the procedure of Neville[4]. Protease inhibitors (2 mM phenylmethylsulphonyl fluoride; 1,000 trypsin inhibitor units per ml aprotinin) were added throughout the purification beginning with the first step of homogenization. The plasma membrane fraction was solubilized by 1% (v/v) Triton X-100 in 50 mM HEPES buffer, *p*H 7.6, containing protease inhibitors. The insulin receptors were further enriched by chromatography on a wheat germ agglutinin–agarose column[7] after elution by 0.3 N *M*-acetyl glucosamine in 50 mM HEPES buffer, *p*H 7.6, containing 0.1% (v/v) Triton X-100. Aliquots of these eluted fractions (150–300 μg per tube) were incubated with or without insulin (10^{-6} M) overnight at 4 °C. A 1-h incubation with insulin at room temperature was also used. Essentially the same result was obtained in the two different incubation conditions. The aliquots were then assayed for the incorporation of ^{32}P from [γ-^{32}P]ATP at 4 °C in a final volume of 1,350 μl. For the experiment shown, the reaction mixture contained 6 mM $MgCl_2$, 2 mM $Mn(CH_3COO)_2$, 5 μM [γ-^{32}P]ATP (~30 μCi $nmol^{-1}$) in 30 mM HEPES buffer, *p*H 7.6. Similar results were obtained with 20 mM $MgCl_2$ and 1 mM $MnCl_2$ in a 100 mM HEPES buffer, *p*H 7.4. Assays were initiated by the addition of ATP. After 10 min incubation, NaF, sodium pyrophosphate, EDTA, ATP and Triton were added to get final concentration of 50, 10, 5 and 5 mM and 0.1% (v/v) respectively. The insulin receptor was quantitatively immunoprecipitated by serum containing antibody against insulin receptor (serum B-2, 1:200 dilution) or normal control serum[8]. After 2.5 h at 4 °C, 200 μl of Protein A (Pansorbin; 10% w/v) were added and the incubation continued for 1 h at 4 °C. The precipitates were then collected by centrifugation at 10,000*g* for 5 min at 4 °C and washed twice with 1% Triton and 0.1% SDS[8]. Immunoprecipitates were solubilized by boiling for 3 min in 2% SDS in 10 mM sodium phosphate, *p*H 7.0, with (*A*) or without (*B*) dithiothreitol (DTT). The labelled components were separated electrophoretically in 5 or 7.5% polyacrylamide slab gels in the presence of 0.1% SDS as described by Laemmli[32]. After electrophoresis, the slab gels were stained, destained, dried and autoradiographed for 3–7 days as previously described[8]. Subunit molecular weights were calculated by using as standards (M_r): filamin (250,000), myosin (200,000), β-galactosidase (116,000), phosphorylase *b* (94,000), bovine serum albumin (68,000) and ovalbumin (43,000).

is labelled by ^{35}S-methionine or ^{3}H-sugars and analysed without reduction[11]. Using two-dimensional (non-reducing/reducing) gel electrophoresis, we have previously shown that the two highest molecular weight bands are composed of α and β subunits, and three other bands are an α–α dimer and 'free' α and β subunits respectively[11]. After incubating with insulin (10^{-6} M), the phosphorylation of all five bands was increased approximately five- to six-fold.

To evaluate further the mechanism of phosphorylation of insulin receptors, the solubilized fractions were incubated with several concentrations of insulin (10^{-10} to ~10^{-6} M), desoctapeptide (DOP) insulin and multiplication-stimulating activity (MSA), one of the insulin-like growth factors, and the phosphorylation was carried out as described above. Physiological concentrations of insulin (3×10^{-10} M) increased the phosphorylation of both subunits approximately threefold (Table 1). Stimulation was maximal with insulin concentrations of 10^{-8} to ~10^{-6} M (Table 1; Fig. 1). DOP insulin, which has ≤1% of the potency of porcine insulin in displacing bound ^{125}I-insulin from rat liver membrane insulin receptor and stimulating glucose metabolism[6], stimulated phosphorylation only minimally. MSA (10^{-7} M) was also far less potent than the same concentration of porcine insulin (Table 1), as expected from previous studies of the affinity of MSA for the insulin receptor in rat liver plasma membrane[12,13]. Thus, the 135,000- and 95,000-M_r bands were phosphorylated in dose-dependent fashion and specificity consistent with the affinity of the insulin receptor for insulin analogues.

To determine the phosphoamino acids of the β subunit of the insulin receptor, this ^{32}P-labelled phosphoprotein was cut from the gel and partially hydrolysed in 6 M HCl for 2 h at 110 °C. The resulting hydrolysates were separated by two-dimensional electrophoresis (*p*H 2.0 and *p*H 3.5) in the presence of unlabelled phosphoserine, phosphothreonine and phosphotyrosine, and the autoradiograms of the separated phosphoamino acids were compared with the ninhydrin-stained standards. Only trace amounts of phosphotyrosine could be detected in the basal state (data not shown). After insulin stimulation (10^{-7} M), there was a dramatic increase in the amount of phosphotyrosine (Fig. 2). Because of the low radioactivity, phosphoamino acid in α subunit could not be identified.

There is considerable evidence that phosphorylation and dephosphorylation may have various roles in insulin action[14–20]. Recently, we found that insulin stimulates the phosphorylation

Table 1 Effects of insulin and insulin analogues on ^{32}P incorporation into solubilized insulin receptor subunits from rat liver plasma membrane

Addition	Concentration (M)	^{32}P incorporated into insulin receptor subunits (arbitrary units)	
		M_r 135,000	M_r 95,000
Expt 1			
None	—	3.7	20.2
Porcine insulin	3×10^{-10}	12.9	64.0
Porcine insulin	1×10^{-7}	21.5	116.0
Desoctapeptide insulin	1×10^{-7}	4.1	27.2
Expt 2			
None	—	<0.5	5.2
Porcine insulin	1×10^{-7}	4.0	38.2
Multiplication-stimulating activity	1×10^{-7}	<0.5	6.6

Experiments 1 and 2 were performed with solubilized fractions derived from different membrane preparations. The studies were carried out as described in Fig. 1 legend. The autoradiograms were scanned in a Joyce-Loebl microdensitometer and the peak areas corresponding to the 135,000- and 95,000-M_r bands were calculated and expressed in arbitrary units.

of the β subunit of the insulin receptor in intact cells, indicating that this may be an early step in insulin action. This study demonstrates that the same phenomenon can be reproduced in cell-free systems and suggests several interesting points. First, although we are unable to determine the source of the phosphate used to phosphorylate the 95,000-M_r protein in an intact cell, in the broken cell system this protein clearly accepts the phosphate from γ-labelled ATP. Second, the results suggest that an endogenous protein kinase(s) is(are) involved in this reaction and that this endogenous protein kinase activity exists in the plasma membrane fraction and after affinity chromatography on wheat germ agglutinin–agarose. Furthermore, insulin stimulates the incorporation of ^{32}P into the β subunit of insulin receptor at tyrosine residues only. Phosphorylation of tyrosine is rare in normal cells[21], but specific tyrosine phosphorylation of other proteins has been observed after cellular transformation by RNA tumour viruses[21–25] or stimulation of cell growth by epidermal growth factor (EGF)[26,27], platelet-derived growth factor[28] and a human transforming growth factor[29]. Insulin is also a strong growth promoter.

Although phosphorylation has been demonstrated in both the intact and broken cell, there are some differences between them. First, the dose–response curve of phosphorylation is shifted to the left, that is, it is more sensitive, in a cell-free system than in the intact cell. This may depend on several factors, including the conditions of assay and the source of membranes. Second, in the intact cell only the β subunit is phosphorylated, whereas in the cell-free system, both subunits of the insulin receptor are phosphorylated. This suggests the α subunit can also be a substrate for endogenous protein kinases, although the amount of phosphorylation of the α subunit is usually 15% or less than that of the β subunit. The reason we cannot detect the phosphorylation of α subunit in intact cells may be related to the low level of phosphorylation, to the topography of insulin receptor subunits in intact cells, to differences in the level of endogenous phosphorylation, or to differences between these liver membranes derived from normal rats and cultured tumour cells. Third, we have found that in the intact cell, the content of both phosphoserine and phosphotyrosine in the β subunit of the insulin receptor is increased after insulin stimulation[30], although in the intact cell the absolute amount of phosphotyrosine is very small compared with phosphoserine. In the broken cell system, however, only phosphotyrosine is found. These results suggest that the tyrosine phosphorylation of the β subunit may be the initial reaction which occurs on insulin binding and that phosphorylation of serine requires other components absent in cell-free systems. Similar differences of phosphoamino acid composition between intact cells and cell-free systems have been observed in the phosphorylation of RNA tumour virus oncogene products[21,23–25], and the receptor for EGF[26,27].

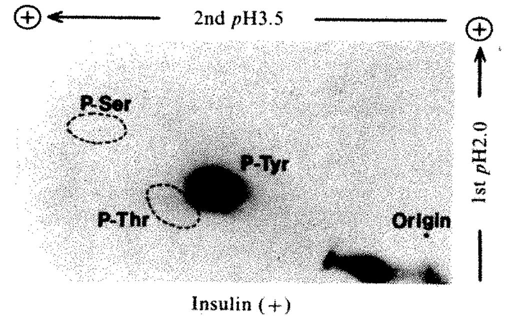

Fig. 2 Identification of phosphoamino acids in the 95,000-M_r phosphoprotein. The phosphoamino acids were analysed by a modification of the method of Hunter and Sefton[21]. The phosphorylation of the 95,000-M_r protein (β subunit of insulin receptor) was stimulated by insulin (10^{-7} M) as shown in Fig. 1. The 95,000-M_r bands, localized by autoradiography, were excised from the gel and the proteins eluted by electrophoresis at 150 V for 20 h into a dialysis bag containing 10 mM sodium phosphate buffer (*p*H 7.0) and 0.05% SDS. The samples were dialysed against 10 mM NH_4HCO_3, lyophilized, extracted by ethanol/ether (1 : 1 v/v) and then subjected to acid hydrolysis in 6 M HCl for 2 h at 110 °C. After lyophilization, the hydrolysates were spotted on Whatman 3MM paper. Electrophoresis was performed at *p*H 2.0 (formic acid/acetic acid/H_2O, 81 : 25 : 879) and 550 V for 60 min at 12 °C in the first dimension, and at *p*H 3.5 (pyridine/acetic acid/H_2O, 1 : 10 : 189) and 1,000 V for 105 min in the second dimension. Samples of authentic phosphoserine (Sigma), phosphothreonine (Sigma) and phosphotyrosine (a gift from Dr T. Hunter, Salk Institute) were added to all radioactive samples analysed. The standards were located by ninhydrin and are delineated by the broken lines. The radioactive material was located by autoradiography.

Our results provide the first demonstration, in a cell-free system of a covalent modification of the solubilized insulin receptor as a consequence of insulin–receptor complex formation. The mechanism by which insulin stimulates the incorporation of ^{32}P from [γ-^{32}P]ATP into its own receptor at tyrosine residue is not known. This system does, however, provide the opportunity to investigate whether the insulin receptor is a tyrosine protein kinase, as suggested for the EGF receptor[31], or a regulator of phosphoprotein phosphatase.

We thank Dr K. Yamada, J. Rath and M. Rechler for critical reading of the manuscript and for the gift of multiplication-stimulating activity. M.K. is a Capps Diabetes Scholar. This work was supported in part by a grant from the Juvenile Diabetes Foundation.

Insertion of diphtheria toxin into and across membranes: role of phosphoinositide asymmetry

James J. Donovan*†, Melvin I. Simon* & Mauricio Montal*†

Departments of *Biology and †Physics, University of California, San Diego, La Jolla, California 92093, USA

Diphtheria toxin (DT), a 63,000-molecular weight soluble protein, is toxic to most mammalian cells. The mechanism of intoxication involves a step in which one part of the molecule inserts into a membrane, facilitating the transport of the enzymatic fragment of the protein into the cytoplasm[1,2]. This event requires an acidic environment and seems to occur at the membrane of an endocytic vesicle[3,4]. Different cell lines and species differ in their sensitivities to DT—this is due at least in part to differences in the number of DT surface receptors on the cells[5], but may also arise from differences in the membrane transport step. It is generally recognized that protein–lipid

0028–0836/82/320669—04$01.00

interactions are of critical importance in membrane transport phenomena (see ref. 6). Thus, it is of interest to determine whether the interaction of DT with membranes is modulated by their composition. We have shown previously that DT interacts with planar lipid bilayers at acidic *p*H to produce voltage-dependent channels[7]. We report here that this interaction of DT with bilayers depends on membrane phospholipid composition; the interaction is optimal when inositides are present within the membrane, and the inositides are required on the side of the membrane opposite to that in which DT is introduced.

We investigated the effect of membrane composition on the interaction of DT with lipid bilayer membranes. Figure 1*a* illustrates the time course of the membrane current at a constant applied voltage of −40 mV recorded from two different membranes. The upper trace corresponds to a phosphatidylethanolamine (PE) membrane and the lower to an asolectin (AL, soybean phospholipids) membrane. AL is a mixture of phospholipids, the major components of which are PE, phosphatidylcholine (PC), phosphatidylinositol (PI), and phosphatidylserine (PS), and contains a small amount of α-tocopherol. The conductance of each unmodified membrane was low, as indicated by the small current in response to a voltage step. On addition of DT to the aqueous compartment, the conductance of the asolectin membrane increased due to the formation of ionic channels, whereas the current through the PE membrane remained almost unchanged. Channels do form in PE membranes if sufficient time is allowed, and if higher DT concentrations are used, but PE membranes are consistently much less sensitive to DT.

Alving *et al.*[8] have shown that the binding of DT to phospholipid vesicles at acidic *p*H is correlated with the membrane surface charge. This suggests that the difference between asolectin (~20% negative lipids) and PE membranes might be due to differential binding resulting from differences in surface charge or lipid composition. To evaluate this hypothesis, we tested a variety of lipids in our bilayer system. The data are summarized in Table 1, where the average rate of conductance increase for several lipids is shown normalized to the rate of increase for asolectin at a DT concentration of 100 ng ml^{-1}. Membranes consisting of the neutral lipids PC and PE are relatively insensitive to DT, but the same is true for the negative phospholipid, PS and the negative lipid oleoyl phosphate (OP) at surface charge concentrations comparable to asolectin. Similarly, glycolipids or gangliosides do not sensitize the membrane to DT. Diphosphatidylglycerol (DPG, cardiolipin) seems to confer some slight sensitivity to DT, but greater effects result from the presence of inositides in the membrane. As phosphatidylinositol is a major component of asolectin (~14%)[9,10], we believe that the PI in asolectin membranes is responsible for their sensitivity to DT. The fact that the PI–PC mixture is less DT-sensitive than asolectin could be due to the phytanoic acid chains on the PC because the acyl chain composition of the lipids affects DT binding[8]. Indeed, membranes formed with purified soybean PC, PE and PI exhibited DT-induced conductances comparable to asolectin, whereas substitution of PS for PI in this mixture rendered the membranes insensitive to DT (see Table 1). Channels do form in inositide-free membranes, but at a slower rate.

The rate of channel formation induced by DT is enhanced by the presence of a *p*H gradient. Similar results have been reported by Kagan *et al.*[11] who showed that a mutant form of DT, CRM 45, forms channels, and that the rate of conductance increase is greater in the presence of a *p*H gradient. For DT, we observed that in the presence of a 2-unit *p*H gradient (4.9–6.9, acid on the DT-containing side), the rate of channel formation was enhanced ~50-fold, regardless of the composition of the membrane. Thus, the relative conductances are unchanged by the *p*H gradient. To separate clearly the effects of *p*H and membrane composition, all the experiments reported here were performed with both sides of the membrane at *p*H 4.85.

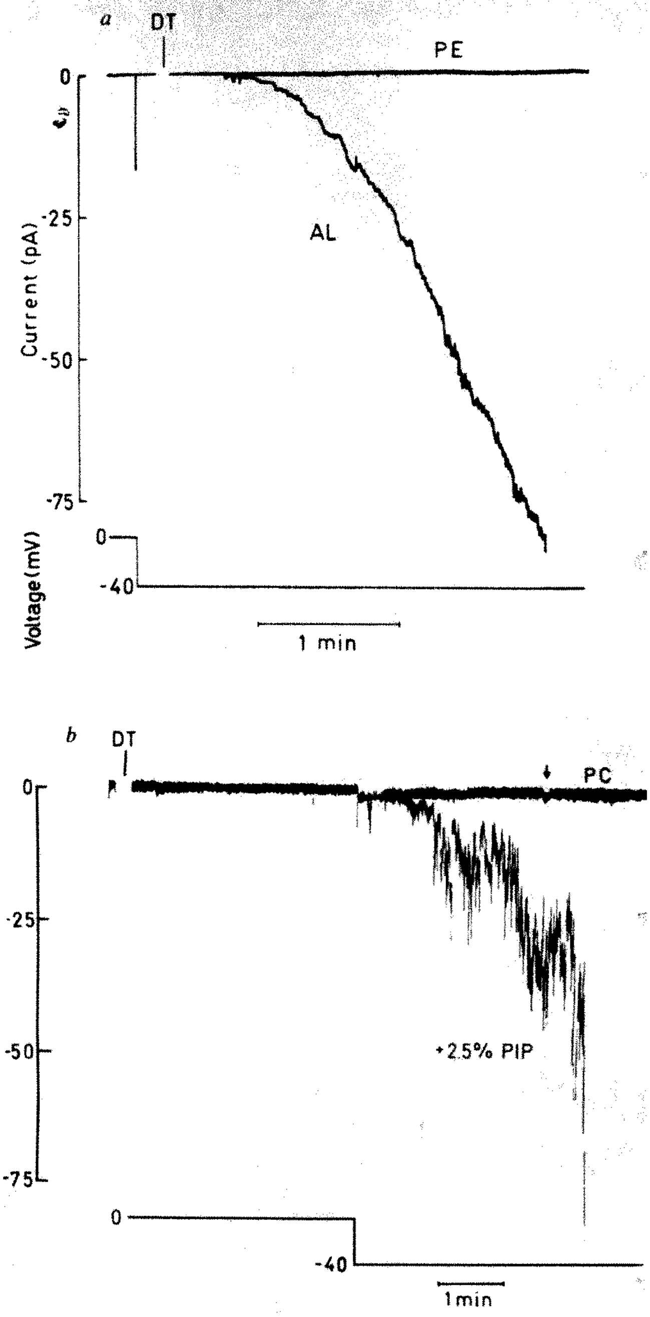

Fig. 1 Membrane currents at a constant applied voltage through symmetrical membranes treated with DT. Planar lipid bilayers were formed from monolayers as described elsewhere[23] across a 200-μm hole in a 12 μm-thick Teflon partition separating two 4-ml capacity Teflon compartments. The hole was treated with a 1% solution of squalene in pentane. Voltage was applied, and current measured using Ag/AgCl electrodes with an Analog Devices AD515 amplifier having a 1-GΩ feedback resistor. The DT-containing compartment is defined as being at zero potential, and positive current is the flow of positive ions into this compartment. *a*. Shows the current through two membranes before and after the addition of DT. The upper trace corresponds to a PE membrane, and the lower trace to an AL (soybean lipids purified by the method of Labarca *et al.*[24]) membrane. *b* Shows two current traces: the upper trace is from a membrane consisting of 100% PC (diphytanoyl phosphatidylcholine, DPPC) and exhibits a low conductance during which a single channel of DT opens and closes (arrow). The lower trace is from a membrane containing 97.5% PC and 2.5% PIP. Because of the low solubility of PIP in alkane solvents, the lipid solution was sonicated briefly before spreading the monolayers. All experiments shown were done at room temperature using 0.2 M NaCl/20 mM citrate buffer, *p*H 4.85. The DT concentration was 100 ng ml^{-1}. DT (Connaught) was purified by DE52 chromatography[25].

Another parameter which affects the potency of DT is nicking of the toxin. DT was nicked according to Drazin *et al.*[12]. The conductance induced by nicked toxin was increased relative to un-nicked toxin by an order of magnitude, and showed less variability.

Most interesting among the lipids studied here is phosphatidylinositol-4-monophosphate (PIP)[8]. This lipid (PI with an extra phosphate on the inositol ring) has a double negative charge at the *p*H of these experiments. It is most effective at sensitizing the membrane to DT, which seems to be due to the inositol or phosphoinositol moiety and not the charge, as diphosphoglycerate is also doubly charged, but is much less effective. Figure 1*b* illustrates the ability of PIP to sensitize a membrane to DT. The two superimposed current traces are for two different membranes, one of 100% PC and another of 97.5% PC with only 2.5% PIP. The addition of this small amount of PIP caused the current to increase dramatically in the presence of DT, even though the surface charge density was about one-quarter that for an asolectin membrane. Such current increases were not seen in the absence of DT.

The simplest explanation for these data is that DT binds to inositides, especially PIP, on the bilayer surface[8,13]. To test this notion, we prepared asymmetric lipid bilayers containing PIP exclusively in one monolayer. These membranes were made with lipid mixtures designed to have the same surface charge density in both monolayers. All other conditions, including DT concentration and *p*H, were also symmetric. Two superimposed traces of the current through asymmetric bilayers after the addition of DT are shown in Fig. 2*a*. When DT was added to the chamber in contact with the PIP face of the membrane, the membrane current was unaffected, except for some incidental current drift. In contrast, when DT was added to the PS side, the current increased dramatically after a significant lag time. Thus, although PIP does bind DT[8], it does not mediate channel formation primarily through DT binding, but has a more subtle role. We have shown previously[7] that the DT insertion and channel formation steps are distinct from the binding step. Our results indicate that phosphoinositides exert their effect not so much on the binding of DT but rather on either the insertion or channel formation step, and that they mediate this effect from the side opposite to that on which the DT is bound.

Table 1 Relative conductances induced by DT in symmetrical lipid bilayers of different composition

Membrane composition	Relative conductance*	
Asolectin	1.0±0.2	(10)
PE	≤0.001	(2)
DPPC	0.015±0.006	(3)
20% PS/80% DPPC	0.02±0.006	(3)
33% OP/67% DPPC	≤0.001	(2)
10% Glucocerebroside/90% DPPC	0.01±0.007	(2)
25% DPG/75% DPPC	0.058±0.022	(4)
10% Ganglioside/90% DPPC	0.02±0.015	(5)
25% PI/75% DPPC	0.16±0.07	(4)
5% PIP/95% DPPC	0.31±0.023	(3)
40% Soybean PC/40% PE/20% PI	0.82±0.022	(3)
40% Soybean PC/40% PE/20% PS	0.08±0.06	(3)

Values shown are mean conductance ±s.e.m. divided by the mean conductance for asolectin (number of experiments in parentheses). All conductances were obtained by incubating the membrane in the presence of DT for 4 min at 0 mV applied potential. Then, the potential was switched to −30 mV, and the conductance measured 1 min later. Asolectin membranes were generally treated with 100 ng ml^{-1} of DT; other membranes often needed higher DT concentrations. In these cases, the rate of conductance increase was taken as proportional to the square of the DT concentration[7,11]. Other conditions were as indicated in Fig. 1 legend. PE, PS, PI, PIP and soybean PC were obtained from Sigma, diphytanoyl phosphatidylcholine (DPPC) from Avanti, glucocerebroside and DPG from Supelco; OP was from Hooker Chemical. Gangliosides (mixed bovine brain) were the gift of E. Yavin; HPLC-purified soybean PC was given by M. Conrad. Lipids were dissolved in $CHCl_3$ (PIP in water-saturated $CHCl_3$) or $CHCl_3$/MeOH (2:1), and stored at −80 °C until use.

The effect of phosphoinositides seems to be due to an interaction of the inositol phosphate moiety with DT which is satisfied even if the inositol is added to the solution in contact with the membrane. Figure 2*b* shows the effect of adding inositol hexaphosphate (IHP, phytic acid) to the compartment on the toxin-free side of a PS-containing membrane. A current increase was apparent after DT addition only after IHP was added to a concentration of 0.5 mM; further addition of IHP further increased the conductance. In membranes untreated with DT, IHP had no effect on membrane conductance, and addition of IHP to the DT-containing side also had no effect (Fig. 3). The effect of IHP was the same in the presence of 1 mM EGTA or 1 mM Ca^{2+}, indicating that this effect is not due to any Ca^{2+} bound to the phosphate groups of the IHP. Rather, the inositol phosphate moiety seems to be essential for channel formation.

It is known that DT in solution binds IHP together with nucleotides and other polyphosphates[14,15]. Thus, the inositol phosphate effect could conceivably be due to its binding to the DT phosphate binding site, thereby anchoring the DT in a transmembrane conformation. If this were the case, presumably any polyphosphate should have the same effect. However, ATP, when added to the *trans* side of the membrane, does not affect DT channel formation (data not shown). Thus, the effect is specific: only phosphoinositide (or inositol phosphate) on the opposite side of the membrane induces DT channel formation.

We suggest a mechanism in which the DT first binds to the membrane surface, and then extends a process across the

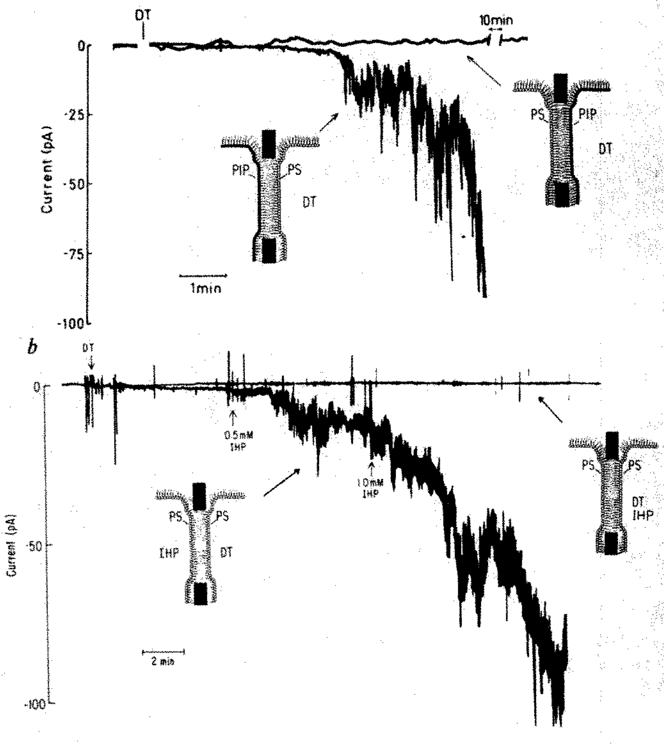

Fig. 2 *a*, Membrane currents through two asymmetric membranes treated with DT. The membranes were formed from two monolayers of different composition: one monolayer contained 10% PS and 90% PC, the other contained 5% PIP and 95% PC. The upper and lower traces show the current through the membrane when DT was added to the solution on the PIP-containing and PS-containing side, respectively. The applied potential was −30 mV throughout. DT concentration, 100 ng ml^{-1}. *b*, Membrane current through two symmetrical membranes in the presence of IHP. The membrane composition was 20% PS, 80% PC. The addition of DT to a concentration of 100 ng ml^{-1} caused no significant increase in conductance in either membrane. The lower trace shows the current after IHP (Sigma) was added to the side of the membrane opposite to that to which DT was added, and the upper trace shows the current obtained when IHP was added to the same side of the membrane as DT. The voltage was kept constant at −30 mV for both traces.

membrane core which probes the other side. If the DT finds phosphoinositide, and binds to it, anchoring it in place and allowing channel formation to occur. Thus, the critical steps in intoxication may be as follows. DT binds to a cell-surface receptor and is internalized. Once in the endosome, the acidic environment induces a conformational change in DT that, in concert with the membrane potential, promotes the binding and insertion of DT into the endosomal bilayer. The consequent binding to phosphoinositides anchors DT, allowing channel formation and, concomitantly, the translocation of the enzymatic moiety of DT into the cytoplasm. The notion that translocation of proteins across membranes involves conformational changes in the protein and the insertion of portions of the polypeptide chain has been suggested in a variety of contexts[16–19]. The requirements for insertion of the 'signal sequence' of some polypeptides are very similar to the requirements for DT channel formation[20–22]. The remarkable observation that channel formation is facilitated by the presence of inositides in the transmembrane monolayer suggests that specific polypeptide–lipid interactions can play a part in protein translocation.

Genetic recombination and directional selection for DDT resistance in *Drosophila melanogaster*

Phillip B. Flexon

School or Medicine, Case Western Reserve University, Cleveland, Ohio 44106, USA

Charles F. Rodell*

Department of Biology, College of St Benedict–St John's University, Collegeville, Minnesota 56321, USA

It is generally agreed that recombination offers a long-term evolutionary advantage[1,2]. It is argued, however, that because genetic variability exists for recombination rates in natural populations, response to immediate demands for adaptation should result in reduced recombination regardless of the long-term consequences. Nevertheless, genetic recombination persists. Numerous models have been developed to examine this fact[1,2]. There exists, however, a notable lack of empiricism on the recombination question. Here we demonstrate in *Drosophila* that the response of a polygenic character (DDT resistance) to directional selection is sufficiently correlated with the genetic variability generated by recombination to bring about a corresponding increase in recombination rate. We draw attention to the relationship of these results to existing models, notably the 'hitch-hiking' model[3].

Twenty-eight single female lines of *Drosophila melanogaster*, free from chromosomal inversions, were cultured from individuals collected in central Tennessee. On 8 August 1978, five inseminated females from each line were combined to establish two control populations (C1 and C2) and three selected populations (R1, R2 and R3). Populations were maintained in population units consisting of two 1/2-pint bottles united by a 7.6-cm piece of hose[4]. The cultures were maintained at 25 ± 1 °C and the bottles replaced alternatively every 2 weeks throughout the study. On 20 August 1978, selection for DDT (1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane) resistance was initiated on populations R1, R2 and R3 by placing a 2.5 × 7.5 cm strip of filter paper impregnated with DDT on the medium surface in each fresh bottle. Selection was carried out by gradually increasing the amount of DDT from 0.1 mg to 190.0 mg over the next 555 days.

Three kinds of data were gathered from these populations. Population levels of DDT resistance were measured to demonstrate that directional selection had occurred; cross-over frequencies for portions of chromosomes I, II and III were determined to detect differences in recombination rates between initial, control and selected populations; and individual chromosomes from the selected populations were tested for resistance. The level of chromosomal resistance attained was then related to changes in chromosomal recombination rates.

DDT resistance was measured by subjecting the daughters of sampled females to a knockdown test[4]. After 330 days of selection, populations R1, R2 and R3 achieved resistance levels 10–40 times greater than those of the control populations, demonstrating that selection was effective. The median effective dose (ED_{50}) for DDT was 5.3 and 6.4 mg for populations C1 and C2, respectively, and 207.5, 160.4 and 54.1 mg for R1, R2 and R3, respectively[5]. Population levels of DDT resistance were not tested again even though selection continued for another 165 days.

The 'recombination index' represents the number of recombination events observed divided by the total number of possible recombination events.

* Populations C1 and C2 were not exposed to DDT but in all other aspects were treated identically for the period of time shown.

† Recombination index determined for markers *w,m,f*.

‡ Recombination index determined for markers *dp, cn, bw*.

† Recombination index determined for markers *wmf*.

§ Recombination index determined for markers *Gl, Sb*.

The recombination data are summarized in Table 1. Following selection, recombination rates between loosely linked markers were determined for the major chromosomes in all populations. Initial rates were also determined for chromosomes I and III. It became necessary to change the markers for chromosome II after the experiment began; because of this change there are no initial data for that chromosome. These rates were obtained by crossing daughters of sampled females to marker stock males. F_1 daughters were again crossed to marker males and F_2 individuals scored for recombinant phenotypes. The data are expressed as a recombination index, representing the number of recombination events observed divided by the total number of possible recombination events. For chromosomes I and II with three markers per chromosome, the recombination index is computed by dividing the number of recombination events among F_2 individuals by twice the total number of F_2 individuals, as it is possible to observe a maximum of two recombination events in each individual. Chromosome III data are based on two markers; thus, the recombination index is the number of recombination events observed divided by the total number of F_2 individuals. One-way analysis of variance of the recombination index values for each chromosome indicated significant differences between populations for chromosomes II ($F_{4,137} = 8.64$; $P < 0.001$) and III ($F_{5,138} = 3.34$; $P < 0.01$) but no significant differences for chromosome I ($F_{5,127} = 0.45$; $P > 0.10$). Least-squares difference tests for the chromosome II values indicated no significant difference between the mean recombination index values for populations C1 and C2 and no significant differences between the means of the selected populations. However, each of the selected populations has a recombination rate ratio index significantly greater than each control population ($P < 0.05$ for all comparisons). The same results were obtained for the chromosome III data, that is $P < 0.05$ for each R population compared with each C population. These results indicate that a change in the level of DDT resistance brought about by directional selection was accompanied by a significant increase in the intrachromosomal recombination rate for portions of two of the three major chromosomes in this species.

The final step consisted of testing the level of DDT resistance for each chromosome separately. The rationale behind this step is as follows. If genes affecting recombination rates are maintained to any significant extent in populations as a result of producing new favourable recombinants, then the recombination genes must be sufficiently linked to these recombinants in order to 'hitch-hike' their way to a higher frequency. As significant increases in recombination frequency were found on chromosomes II and III, the hitch-hiking hypothesis predicts that these same chromosomes would possess the major genetic component for DDT resistance.

Individuals with the desired combination of unselected (C) and selected (R) chromosomes were obtained from a series of crosses by using inversion-containing marker chromosomes (Fig. 1). Again, females alone were evaluated for resistance by knockdown tests[4]. The results are striking when the chromosomal level of resistance, as indicated by the ED_{50} values[5], is compared with the ratio of selected chromosome recombination rate to that of the control chromosomes (Fig. 2), that is, chromosomal response for DDT resistance compared with chromosomal response in recombination rate. The greater the chromosomal response in recombination rate, the greater was the chromosomal response for DDT resistance; this significant positive correlation supports the hitch-hiking hypothesis.

It is necessary to consider whether the increases in recombination rate observed in the selected populations might be due to some factor other than selection. It seems unlikely that mutation could have caused this change. Studies on the

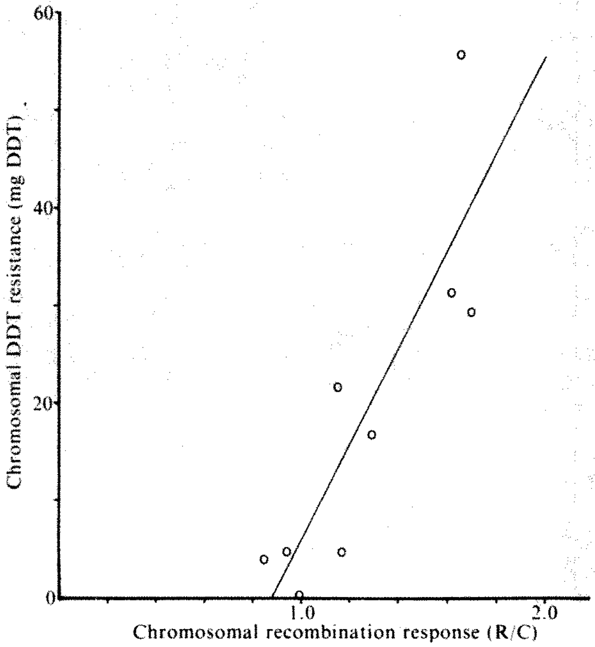

Fig. 2 The relationship between the level of chromosomal DDT resistance and chromosomal recombination response. The latter is taken as the ratio of the R population recombination index to the mean recombination index of the two C populations for a given chromosome: $y = 49.7x - 43.7$; $r_{yx} = 0.86$, $P < 0.01$ for H_0: $r_{yx} = 0$.)

mutagenic ability of DDT indicate that it is either nonmutagenic[6-9] or is only a weak mutagen[10,11]. It is possible that the increases were brought about by genetic drift. Because the selected populations were smaller in number than the control populations, the high rate alleles may have drifted to high frequencies. However, the fact that all populations responded in the same way favours directional selection as the major determinant of recombination rate increases.

These results are of interest in two respects: they provide the first demonstration of increased recombination correlated with the response to directional selection by a different quantitative character, and confirm the proposal that recombinant genes generating genotypes favoured by selection can 'hitch-hike' to increased allele frequencies[3]. For hitch-hiking to be a major factor in maintaining recombination in natural populations, these populations must experience either continuing directional selection or normalizing selection with a moving optimum[12]. Whenever a balancing selection model is analysed , selection for decreased recombination results[1,2,13]. The question becomes one of the relative importance of normalizing selection with a stable optimum as opposed to selection where the optimum is changing with time. The stabilizing selective mode might be favoured by those who prefer to think of adaptation as a response primarily to abiotic stresses such as temperature and humidity, or intraspecific interactions such as courtship, which present a more or less fixed range in which the species must adapt. It can be argued that adaptations to interspecific biotic stresses may be more important and more prevalent than those to abiotic stress[14-16]. Such co-evolutionary relationships are more likely to involve selection of the kind favouring recombination.

We thank Lisa D. Brooks, David J. Merrell and Michael J. Simmons for their critical comments on an earlier version of the manuscript. The marker stocks were supplied by the Mid-America Drosophila Stock Center, Bowling Green, Ohio.

Maintenance of broad host range plasmid RK2 replicons in *Pseudomonas aeruginosa*

Christopher M. Thomas, Atta A. K. Hussain & Christopher A. Smith

Department of Genetics, University of Birmingham, PO Box 363,
Birmingham B15 2TT, UK

Certain members of the *Escherichia coli* plasmid incompatibility group P are capable of efficient transfer between and maintenance in most Gram-negative bacterial species[1-4]. Of fundamental interest is whether this broad host range results from differences between the mechanisms of replication and partitioning during cell division used by IncP plasmids and by narrow host range plasmids. The genetic regions of IncP plasmid RK2 (similar or identical to RP4 and RP1) required for plasmid maintenance in *E. coli* have previously been defined as a vegetative replication origin (ori_{RK2}) and a gene specifying a positively required *trans*-acting product (*trfA*)[5-8]. Here we have tested various mini RK2 replicons for their ability to become established after transformation into *Pseudomonas aeruginosa* PAO as a model non-*E. coli* host. We chose *P. aeruginosa* for this purpose as it is a Gram-negative species relatively phylogenetically distant from *E. coli*. Our studies have defined a plasmid segment that contains a region which must be linked in *cis* to the ori_{RK2} replicon to allow mini RK2 plasmid maintenance in *P. aeruginosa* PAO and suggest that RK2 may carry genes which adapt the basic replicon to allow autonomous maintenance in specific groups of hosts.

A simplified physical and genetic map of plasmid RK2 is shown in Fig. 1. A segment of the plasmid genome (from coordinates 54.0 to 56.0 kilobases (kb)) has been designated the *trfB* region because experiments carried out in *E. coli* indicate that it contains a gene, *trfB*, that specifies a *trans*-acting product acting in plasmid replication or maintenance when the *trfB* region is part of the RK2 replicon[7,8]. The requirement for at least part of this region for establishment in *P. aeruginosa* has been suggested by the inability of unstable RP4 mutants with transposon Tn*7* inserted in the *trfB* region to transfer from *E. coli* to *P. aeruginosa*[9]. Also, a mutation has been described[10] that renders RP4 temperature-sensitive for maintenance in *P. aeruginosa* but not in *E. coli* and which physically maps in a plasmid segment that contains *trfB* but not *trfA* or ori_{RK2}.

We have analysed the *trfB* region requirement by testing the ability of mini replicons derived from RK2 by *in vitro* recombination and isolated from *E. coli* to be introduced by transformation into the restriction-deficient *P. aeruginosa* PAO1161. The structures of the plasmids we have used are shown in Fig. 2 and the results of transformation in Table 1. If a plasmid seemed to become established in PAO1161, plasmid DNA was isolated by the alkaline extraction method of Birnboim and Doly[11] and its structure verified by restriction endonuclease digestion pattern analysis. Our initial observation was that whereas mini RK2 replicons carrying all three regions, ori_{RK2}, *trfA* and *trfB* (pRK248), were capable of establishment in PAO1161,

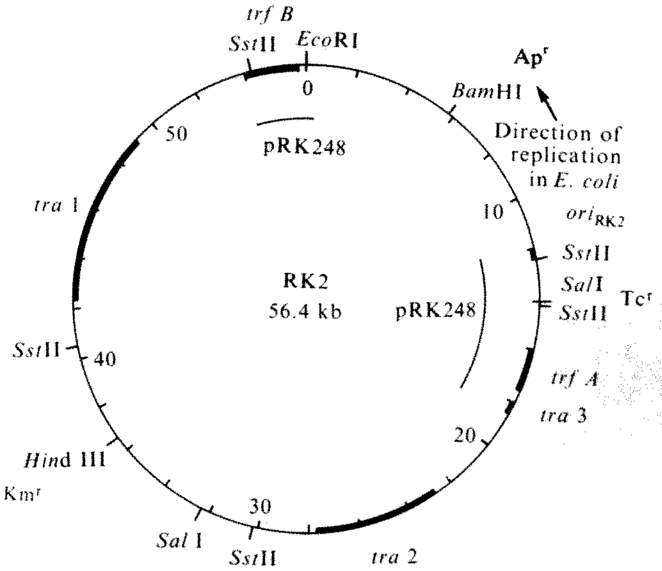

Fig. 1 Simplified physical and genetic map of broad host range plasmid RK2 (RP4 and RP1). Only a few restriction sites are shown as reference points. The single *Eco*RI site is used as the origin of kilobase pair (kb) coordinates. The regions specifying resistance to ampicillin (Ap^r), tetracycline (Tc^r) and kanamycin (Km^r) are shown together with regions (indicated by heavy lines) specifying genes required for conjugal transfer (*tra*), the vegetative replication origin (ori_{RK2}) and regions containing genes specifying *trans*-acting replication or maintenance functions (*trf*). The segments of RK2 present in the mini replicon pRK248 are shown.

Table 1 Results of transforming *P. aeruginosa* PAO1161 (Leu$^-$Res$^-$Mod$^+$) with DNA of mini RK2 replicons isolated from *E. coli* K12 C600 ΔtrpE5

	Average no. of transformants per plate*		
Plasmid	PAO1161	PAO1161 (pCT407)	PAO1161 (pCT408)
pRK248	2,000	89	2,000
pCT201	0	0	0 (6)†
pCT398	1,500	104	1,500
pCT427	200	14	1,000
pCT428	600	20	1,200

PAO1161 was made competent for transformation by pelleting 10 ml of late exponential phase culture ($A_{1\text{cm},625} \approx 1.0$) grown in L broth (10 g tryptone, 5 g yeast extract, 5 g l^{-1} NaCl) at 30 °C, washing with 4 ml ice-cold 100 mM $MgSO_4$, incubating in 4 ml ice-cold 100 mM $CaCl_2$ for 20 min and finally resuspending in 1 ml ice-cold 100 mM $CaCl_2$. Approximately 1 μg of DNA was mixed with 100 μl of competent bacteria and incubated at 0 °C for 60 min. After 2 min at 42 °C, 1.0 ml of L broth was added and after 120 min at 30 °C, 9 ml of L broth with tetracycline to 10 μg ml^{-1} was added. After overnight incubation at 30 °C, 0.2-ml samples were plated on L agar (L broth with 15 g l^{-1} agar) with 100 μg ml^{-1} tetracycline and incubated at 30 °C. pCT407 is an IncQ plasmid, R300B[9] (conferring resistance to streptomycin and sulphonamide) linked to *trfB*. pCT408 is R300B linked to *trfA* and *trfB*.

* If Tc$^{\text{r}}$ transformants were obtained the presence of independent plasmid DNA was verified by extraction and examination of plasmid DNA[11].

† On one occasion Tc$^{\text{r}}$ transformants were obtained but examination of plasmid DNA indicated that the tetracycline resistance was conferred by a recombinant between pCT201 and pCT408.

pCT201, which lacks all but 150 base pairs of the *trfB* region, was not. The *trfB* region was reinserted into pCT201 by *in vitro* recombination and the resultant plasmid (pCT398) was found to be capable of transforming and being maintained in PAO1161 (pCT398 is lost from PAO1161 at ~4–5% per generation in the absence of selection for plasmid markers). Therefore, the inability of pCT201 to transform PAO1161 is due to the lack of the *trfB* region rather than to a secondary defect located elsewhere on the plasmid.

To determine whether the requirement for all or part of the *trfB* region is solely to provide a *trans*-acting product necessary for *ori*$_{\text{RK2}}$ or *trfA* function in PAO1161, we cloned both *trfB* alone (pCT407) and *trfA* together with *trfB* (pCT408) into IncQ broad host range plasmid R300B by *in vitro* recombination and introduced these plasmids into PAO1161. The presence of *trfA* and *trfB* in the PAO1161 host did not significantly increase its ability to be transformed by pCT201. In one experiment, transformants were obtained but the restriction pattern of the plasmid DNA isolated from these transformants suggested that they contained a hybrid plasmid resulting from recombination between pCT201 and pCT408 after entry rather than pCT201 and pCT408 existing as separate plasmids. These results were interpreted to mean that part or all of the *trfB* region is needed linked in *cis* to pCT201 to allow establishment and maintenance in PAO1161 rather than simply for DNA entry into competent bacteria. Insertion of only part of the *trfB* region into pCT201 also restores the plasmid's ability to transform PAO1161, although the stability of these plasmids (pCT427 and pCT428) without selection for plasmid markers in PAO1161 is less than for pCT398 (pCT427 is lost at 5–10% per generation and pCT428 at 8–12% per generation). The limits of the essential segment of the *trfB* region are not known. The orientation of the inserted *trfB* segment relative to *ori*$_{\text{RK2}}$ and *trfA* (pCT427 and pCT428) does not matter so it seems unlikely that the *trfB* region is providing a transcription promoter active in *P. aeruginosa* that is necessary for *ori*$_{\text{RK2}}$ or *trfA* function.

As these results indicate that *ori*$_{\text{RK2}}$ and *trfA* as defined in *E. coli* are not sufficient for establishment and maintenance in *P. aeruginosa*, it could be that one or both of these regions is not needed in *P. aeruginosa*. However, we were unable to transform a plasmid containing *trfA* and *trfB* but lacking *ori*$_{\text{RK2}}$ (pCT141) into PAO1161. Also RP4.ColE1 hybrids with transposon Tn*7* inserted either into *ori*$_{\text{RK2}}$ or *trfA* (obtained from A. Stepanov) are incapable of conjugal transfer from *E. coli* to *P. aeruginosa* and *trfA* temperature-sensitive mutants are unstable at the non-permissive temperature in *P. aeruginosa*.

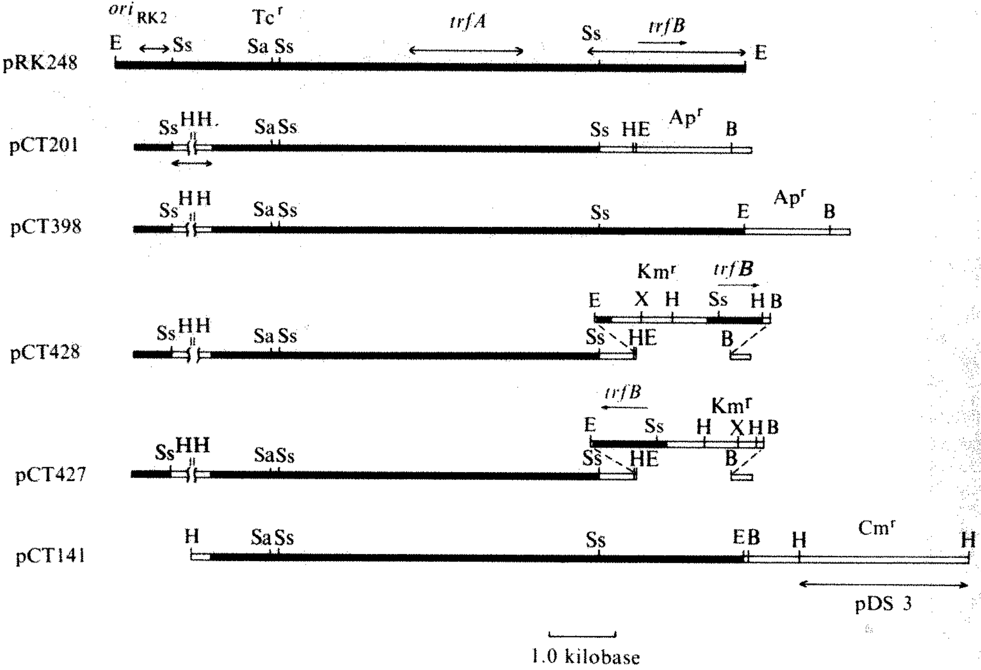

Fig. 2 Structure of mini RK2 replicons used to investigate the requirement for segments of the *trfB* region in *P. aeruginosa*. Sites for restriction endonuclease cleavage are labelled as follows: *Bam*HI, B; *Eco*RI, E; *Hin*dIII, H; *Sal*I, Sa; *Sst*II, Ss; *Xho*I, X. The segments of DNA derived from RK2 are shown as solid lines, non-RK2-derived DNA as open lines. The circular plasmids are represented as linear molecules with the break point defined by the *Eco*RI site for pRK248 and the other plasmids aligned with respect to the RK2 maintenance functions. pRK248 (9.6 kb) was produced indirectly from RK2 by partial digestion with restriction endonuclease *Hae*II and ligation[7] (Fig. 1). pCT201 (10.5 kb) was constructed by ligating two *Hin*dIII fragments, one containing Tc$^{\text{r}}$, *trfA* and ~150 base pairs of the *trfB* region and the other Ap$^{\text{r}}$ and *ori*$_{\text{RK2}}$. pCT398 (12.0 kb) was constructed by linking pCT201 to a hybrid plasmid carrying *trfB* and then carrying out *Sst*II partial digestion to delete the intervening DNA segment and join the partial *trfB* segment already present in pCT201 to the rest of the region containing *trfB*. pCT427 and pCT428 were constructed by replacing the Ap$^{\text{r}}$ *Bam*HI to *Eco*RI segment of pCT201 by a Km$^{\text{r}}$ *Bam*HI to *Eco*RI segment from hybrid plasmids containing segments of a mini RK2–Km$^{\text{r}}$ plasmid inserted into the *Cla*I site of pBR322. The two derivatives used have Km$^{\text{r}}$ and part of the *trfB* segment as shown inserted in opposite orientations relative to the *Bam*HI and *Eco*RI sites. pCT141 (11.8 kb) is a hybrid with a Tc$^{\text{r}}$ *Hin*dIII fragment carrying *trfA* and *trfB* inserted into a chloramphenicol resistance-conferring (Cm$^{\text{r}}$)Tc$^{\text{s}}$ derivative, pDS3, of pACYC184.

We therefore concluded that both ori_{RK2} and *trfA* are required in *P. aeruginosa* as well as part of the *trfB* region.

In *E. coli*, RK2 is known to code for several host lethal functions (*kil*) whose effects are normally suppressed in *trans* by other RK2 genes (*kor* functions)[12]. However, it seems unlikely that the phenomenon described here is solely due to the action of such a *kil* function that is active in *P. aeruginosa* but not in *E. coli*, because these might be expected to be suppressed by *trfB* in *trans* as well as in *cis*, which is not observed. Although we have demonstrated a *cis* requirement for part of the *trfB* region the results do not rule out the possibility that the *trfB* region also provides a necessary *trans*-acting product. The requirement for this extra DNA in *P. aeruginosa* may be at any or all of the stages of establishment (between DNA entry by transformation or conjugation and steady-state maintenance), replication or segregation. A defect in segregation, however, might be expected to lead only to unstable maintenance rather than to an absolute defect in maintenance[13–15]. Possible *cis* functions for the *trfB* region in establishment or replication in *P. aeruginosa* but not *E. coli* include: the provision of a replication origin used in *P. aeruginosa* (the mode of replication of RK2 in *P. aeruginosa* might require two functionally distinct replication origins, as in animal mitochondrial DNA replication[16]); the provision of a binding site for a protein that may subsequently migrate to a site of action elsewhere in the replicon—for example, at ori_{RK2}; the provision of a recombination site functional in *P. aeruginosa*, to allow the resolution of plasmid multimers, as these are thought to interfere with plasmid maintenance in other systems[17,18].

It is clear in the case of the mini RK2 derivatives used in the present study that whereas ori_{RK2} and *trfA* are sufficient to form a functional replicon in *E. coli*, they are not sufficient in *P. aeruginosa*. Linkage of the *trfB* region in *cis* to ori_{RK2} and *trfA* can overcome this defect, forming a replicon functional in *P. aeruginosa*. However, it is not known whether the *trfB* region is essential in any other bacterial host. One interpretation of our results is that RK2 may possess a basic replicon similar to that of other plasmids (ori_{RK2} and *trfA*) plus additional genetic information which enables this replicon to function in diverse Gram-negative bacterial species, for example, the *trfB* region in *P. aeruginosa*. We do not know whether other broad host range plasmids contain regions functionally analogous to the *trfB* region of RK2. If they do, analysis of the role of the *trfB* region in RK2 maintenance may shed light on the reason that certain groups of plasmids have a broader host range than many others.

Point mutations during generation of expression-linked extra copy of trypanosome surface glycoprotein gene

Allison C. Rice-Ficht, Kenneth K. Chen & John E. Donelson

Department of Biochemistry, University of Iowa, Iowa City,
Iowa 52242, USA

Trypanosomes exhibit antigenic variation by the sequential expression of a series of antigenically distinct variable surface glycoproteins (VSGs). On the basis of cDNA sequencing and/or terminal amino acid analyses of 10 *Trypanosoma brucei* VSGs[1–6], the approximately 500 amino acids of a nascent VSG can be divided into (N-terminus to C-terminus) a hydrophobic signal peptide (~20 amino acids), a variable region (~360 amino acids), a homology region (~100 amino acids) which can be used to classify the VSGs into one of two homology subsets and a hydrophobic tail (~20 amino acids) that is not present in the mature VSG[4,5]. Expression of some VSGs is accompanied by the production of an expression-linked extra copy (ELC) of a basic copy (BC) VSG gene[7–9]. We have now compared the sequence of a cDNA representing an ELC gene with its corresponding BC gene sequence. We find that the codons specifying the variable region contain nucleotide changes at 4% of the positions, while those specifying the homology region of the VSG are identical and the 17 codons specifying the C-terminal hydrophobic tail contain 11 nucleotide changes. The 3′-nontranslated region between the termination codon and the poly(A) (in the cDNA) is quite different in the two sequences. As the trypanosome serodeme contains only one BC gene coding for this VSG, point mutations seem to be actively introduced into specific areas of the coding sequence during the generation of the ELC gene. These point changes potentially increase the repertoire of immunologically distinct VSGs available to the trypanosome, similar to the way in which somatic mutations contribute to the diversity of the variable regions of immunoglobulins[10]. An alternative interpretation that cannot be completely eliminated is that a second BC gene is lost during the generation of the ELC.

One hundred or more different VSG genes exist in the trypanosome genome, and only one of them appears to be expressed at a given time (see refs 11–13 for reviews). The evidence suggests that this differential expression is controlled at the level of DNA transposition/recombination. On the basis of Southern hybridization data, these transpositions involve either the production of a transcriptionally active ELC from a transcriptionally silent BC gene[7,9,14] or a rearrangement of sequences flanking the 3′ end of a transcribed VSG gene[7,8,15]. For example, we have recently reported[4] the cDNA sequences of four VSGs from well-characterized *T. brucei* clones[9,15,16] that are serially related as follows:

$$\begin{tikzcd}[row sep=tiny] & & \text{ILTAT 1.3} \\ \text{ILTAT 1.1} \arrow[r] & \text{ILTAT 1.2} \arrow[ur] \arrow[dr] & \\ & & \text{ILTAT 1.4} \end{tikzcd}$$

Southern hybridization data described previously[9] indicated that a single BC gene for the ILTAT 1.1 (clone A in ref. 9) VSG is expressed via the ELC mechanism. In contrast, the VSGs expressed in ILTATs 1.2, 1.3 and 1.4 (clones B, C, D in ref. 9) are each specified by a pre-existing gene (one of two to four closely related genes) in which rearrangements on the 3′ side of the termination codon are detected in the different trypanosome clones[9,15,16].

The BC gene for the ILTAT 1.1 VSG occurs on a 2.8 kilobase (kb) *Eco*RI fragment in the genomic DNAs of all four ILTATs while its corresponding ELC occurs in the genomic DNA of only ILTAT 1.1 on an *Eco*RI fragment of ~20 kb (ref. 9, Fig. 3). Attempts to identify the ELC in a partial *Sau*3A

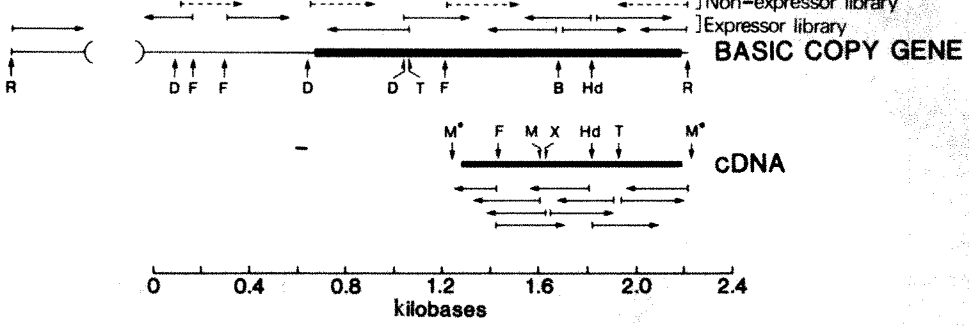

Fig. 1 The regions sequenced (indicated by horizontal arrows) in the BC gene and the cDNA for the VSG of ILTAT 1.1. The BC gene (thick line of upper diagram) is on a 2.8 kb *Eco*RI fragment that was initially identified in bacteriophage λ Charon 4A libraries of ILTAT 1.1 (expressor library) and ILTAT 1.3 (non-expressor library) genomic DNA. The 2.8 kb *Eco*RI fragment isolated from a phage clone of each library was subcloned into the *Eco*RI site of pBR322 for sequence determination using the Maxam–Gilbert technique[18]. The dashed arrows show the locations of sequences determined in the 2.8 kb fragment isolated from the ILTAT 1.3 (non-expressor) library and the solid arrows sequences determined in the same fragment isolated from the ILTAT 1.1 (expressor) library. Parentheses show a region of about 250 bp where the sequence was not obtained. The bottom diagram shows the restriction sites used to determine the sequence of the cDNA. In both diagrams, arrows pointing to the left and right are sequences obtained on the upper and lower strands respectively. Restriction sites labelled by the DNA polymerase I repair reaction[33] for Maxam and Gilbert sequencing were *Eco*RI (R), *Dde*I (D), *Hin*fI (F), *Taq*I (T), *Bam*HI (B), *Hin*dIII (Hd), *Xba*I (X), *Msp*I (M) and *Msp*I sites in pBR322 (M*).

library of ILTAT 1.1 DNA cloned in bacteriophage λ Charon 28 have not been successful (J. R. Young, P. A. O. Majiwa, P. T. Englund, R. O. Williams and J.E.D., unpublished) for unknown reasons that may be related to flanking repetitive sequences and/or the chromosomal location of the ELC[17]. However, the 2.8 kb *Eco*RI fragment containing the BC gene was found in bacteriophage libraries of all four ILTAT DNAs. This fragment was isolated from a phage clone of the ILTAT 1.1 DNA (expressor) library and an ILTAT 1.3 DNA (non-expressor) library and both fragments were subcloned into the *Eco*RI site of plasmid pBR322 for sequence determination via the Maxam and Gilbert technique[18]. Figure 1 shows the strategies used to determine these two genomic DNA sequences and the sequence of an ILTAT 1.1 VSG cDNA. More than 95% of the BC gene sequence was determined in the 2.8 kb fragment from the non-expressor library (dashed arrows) and about 90% in the fragment from the expressor library (solid arrows), so that taken together the complete sequence of the BC gene could be deduced. No differences were detected in the 2,100 nucleotides of each of the two genomic fragments that were determined separately, but many differences with the ILTAT 1.1 VSG cDNA were found.

Figure 2 compares the BC gene and cDNA sequences. Boxes indicate the non-homologous nucleotides. Also shown is the VSG amino acid sequence predicted by the BC gene sequence and those amino acids affected by the cDNA differences. The 696 nucleotides preceding the BC gene contain many termination codons in all three reading frames. A potential initiator methionine codon at position 697 is followed by an open translation reading frame of 471 codons which would code for a protein in the size range reported for different VSGs[12]; this suggests that the gene is not split by an intervening sequence. The first 15 codons specify a rather hydrophobic N-terminus which may be a signal peptide, although this cannot be confirmed on the basis of nucleotide sequence alone. The comparison with the cDNA sequence starts at nucleotide position 1,287 and in the next 450 nucleotides, there are 18 nucleotide differences (4% of the nucleotides) which affect 13 of the amino acids specified (9% of the amino acids). There is no obvious pattern to these changes with respect to either relative position or purine versus pyrimidine replacements. No differences occur in the next 324 nucleotides but then 11 changes occur in the last 46 nucleotides before the termination codon. The two sequences are very different in the 3′-non-translated region.

To ensure that these nucleotide differences were not the result of copying mistakes by enzymes used *in vitro* to construct the cDNA, portions of the sequences of two additional cDNAs containing the ILTAT 1.1 VSG coding sequence were determined (not shown). The same point changes were also present in the other two cDNAs, reducing substantially the possibility that they were the result of copying or cloning mistakes. Interestingly, one of the cDNAs did contain only four adenosines at positions 1,689–1,693 (and four thymidines in the complementary strand) in comparison with the five adenosines at this location in the other two cDNAs and the two genomic fragments. Since other cloned cDNAs with sequence errors have been reported previously[19,20], it seems likely that this single base pair deletion is the result of an enzymatic mistake during the synthesis of that cloned cDNA molecule *in vitro* or during its replication after transformation into *Escherichia coli*. Another less likely possibility is the occurrence of incorrect VSG mRNA transcription *in vivo*. At the very least, this observation demonstrates the hazard of relying on a single cloned cDNA molecule to determine a coding sequence.

Further confirmation that the point changes occur during the generation of the ELC *in vivo* was derived from previous Southern hybridization data which predicted that the ILTAT 1.1 BC gene contains a *Bam*HI site while the ELC gene does not[9]. And indeed, the sequence of the BC gene has a *Bam*HI site at positions 1,697–1,702 while the cDNA sequence does not because of a single nucleotide difference at position 1,700. Similarly, Southern hybridizations demonstrate that if there are two copies of the BC gene because the parasite is diploid[21], then both copies contain a *Bam*HI site while the ELC does not. Thus it appears that these nucleotide changes occur during the duplication and translocation events that generate the ELC from the pre-existing BC.

Figure 3 shows the locations of the nucleotide changes with respect to the different VSG regions specified. Eighteen changes occur in the variable region, none in the homology region, eleven in the hydrophobic tail and many in the 3′-non-translated region which possesses no more homology than would be expected of two random 80% (dA + T) sequences (49 differences in 84 nucleotides = 58%).

An alternative explanation of the results is the loss of a second BC gene concomitant with the appearance of the ELC but this seems unlikely for at least two reasons. Unfortunately this possibility cannot be formally eliminated, however, because ILTAT 1.1 is the first clone in the ILTAT series to be maintained (R. O. Williams, personal communication) so that genomic DNA from a trypanosome clone preceding ILTAT 1.1 is unavailable. However, when ILTAT 1.1 cDNA is used as a radioactive probe in Southern hybridizations with genomic DNA from *T. brucei* clones unrelated to the ILTAT series, only one BC gene is detected (not shown). In addition there is no evidence that the appearance of ELCs of other VSG genes being studied by other research groups is accompanied by the loss of a BC gene[5–8,14]. Thus if a second BC gene existed, the simultaneous loss of one BC gene and appearance of an ELC would represent a third type of DNA rearrangement associated with VSG expression. Furthermore, a hypothetical second BC gene still would not account for the confinement of random

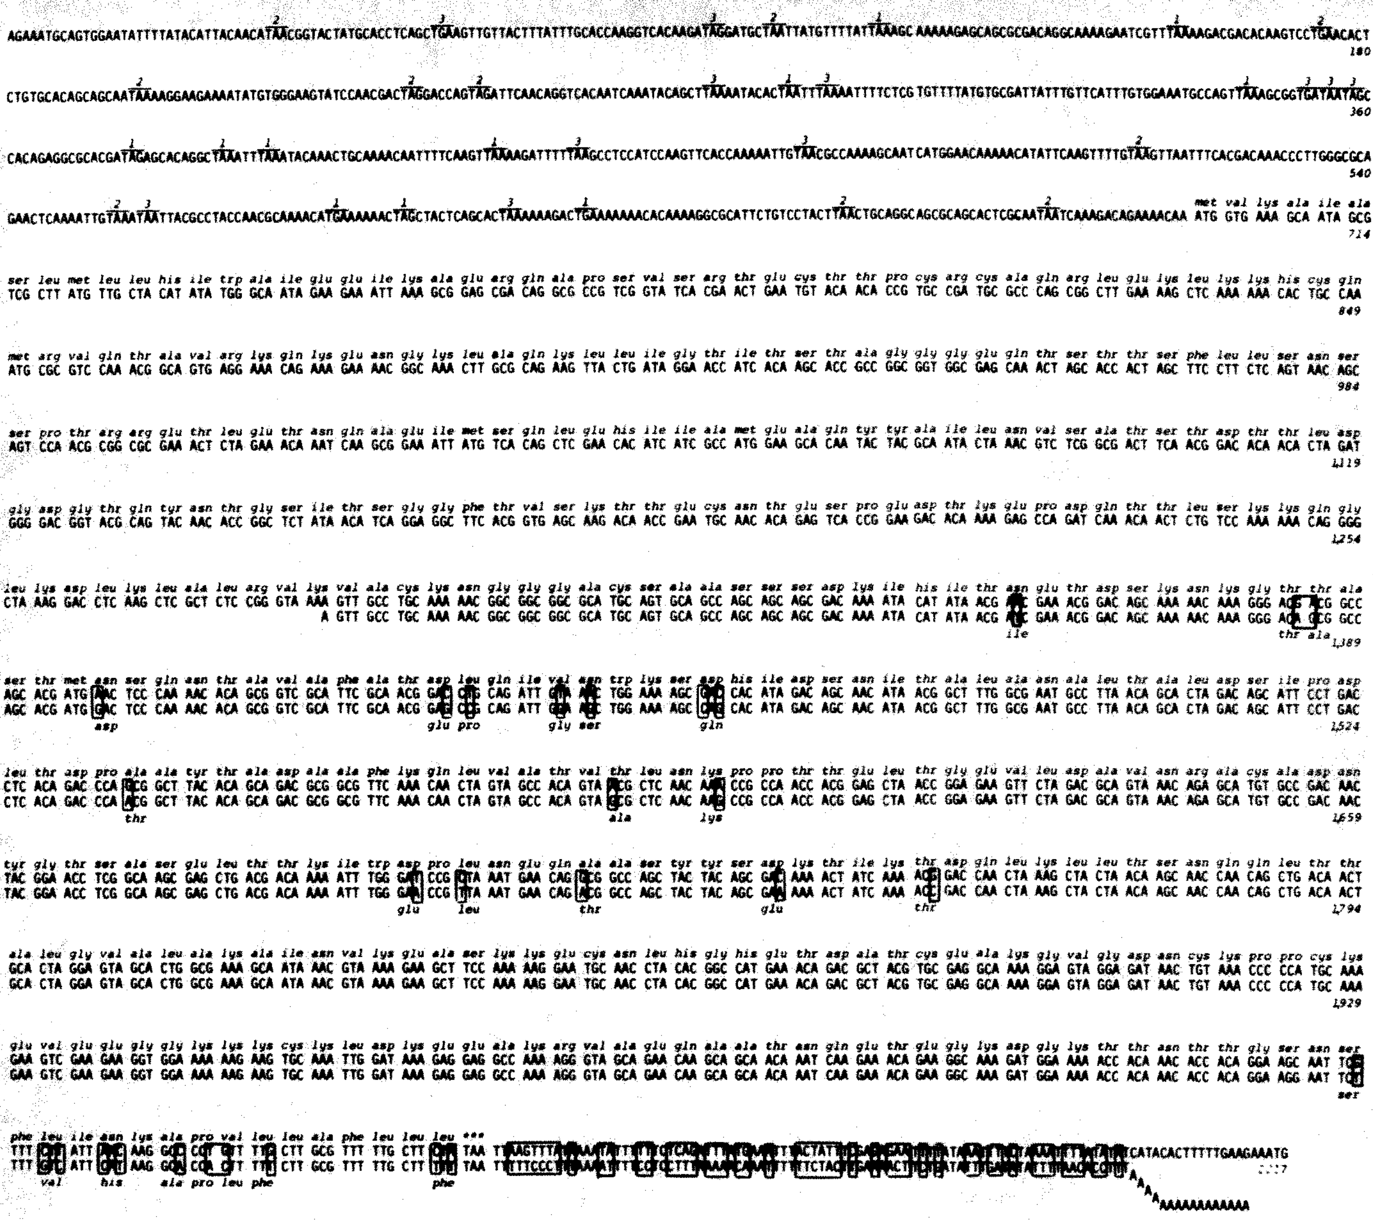

Fig. 2 Comparison of the coding strands of the BC gene (upper sequence) and the cDNA (lower sequence beginning at nucleotide 1,287) and the corresponding amino acid sequences predicted by the two nucleotide sequences. Boxes indicate nucleotides that differ in the two sequences. The amino acids below the cDNA are predicted from the cDNA sequence at locations where the cDNA and BC gene sequences differ. At all other locations the predicted amino acids are the same. ***, The termination codon at the end of the basic copy gene. The numbers above the first 696 nucleotides before the start of the BC gene indicate in which of the three reading frames the termination codons occur. The BC gene itself is in reading frame 1.

point changes to only the sequence coding for the variable and hydrophobic tail regions (see next paragraph).

Therefore the simplest interpretation of the data is that the generation of the ELC involves (1) a homologous recombinational event at a site just before or including the region coding for the hydrophobic tail and (2) a DNA polymerase system that replicates with low fidelity during the duplication event. Unexplained is the absence of point mutations in the homology region. If nucleotide changes were introduced with the same frequency here as in the variable region (4%) one would expect about 13 differences instead of none. Thus it seems unlikely that this region has escaped mutation just by chance although this possibility cannot be eliminated on the basis of this one example. Other possibilities are that a localized mutagenesis mechanism exists which does not act on this area or that mutations in this area are lethal because they result in a VSG that is non-functional. The latter possibility also seems unlikely because we have shown previously[4] that, although the homology region is highly conserved in VSG subsets, many amino acid changes and even deletions are tolerated. Although localized mutagenesis seems the most feasible explanation for this one example, sequence comparisons of other BC genes with their ELCs or cDNAs are needed to confirm its occurrence.

Although the mechanism(s) that generate(s) these mutations may be obscure, their biological significance is not. In influenza virus, a difference in less than 5% of the amino acids of the surface antigen is sufficient to change the antigenic specificity[22]. Therefore the trypanosome mutations could potentially increase the repertoire of immunologically distinct VSGs that are coded for by a limited number of different genes. They may in fact generate virtually an infinite number of potential VSGs for the trypanosome in the same way that somatic mutations are responsible, in part, for the immense diversity of antibodies generated by lymphocytes in the immune response (for a recent review, see ref. 10). These somatic mutations in the V segments of antibody genes occur in both the hypervariable regions and the framework residues and sometimes occur during the isotype switch from one constant region gene to another[23], so they may be introduced by a different and less localized mutation than the changes described here in the generation of the ELC. The

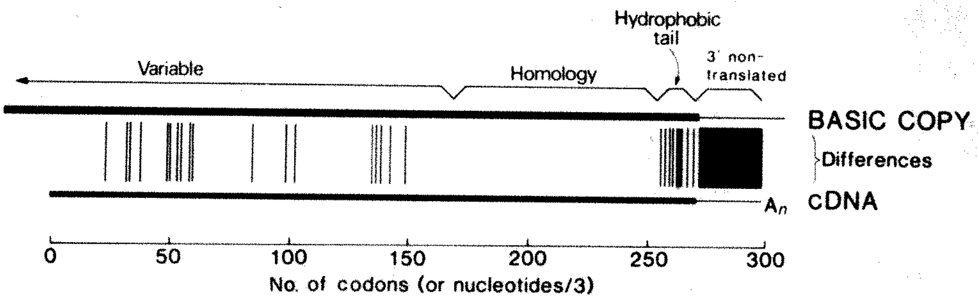

Fig. 3 Schematic comparison of the sequences of the BC gene and cDNA showing the 3'-non-translated region and poly(A)$_n$, the locations of coding portions that specify the various regions in the VSG (variable, homology and C-terminal hydrophobic tail regions) and the locations of nucleotide differences between the basic copy gene and the cDNA (vertical lines and solid rectangle).

two mutational processes are similar, however, in that there is no simple preference for purines or pyrimidines and some mutations are silent. Both processes are clearly important for generating the diversity of amino acid sequences found in the two types of protein.

Van der Ploeg *et al.*[17] have recently reported from Southern hybridization data (see below) that the DNA segment duplicated and translocated to generate the ELC of another VSG gene, VSG 117, begins 1–2 kb before the start of the BC gene. If the ILTAT 1.1 system is similar, then the 696 nucleotides reported here that precede the initiator methionine codon probably do not contain the 5'-recombination site. Indeed, by inspection or computer searches, we have been unable to identify a sequence that resembles switch sites of immunoglobulin genes or the yeast mating-type locus[24–27], sequences common to other eukaryotic transposable elements[28,29] or bacteriophage 'Chi' site sequences[30]. The sequence of another 300 nucleotides upstream has been determined (from the left-hand *Eco*RI site shown in Fig. 1) but is not shown in Fig. 2 because it is not contiguous with the sequence presented. This 300 nucleotide sequence, which is within 1–2 kb in front of the BC gene, also does not contain an obvious potential recombination site.

Bernards *et al.*[31] have reported a partial sequence comparison of the BC gene of VSG 117 and its corresponding cDNA which includes the hydrophobic tail and 3'-non-translated regions, but not the homology region or variable region. The VSG 117 system, like ILTAT 1.1, exhibits nucleotide changes in the hydrophobic tail region. Some of these changes, however, are nucleotide additions in the cDNA relative to the BC gene, a feature not present in the ILTAT 1.1 system. Another difference is that the VSG 117 system exhibits substantially more homology in the 3'-non-translated regions of the cDNA and BC gene than does the ILTAT 1.1 system. The significance, if any, of these differences is not known. Recently, Frasch *et al.*[32] reported Southern hybridization studies that suggested the occurrence of 'local hypermutagenesis' in subsets of closely related (cross-hybridizing) VSG genes which may correspond to the localized mutagenesis observed in the variable region of the ILTAT 1.1 BC gene (Fig. 3). Thus the occurrence of mutations during the generation of ELCs may be part of a general property of the entire VSG gene family, further demonstrating the intricate mechanisms that evolved in trypanosomes, permitting them to evade their hosts' immune defences.

This research was supported by USPHS grant AI16950. A.C.R.-F. is supported by USPHS postdoctoral grant AM07018. We thank John Young, Phelix Majiwa and Richard Williams in whose laboratory J.E.D. spent a sabbatical leave and where the ILTAT 1.1 cDNA clones and genomic library were constructed and identified.

Malignant transformation of cells by acute transforming RNA tumour viruses is mediated by the expression of certain specific proviral DNA sequences ('oncogenes'). These sequences have been well characterized and, in many cases, molecularly cloned[1–8]. These viral oncogenes are related to similar genes found in normal uninfected cells[9,10]. Moreover, these particular sequences are highly conserved in evolution[4,11], suggesting that these genes have an important, albeit unknown, role in normal cell function. It has been suggested that an increased dosage of products of such endogenous oncogenes may be responsible for malignant transformation[10,12,13]. For example, increased expression of the endogenous chick c-*myc* oncogene has been observed in avian leukosis virus-induced transformation of chick bursal lymphocytes[12]. Here we demonstrate that sequences in normal human DNA homologous to the avian *myc* oncogene are present in multiple copies in the chromosomal DNA of the human leukaemia cell line HL-60. Other transformation-specific genes derived from the Abelson leukaemia virus[4] and feline sarcoma virus[6] are not amplified in HL-60. This *myc*-related gene amplification is not present in other cultured human myeloid leukaemia cells, including K-562[14] and KG-1[15].

The HL-60 cell line is a culture of malignant promyelocytes derived from the peripheral blood leukocytes of a patient with

0028–0836/82/320679—03$01.00

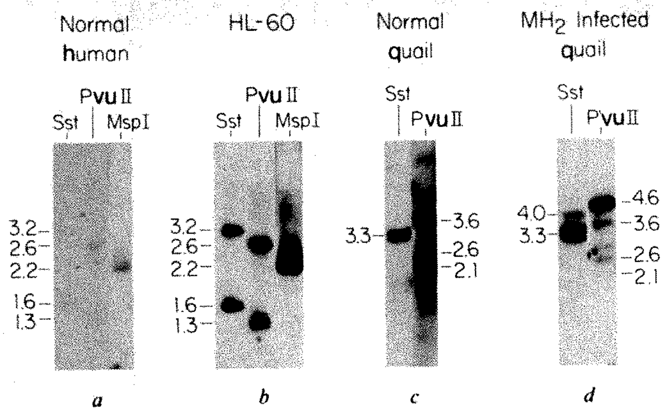

Fig. 1 *myc*-related sequences in DNA of HL-60, normal human and avian cells. Cells analysed included: *a*, normal human cells obtained by PHA stimulation of peripheral blood mononuclear cells from a normal human donor; *b*, HL-60 cells, passage 40, cultured as previously described[16]; *c*, normal quail embryo fibroblasts; *d* a cloned subline of quail embryo fibroblasts non-productively transformed with the MH$_2$ virus (a member of the MC-29 family of avian retroviruses) and obtained from M. Linial. DNA from these cells were restricted with the designated enzymes, subjected to agarose gel electrophoresis (1.2%) (10 μg of DNA per lane) followed by Southern blot hybridization[26] using a ^{32}P-labelled probe prepared by nick translation[27] of the c-*myc* probe. c-*myc* is a 3.3-kb *Sst* fragment obtained from a bacteriophage clone of c-*myc* that was isolated from a library of random chicken DNA fragments. This fragment encompasses almost the entire c-*myc* locus as detailed elsewhere[28]. The c-*myc Sst* fragment was subcloned in a derivative of pBr322 containing a single *Sst* site. Hybridizations were carried out in 50% formamide, 10% dextran sulphate 3 × SSC at 42 °C. Following hybridization, the filters were washed in 0.1% SDS, 0.1 × SSC at 50 °C and then exposed to Kodak XAR-5 film with intensifying screens. All blots were exposed for 72 h. Molecular weights of fragments are given in kilobases.

acute promyelocytic leukaemia[16]. DNA samples extracted from cells of this line and from phytohaemagglutinin (PHA) stimulated peripheral blood lymphocytes from a normal donor were digested with restriction endonucleases, separated by electrophoresis on agarose gels and transferred to nitrocellulose. The resultant blots were hybridized to a ^{32}P-labelled DNA probe specific for the chick c-*myc* gene, the cellular homologue of the transforming sequences of acute transforming retroviruses within the MC-29 family[17,18]. This c-*myc* probe gave faint but distinct bands when hybridized to various endonuclease digests of normal human DNA (Fig. 1*a*), indicating homology between certain sequences within the human genome and the chick c-*myc* probe, as reported by others[19]. From the same blot, bands of identical size were noted in endonuclease digests of HL-60 DNA, but the intensity of hybridization was much greater (Fig. 1*b*). The total amount of normal human and HL-60 DNA loaded in each lane was the same for all DNA preparations (10 μg). Moreover, when the same normal and HL-60 samples were hybridized with other ^{32}P-labelled probes, bands of similar intensity were noted in both normal and HL-60 DNA (Fig. 2). This indicates that the enhanced hydridization of the c-*myc* probe to HL-60 DNA is not a result of differences in the amount of DNA loaded on the gels.

The intensity of hybridization of the c-*myc* probe to HL-60 DNA is comparable with that noted in DNA extracted from normal avian cells and from avian cells infected with the acute transforming MH$_2$ virus (Fig. 1*b*–*d*). However, the similarity in restriction patterns of HL-60 and normal human DNA using the c-*myc* probe (Fig. 1*a*, *b*) makes it unlikely that the intense hybridization seen with HL-60 DNA is a result of inadvertent infection of HL-60 cells with a retrovirus such as MH$_2$ containing *myc* sequences or of contamination of HL-60 DNA with avian DNA.

The increased hybridization of the c-*myc* probe to HL-60 DNA compared with normal human DNA could be the result of either multiple copies (amplification) in HL-60 cells of the endogenous human sequences homologous to c-*myc* or to increased homology of these endogenous HL-60 c-*myc*-related sequences to the chick c-*myc* probe. The similarity in restriction enzyme patterns of HL-60 and normal human DNA hybridized to c-*myc* (Fig. 1) indicates that HL-60 and normal human *myc*-related DNA sequences are similar. Therefore, this increased HL-60 hybridization to c-*myc* most probably results from amplification in HL-60 DNA of c-*myc*-related sequences. To confirm this, we 'dot-blotted' serial dilutions of HL-60, normal human and avian DNA onto nitrocellulose as previously described[20], hybridized the filter with ^{32}P-labelled c-*myc* probe, and then estimated the melting point of the resultant hybrids by washing the filters at progressively higher temperatures (Fig. 3). If the enhanced hybridization of HL-60 DNA to the c-*myc* probe results from increased homology of *myc*-related HL-60 sequences to this probe, the melting points of avian and HL-60 c-*myc* hybrids should be similar. Alternatively, if endogenous *myc*-related genes are amplified in HL-60, then the melting points of HL-60 and normal human DNA-*myc* hybrids should be similar and should be lower than that seen with avian DNA. As demonstrated in Fig. 3, the intensity of hybridization of the *myc* probe to equal quantities of HL-60 and avian DNA is similar, but both HL-60 and normal human DNA c-*myc* hybrids are denatured at lower temperatures than avian DNA c-*myc* hybrids. The relative denaturation of both HL-60 and normal human DNA hybrids at a given temperature appears similar (Fig. 3). These results indicate that the enhanced hybridization of the c-*myc* probe to HL-60 DNA is a result of HL-60 amplification of the endogenous human *myc*-related sequences rather than to increased homology of these sequences to the c-*myc* probe. Moreover, one can estimate by comparing the intensity of hybridization of the c-*myc* probe to serial dilutions of HL-60 and normal human DNA (Fig. 3) that c-*myc* related sequences are amplified some 8–16-fold in HL-60 DNA compared with normal human DNA.

Identical restriction fragments are noted when the c-*myc* probe is hybridized to normal human and HL-60 DNA digested

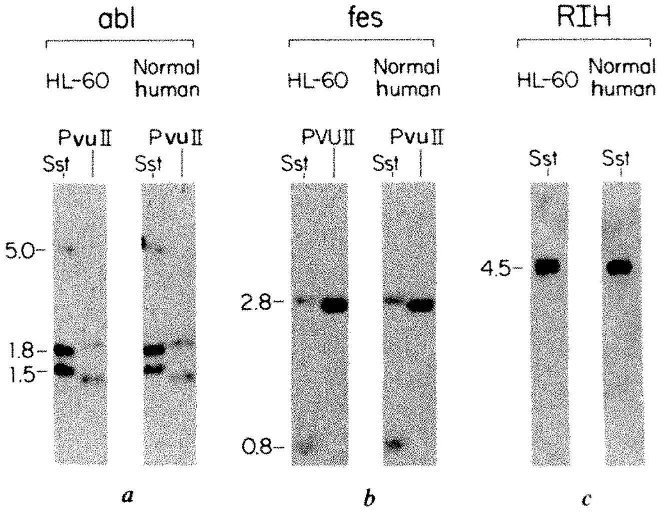

Fig. 2 Absence of amplification of non-*myc* sequences in HL-60 DNA. DNA samples from HL-60 cells and from PHA-stimulated normal human lymphocytes were digested with the designated enzymes, electrophoresed in 1.2% agarose (10 μg DNA per lane), and Southern blot hybridized to the indicated ^{32}P-labelled probes in conditions described in Fig. 1 legend. The *abl* probe contains the transforming sequences of Abelson leukaemia virus[4]. The *fes* probe contains the transforming sequences of the feline sarcoma virus[6]. The RIH probe is a 0.5-kb clone containing flanking sequences between the human γ and ∂ globin genes[29].

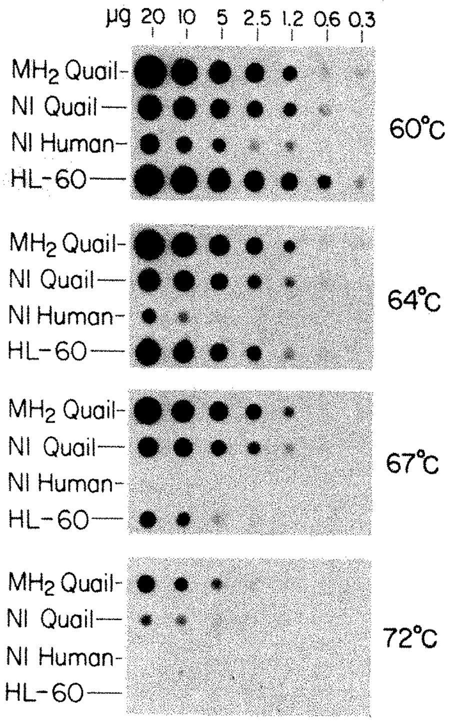

Fig. 3 Melting points of HL-60, normal human and avian DNA c-*myc* hybrids utilizing 'dot-blot' analysis. DNA samples obtained from HL-60 cells, PHA-stimulated human lymphocytes, quail embryo fibroblasts and quail embryo fibroblasts non-productively transformed with the MH_2 virus were treated with RNase A (Sigma) at 50 µg ml^{-1} for 20 min at 37 °C and then serially two fold diluted followed by denaturation in 1 M ammonium acetate and 0.2 NaOH as previously described[20]. The indicated quantities of DNA were then applied to a nitrocellulose filter, previously soaked in 1 M ammonium acetate, using a 'Hybri-Dot' manifold (Bethesda Research Laboratories). The filter was then hybridized to the c-*myc* probe, in conditions described in Fig. 1 legend. Following hybridization, the filter was washed in 0.1% SDS, 0.1 × SSC at 50 °C for 20 min, and then exposed for 24 h to XAR-5 film (Kodak) at −70 °C. Following this initial exposure, the filter on consecutive days was washed for 20 min in 0.1% SDS, 0.1 × SSC at progressively higher temperatures as indicated. After each wash, the filter was reexposed for 24 h to XAR-5 film.

with other enzymes, including *Kpn*, *Eco*RI and *Hin*dIII, although in every case the intensity of hybridization to the HL-60 DNA is much greater (blots not shown). As some of these enzymes presumably cut in sequences flanking, as well as within the human *myc* gene, the identical restriction patterns suggest that the *myc*-containing chromosomal unit amplified in HL-60 may be relatively large. This has been previously noted with amplified CAD[21] and DHFR[22] genes, where the amplified unit seems to be ~500–1,000 kilobases (kb). Thus, as in the examples of CAD and DHFR, it may be difficult to determine by restriction enzyme analysis of HL-60 cellular DNA whether *myc* amplification in HL-60 is tandem or non-tandem.

The *myc* amplification in HL-60 is not a result of hyperdiploidy of the *myc*-containing chromosome because this cell line is hypodiploid (modal chromosome number of 45) and exhibits no hyperdiploidy of individual chromosomes[23]. However, we have noted that some HL-60 metaphases contain double minutes and we are now attempting to determine whether these chromosome structures contain amplified *myc*-related sequences.

Hybridization of HL-60 DNA to other 'oncogene' probes derived from the Abelson leukaemia virus[4] and the feline sarcoma virus[6] gives a pattern and intensity of hybridization similar to those of normal human DNA (Fig. 2*a*, *b*). Moreover, the c-*myc* probe, when hybridized to endonuclease digests of DNA from the human myeloid leukaemia cell lines K-562[14] and KG-1[15] as well as to digests from several fresh leukaemia cells, exhibits a pattern and intensity of hybridization similar to those of normal human DNA (blots not shown). This preliminary screen suggests that amplification of endogenous human c-*myc*-related sequences may be an unusual phenomenon in both cultured and fresh human leukaemia cells.

Current speculations on the origin of cancer suggest that malignant transformation may result from the enhanced expression of certain normal cellular genes[10,12,13]. Indeed, in the case of avian retrovirus-induced bursal lymphomas, increased amounts of c-*myc* RNA as well as amplification of *myc*-related chromosomal DNA sequences have been reported[12,24]. While the levels of *myc*-related RNA in HL-60 cells and other normal or leukaemic human cells have not been rigorously defined, our own unpublished observations (in collaboration with Paul Neiman) and the results of others[30] have revealed relatively high levels of *myc*-related RNA sequences in HL-60. In addition, high levels of *myc*-related RNA have been observed in other leukaemic cells in which the *myc* gene is not amplified (S. Astrin and P. Neiman, personal communications). Thus, these observations may indicate that increased expression of this gene may follow at least two pathways, one involving amplification of c-*myc* DNA (under no obvious selective pressure), and another resulting from increased transcription or stabilization of transcription products from one copy of this gene. It is also possible that the amplification of c-*myc* observed in HL-60 is a normal developmental process in granulocytic differentiation, and that HL-60 represents a specific maturational compartment of these cells, arrested in this state[25].

We thank Mary Peretz and Carol Paschl for help in isolating the c-*myc* clone from the chick library, and Paul Neiman and Hal Weintraub for many helpful discussions. This work was supported by the Veterans Administration and by grants from the NIH and NSF. S.C. is a Special Fellow of the Leukaemia Society of America. M.G. is a Scholar of the Leukaemia Society of America.

We have used a probe (pAS-1) to the human urea cycle enzyme argininosuccinate synthetase (AS) to detect individual variation in restriction enzyme digests of human DNA from lymphocytes, fibroblasts and transformed cell lines (including HeLa). pAS-1 is a 1.55 kilobase (kb) sequence of cDNA from poly(A)$^+$ RNA cloned in pBR322; it represents more than 90% of the AS message[1]. At least 15 genomic fragments are detected with pAS-1 in DNA digested with restriction enzymes recognizing 6-base sequences[2]. This multiplicity of fragments is explained in part by the observation that AS-like sequences are found on more than seven human chromosomes[3]. We report here population data and gene dosage experiments demonstrating an AS-like sequence on the human Y chromosome and confirming an AS-like sequence on the human X chromosome.

The pAS-1 probe was isolated by plasmid-selected mRNA translation and immunoprecipitation from a bank of cloned human cDNA. The cDNA recombinants were prepared in pBR322 plasmid using sucrose gradient-enriched mRNA from a canavine-resistant colony of the human cell line RPMI 2650. The translation product of mRNA selected by pAS-1 has the immunological properties, molecular weight and substrate specificity of human AS[1].

Human genomic DNA produces more than 15 AS-like fragments when digested with restriction endonucleases recognizing 6-base sequences and more than 25 fragments when digested with 4-base enzymes (Figs 1, 2; Table 1). Restriction analysis with pAS-1 of human–hamster cell lines containing one or two human chromosomes demonstrates that AS-like sequences are found on several human chromosomes including chromosomes 6, 9 and X (ref. 3). (The human AS structural gene is tentatively assigned [4,5] to 9q34.) The multiplicity of separable DNA fragments and the wide chromosomal dispersion of AS-like sequences makes pAS-1 an excellent probe for restriction site variation in human populations.

In a population survey of restriction site variation, we isolated DNA from more than 50 individuals, digested the DNAs with a panel of six restriction enzymes and probed with pAS-1 following agarose gel electrophoresis and Southern transfer (see Fig. 1 legend for details). DNA was from peripheral blood lymphocytes ($n = 37$), fibroblasts (12), lymphoblasts (4) and transformed cell lines (RPMI 2650 and HeLa). Considerable population variation was detected but this was independent of the type of cell from which the DNA was isolated. Four enzymes, *Bam*HI, *Hin*dII, *Hin*dIII and *Msp*I, revealed independent, high-frequency polymorphic variation in restriction fragments from more than one human autosome. This variation is described elsewhere (S.P.D., R.S.W., N. Hoffman and T-S.S., in preparation).

A more striking type of variation is apparent in digests with *Bam*HI, *Eco*RI, *Kpn*I and *Msp*I: one or two fragments are always present in males and always absent from females (Table 1, Fig. 1). *Bam*HI, *Eco*RI and *Kpn*I (6-base enzymes) produce one male-specific fragment and *Msp*I (a 4-base enzyme) produces two such fragments. We have observed male-only transmission of these fragments in several three-generation families. Male-specific fragments were also observed in chimpanzees, comparing two male and two female DNAs hybridized with pAS-1.

The most probable explanation for this sexual dimorphism is the presence of an AS-like sequence on the Y chromosome. To confirm this possibility we compared restriction digests of DNA from normal males and from an adult male with an XYY karyotype. (Peripheral blood lymphocytes were used for both DNA and karyotype determination. All of ten cells typed were XYY [Cytogenetics Laboratory, Baylor College of Medicine].) Table 2 shows mean-normal microdensitometry values of the autoradiographs produced in this and related experiments. For the *Bam*HI digest the only significant difference between the normal and XYY male is that the putative Y band (2.45 kb) is nearly twice as dense in the latter, suggesting that roughly twice the normal amount of DNA is present. The male-specific fragments produced by other enzymes (Table 3) are also significantly denser in the XYY DNA. One XX male fibroblast line tested (GM 2626, Human Genetic Mutant Cell Repository, Camden, New Jersey) did not produce a male-specific fragment.

There is one difficulty with this hypothesis: two enzymes, *Hin*dIII and *Pst*I, produce no apparent male-specific fragment. Double digests with *Hin*dIII plus *Pst*I also show no difference. We have since tested a few DNAs with four additional enzymes. Two of these enzymes, *Bgl*II and *Sst*I, do produce male-specific fragments and two, *Bcl*I and *Hin*dII, apparently do not. The most likely explanation for this discrepancy is that male-specific fragments are present in these digests but are obscured by the multiplicity of other fragments. In the typical X ray picture, 20% of the region from 1.0 to 50 kb contains bands that would obscure additional nearby bands unless they are unusually dense. In general, the putative Y bands are relatively less dense

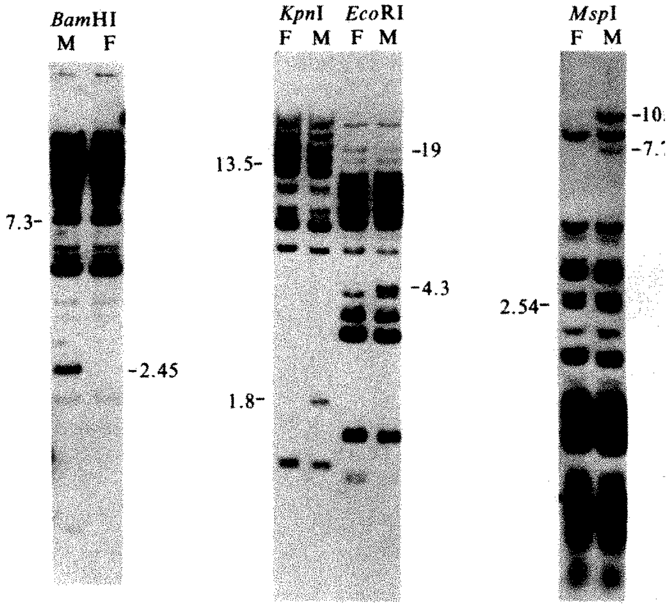

Fig. 1 Human genomic DNA digests probed with ^{32}P-pAS-1: enzymes producing male-specific fragments. DNA was prepared from 30 cm^3 of EDTA–whole blood by recovery of white blood cells from ammonium chloride/ammonium bicarbonate and digestion at 37 °C for 18 h with proteinase K and 0.1% SDS in 50 mM Tris buffer, *p*H 7.8. DNA was extracted twice with buffer-saturated phenol and precipitated in ethanol, resuspended and digested 1.5 h at 37 °C with RNase A, re-extracted with phenol and dialysed extensively against 10 mM Tris, 0.1 mM EDTA, *p*H 7.6 (ref. 17). Digestions were 5 μg DNA with 10–40 U restriction enzyme at 37 °C for 6 h. DNA was separated in 0.8% agarose gels, blotted onto nitrocellulose by Southern transfer and hybridized at 65 °C for 36 h with 8×10^5 d.p.m. per lane of pAS-1 (plasmid insert only) labelled with ^{32}P by nick-translation[18,19]. Hybridized nitrocellulose was washed at 65 °C with 0.1% SDS and decreasing amounts of sodium chloride/sodium citrate (2 × SSC to 0.5 × SSC). Autoradiography was for 4 days at −70 °C on Kodak SB-5 X-ray film using a DuPont Cronex enhancing screen. Higher-stringency conditions (70 °C, 0.1 × SSC) also produce a faint Y-chromosome fragment. F, female; M, male. Labelled bands are X- and Y-chromosome fragments (in kb); see Table 3.

Table 1 Number of individuals with male-specific fragments detected with pAS-1

Enzyme	*Bam*HI	*Eco*RI	*Kpn*I	*Msp*I	*Hin*dIII	*Pst*I
Total no. fragments observed	17	18	16	25	19	16
Male-specific fragments	+ −	+ −	+ −	+ −	None	None
Females	0 20	0 17	0 14	0 17	20	15
Males	30 0	23 0	16 0	18 0	31	22

+, Fragment present; −, fragment absent; none, no male-specific variation observed.

than other bands in the same lane so it is unlikely that microdensitometry alone would detect a male-specific band (Fig. 1; Table 2). (Such density differences may reflect differences in the extent of homology between particular fragments and pAS-1 or differences in the length of homologous sequences.) As no other known biological mechanism would account for these male-specific fragments and since it is certain that some fragments will occasionally obscure other fragments, we believe that all enzymes produce a Y-chromosome fragment containing an AS-like sequence but that these fragments are not always detectable by our methods.

Microdensitometry reveals another type of sexual dimorphism in genomic digests probed with pAS-1: one or two fragments are always denser in females than in males (Table 2). This is consistent with the assignment of an AS-like sequence to the human X chromosome using somatic cell hybridization[3]. Confirmation by microdensitometry is provided by DNA from a human XO (Turner's syndrome) fibroblast line (GM 857) and an XXXX fibroblast line (GM 1415). The putative X fragments are of equal density in males and in the XO DNA, significantly denser in normal females and most dense in XXXX DNA (Table 2).

Note that although the density ratio of the *Bam*HI Y fragment (2.45 kb), comparing normal male with XYY male DNA, is ~1:2 as expected, the ratio of the X fragment (7.3 kb), comparing normal male with normal female with XXXX female DNA, is 1:1.6:1.8, not the expected 1:2:4. (The XXXX karyotype was confirmed by Barr body determination on cells of the same passage as those used for DNA preparation.) The X-fragment differences, though, are statistically significant and in the correct direction. Conversely, the density of autosomal fragments do not differ between males and females. With such complex patterns it is possible that an autosomal fragment underlies the X fragment in *Bam*HI digests; this is the most likely explanation for the discrepancy in X-fragment ratios. Because DNA transfer, hybridization and autoradiography are generally non-linear processes, determination of absolute DNA concentration by microdensitometry is not reliable. In this application, though, with identical internal standards (autosomal fragments) and a sufficient number of controls, microdensitometry is very effective at detecting relative differences in fragment copy number.

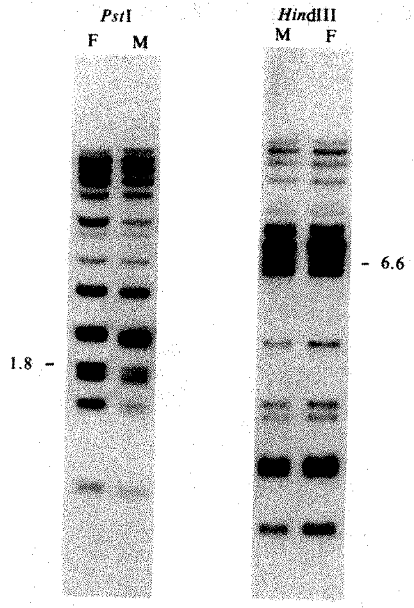

Fig. 2 Human genomic DNA digests probed with ^{32}P-pAS-1; enzymes failing to produce male-specific fragments. Methods as for Fig. 1. Labelled bands are X-chromosome fragments (in kb); see Table 3. M, male; F, female.

Table 3 lists the molecular weights (in kb) of the Y-chromosome and X-chromosome fragments detected in genomic digests and by microdensitometry.

Although Y-chromosome DNA represents ~1% of the total human genome, very few single gene traits have been mapped to this chromosome. 'Hairy ears' has been ascribed to the Y but this assignment is controversial[6,7]. A 'testis-determining factor' is most certainly on the Y and is associated with the Y histocompatibility antigen (H–Y)[8]. The structural locus for the

Autoradiographs were scanned with a Helena Laboratories Microdensitometer. Values were normalized by dividing each peak height by the sum of all peaks in a given lane. Data storage and analysis were done on an Apple II microcomputer. Values are arithmetic mean ± 1 s.d. Putative X and Y fragments are underlined. There is an autosomal polymorphism of the *Bam*HI 8.1 kb fragment and of the *Hin*dIII 2.7 and 3.9 kb fragments. All *Bam*HI individuals in this table are 8.1^{+}; all *Hin*dIII individuals are 3.9^{+}/2.7^{+}. Some very faint fragments are not included.

* Replicates.

Table 3 Summary of molecular weights (in kb) of sex-specific DNA fragments detected with pAS-1

	*Bam*HI	*Eco*RI	*Hin*dIII	*Kpn*I	*Msp*I	*Pst*I
Y chromosome	2.45	4.3	—	1.8	10.9, 7.7	—
X chromosome	7.3	19	6.6	13.5	2.54	1.8

Assignment of Y-chromosome fragments is based on male-specific bands detected in genomic digests; –, none detected. Assignment of X-chromosome fragments is based on microdensitometry and human-hamster hybrid cell lines.

H-Y antigen itself, though, may be on another chromosome with regulatory loci on the X and Y[9]. Genes controlling embryonic gonadal differentiation, spermatogenesis and height have also been assigned to the Y[10]; these may or may not be independent of the other factors. At best it is reasonable to ascribe only four or five mendelian traits to the Y chromosome.

An explanation for the disparity between the amount of DNA present on the Y and the paucity of convincing gene assignments is that at least 50% of the Y is non-functional heterochromatin. There is considerable cytological variation in human heterochromatin, usually resulting in heritable differences in the size of the Y[11]. At the DNA level at least two male-specific mid-repeat sequences are detectable with *Hae*III (or BSu) digestion[12,13]. The heterochromatin and mid-repeat sequences are present on the 'inactive' long arm of the Y, whereas genes involved in sexual differentiation map to the short arm apparently. With the exception of heterochromatin differences (and hairy ears possibly), no polymorphic variation in either Y-chromosome DNA or genes has been reported in humans.

Our observation of a Y-chromosome restriction fragment containing an AS-like sequence in humans may provide a unique tool for probing Y-chromosome organization and function. It is highly probable that polymorphic restriction site variation will be detected with at least one of the dozens of restriction enzymes currently in use. These considerations also apply to the AS-like sequence on the X chromosome, though in this case excellent polymorphic markers are already known and many DNA probes are available[14].

The relationship between the AS structural locus and AS-like sequences on the X and Y chromosomes is not yet known in detail. The sequences are short relative to the structural locus but they contain sequences homologous to both 3′ and 5′ portions of pAS-1 (ref. 3). This arrangement is compatible with pseudogenes that lack introns[15,16]. The extraordinary dispersion of the AS-like sequence to both X and Y chromosomes and to several autosomes is unprecedented and intriguing.

We thank Nancy Hoffman for technical assistance. This work was supported by NIH grant GM 27593, NIH fellowship GM 08199 and grants from the Faculty Research and Fellowship Support Committee, Baylor College of Medicine and the O'Brien family of Houston, Texas.

Initiator tRNAs from archaebacteria show common unique sequence characteristics

Yoshiyuki Kuchino, Makoto Ihara, Yuko Yabusaki & Susumu Nishimura

Biology Division, National Cancer Center Research Institute,
Tsukiji 5-1-1, Chuo-ku, Tokyo 104, Japan

Archaebacteria have recently become of interest in studies on the phylogeny of organisms, for they are quite different from true bacteria as well as from eukaryotes and are thought to be derived from a separate primary line of descents from true bacteria[1]. This conclusion is based mainly on nucleotide sequence analysis of 16S ribosomal RNA by Woese and his co-workers, and other genotypic and phenotypic analysis of archaebacteria. To obtain more information on the phylogeny of archaebacteria, we examined the nucleotide sequences of their initiator tRNAs, because much information is available on initiator tRNAs of various organisms, and distinct differences have been found between the sequences of initiator tRNAs of prokaryotes and eukaryotes[2]. We have now determined the nucleotide sequences of initiator tRNAs from *Sulfolobus acidocaldarius*, *Halococcus morrhuae* and *Thermoplasma acidophilum*, and have found that they have a common unique structural feature that differs from both true bacterial initiator tRNAs and eukaryotic initiator tRNAs.

Initiator tRNAs from *S. acidocaldarius*, *H. morrhuae* and *T. acidophilum* were purified from unfractionated tRNA by successive column chromatographies of DEAE–Sephadex A-50, BD-cellulose and RPC-5 (refs. 3,4). Final purification of these tRNAs was achieved by two-dimensional polyacrylamide gel electrophoresis[5,6]. Heterologous charging of methionine by *Escherichia coli* aminoacyl-tRNA synthetase was adapted to pick up initiator tRNA species during purification[7]. In the case of *T. acidophilum*, two methionine tRNAs were detected when fractionated by BD-cellulose column chromatography (*p*H 7.5). The formylation reaction with *E. coli* enzyme was used to determine which species was initiator; only one species was formylated, and the other was found to be methionine tRNA for elongation[8].

The total primary sequences of the three initiator tRNAs were obtained by post-labelling procedures as described previously[5,6], and the sequences, arranged in cloverleaf form, are shown in Fig. 1. Eukaryotic initiator tRNAs are distinct from prokaryotic initiator tRNAs in having A_1, t^6A_{37}, A_{54}, G_{57}, A_{60} and U_{72} in place of C_1, A_{37}, T_{54} (U or uridine derivatives), A_{57}, U_{60} and A_{72} (ref. 2). These characteristics have been found in all prokaryotic and eukaryotic (cytoplasmic unicellular and multicellular) initiator tRNAs so far sequenced. By contrast, the three archaebacteria initiator tRNAs all contained A_1, A_{37}, uridine derivative$_{54}$, $(N_4)_{57}$ (adenine derivative), U_{60} and U_{72}. In other words, these particular residues in archaebacteria initiator tRNAs are not the same as those of either prokaryotic initiator tRNAs or eukaryotic initiator tRNAs. These data of archaebacteria initiator tRNAs clearly indicate that archaebacteria are unique prokaryotes distinct from true bacteria. This is further supported by the recent sequence data on 5S RNA[9] and ribosomal A protein[10].

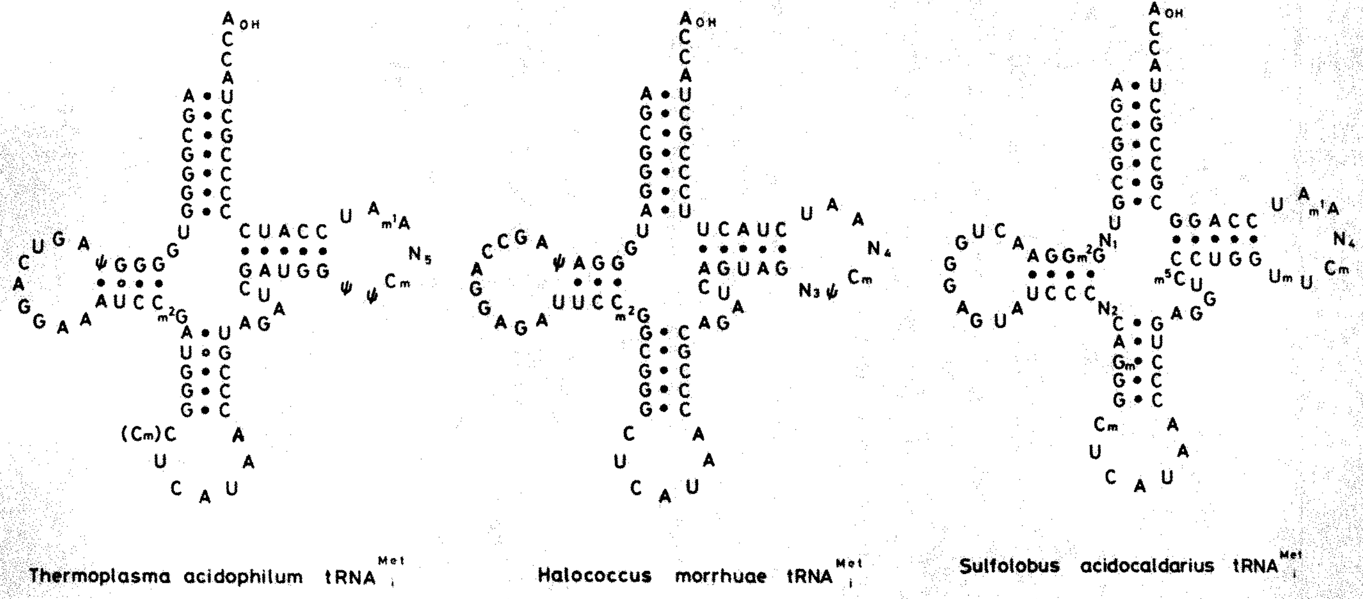
It is also noteworthy that among archaebacteria initiator tRNAs, *S. acidocaldarius* initiator tRNA shows remarkable resemblance to yeast initiator tRNA; the two tRNAs have almost identical sequences in the CCA-stem, anticodon-stem

0028-0836/82/320684—02$01.00

Table 1 Sequence homology of initiator tRNAs from archaebacteria, *E. coli*, yeast, vertebrate and wheat germ

	E. coli	Yeast	Vertebrate	Wheat germ	*Thermoplasma*	*Halococcus*	*Sulfolobus*
E. coli	—	72	71	67	78	71	72
Yeast	—	—	76	73	70	62	82
Vertebrate	—	—	—	87	76	64	74
Wheat germ	—	—	—	—	66	62	71
Thermoplasma	—	—	—	—	—	82	79
Halococcus	—	—	—	—	—	—	72
Sulfolobus	—	—	—	—	—	—	—

D-loops of different chain lengths were arranged to have maximal homology. Unknown modified nucleosides were counted as not having homology. Values are percentage homologies of sequences of initiator tRNAs.



Thermoplasma acidophilum $tRNA_i^{Met}$ Halococcus morrhuae $tRNA_i^{Met}$ Sulfolobus acidocaldarius $tRNA_i^{Met}$

Fig. 1 Nucleotide sequence of initiator tRNAs from *S. acidocaldarius*, *H. morrhuae* and *T. acidophilum* in cloverleaf form. N_3 was recently characterized as 1-methylpseudouridine[11]. N_2, N_4 and N_5 are presumably m_2^2Gm, m^1I and I, respectively (Z. Yamaizumi, Y.K., M.I., W. Zillig and S.N., unpublished results). N_1 is an unidentified modified nucleoside. R. Gupta and C. R. Woese reported (personal communication) that *H. volcani* initiator tRNA contains triphosphate at the 5′ end. As we determined the sequences of the tRNAs by the post-labelling technique, we do not know whether they have triphosphate or monophosphate groups at the 5′ end.

and anticodon-loop[2], and the overall homology of *S. acidocaldarius* initiator tRNA to yeast initiator tRNA is 82% while its homology to *E. coli* initiator tRNA is only 72% (Table 1)[2]. By contrast, *H. morrhuae* and *T. acidophilum* initiator tRNAs do not resemble yeast initiator tRNA, or any other eukaryotic initiator tRNAs (Table 1).

All three archaebacteria initiator tRNAs contain two to four methylated nucleosides in the TψC-loop. In addition, *S. acidocaldarius* initiator tRNA contains three more 2′-O-methylated nucleosides in other regions. This characteristic is probably related to the tolerance of these tRNAs to extreme growth conditions.

A marked similarity among the three archaebacterial initiator tRNAs is the identical sequence of five stretches of base pairs in the CCA-stem, although the overall homology between them is not substantially high (Table 1). Fox and his co-workers reported that archaebacteria can be classified into several major subclusters[1]. Judging the phylogeny from 16S rRNA data, *S. acidocaldarius* seems to have separated first from *H. morrhuae* and *T. acidophilum*. The sequence data on initiator tRNAs reported have also suggested that *S. acidocaldarius* is distinct from *H. morrhuae* and *T. acidophilum*. It will obviously be interesting to compare sequences of initiator tRNAs from other archaebacteria with 16S rRNA data, and work on this line is in progress. The nucleotide sequences of initiator tRNAs from *Halobacterium cutirubrum* and *Halobacterium volcani* have recently been determined by U. L. RajBhandary and S. T. Bayley and by R. Gupta and C. R. Woese (personal communication), respectively. These sequences are almost the same as that of *H. morrhuae* except for a few base alterations in stem regions and thus are consistent with the above conclusion.

We thank Dr W. Zillig of Max-Plank-Institut für Biochemie for gifts of cells of *S. acidocaldarius*, *H. morrhuae* and *T. acidophilum*. This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan.

The amino acid sequences of peptide hormones that terminate in an α-amide group seem usually to be followed by glycine in the sequence of their precursor molecules. Thus it has long been known that the sequence of α-melanotropin, which terminates in Lys-Pro-Val-$CONH_2$ (ref. 1), occurs adjacent to glycine in the sequence of corticotropin[2] and more recently it has been shown that the peptide hormone mellitin, which terminates in glutamine amide[3], is synthesized as a prohormone that terminates in glutaminyl-glycine[4]. A similar relationship is suggested by comparison of the primary structures of adipokinetic hormone[5] and red pigment-concentrating hormone[6]. These observations indicate that biosynthesis of the C-terminal amide may involve the action of a specific enzyme which has a requirement for C-terminal glycine. We present here direct evidence that porcine pituitary contains an enzyme with the ability to convert peptides that terminate in glycine to the corresponding des-glycine peptide amide. We have investigated the substrate specificity of the enzyme and with the aid of isotopic labelling have demonstrated that its mechanism of action involves dehydrogenation and hydrolysis of the glycine-containing substrate.

An assay system for detecting and estimating amidating activity in pituitary was obtained by examining the ability of enzyme preparations to convert the synthetic tripeptide D-tyrosylvalylglycine to the corresponding dipeptide amide D-tyrosylvaline amide. The sequence Val-Gly was selected because it seemed likely to contain the minimum structural elements of corticotropin necessary for formation of the valine amide group present at the C-terminus of α-melanotropin. The D-tyrosine residue conferred stability against degradation by aminopeptidases present in tissue homogenates and provided a site for radioiodination. The ^{125}I-labelled tripeptide D-tyrosylvalylglycine was incubated with pituitary homogenates (0.5 g porcine pituitary in 1 ml of phosphate-buffered saline, *p*H 7.4) or with chromatographed preparations of amidating enzyme obtained from porcine pituitary, and the degree of conversion of the D-Tyr-Val-Gly to D-Tyr-Val-$CONH_2$ was determined by column chromatography of the radiolabelled peptides on sulphopropyl Sephadex C25. The elution positions of the iodinated tripeptide and dipeptide amide were established with the use of synthetic peptides.

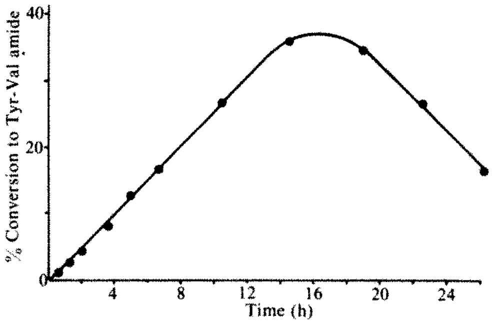

Fig. 1 Formation of D-Tyr-Val amide from D-Tyr-Val-Gly catalysed by an amidating enzyme from porcine pituitary. D-Tyrosylvalylglycine (100 pmol, 10^6 c.p.m. of ^{125}I) was incubated at 37 °C with an enzyme preparation obtained by gel filtration on Sephadex G100, as described in Fig. 3 legend. The incubation was performed with 0.25 ml of the peak fraction in 200 mM sodium chloride, 50 mM sodium phosphate at *p*H 7. At intervals, 20-μl aliquots of the reaction mixture were removed, acidified with 10 μl of 1 M hydrochloric acid and chromatographed on a column (15 × 1 cm) of SP Sephadex C25 eluted in 200 mM sodium chloride and 50 mM sodium phosphate at *p*H 5.5. The yield of D-Tyr-Val amide was calculated from the proportion of the total radioactivity that emerged in a peak corresponding to the position of an ^{131}I-labelled marker peptide. The iodinated tripeptide emerged at 20 ml and the iodinated dipeptide amide at 51 ml.

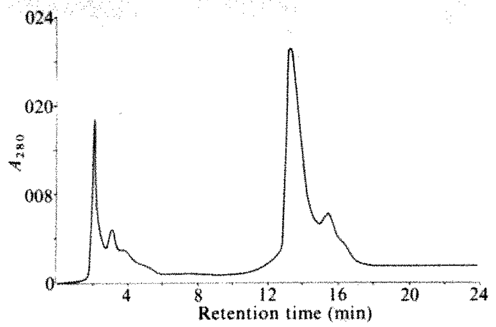

Fig. 2 Isolation of D-Tyr-Val amide produced by incubation of D-Tyr-Val-Gly with amidating enzyme extracted from porcine pituitary. The fraction containing the tritium-labelled dipeptide amide, obtained by ion-exchange chromatography as described in Fig. 1 legend, was concentrated *in vacuo* and submitted to HPLC on a C18 Microbondapak column (25 × 0.4 cm) eluted in 2 mM hydrochloric acid with a linear gradient (20 min) from 5–15% methanol. Fraction size was 0.5 ml. The D-Tyr-Val amide emerged at 27 ml.

Incubation of D-tyrosylvalylglycine with a preparation of the amidating enzyme obtained by gel fitration on Sephadex G100 led to the progressive formation of D-tyrosylvaline amide (Fig. 1). In the conditions used, the yield of the dipeptide amide reached a maximum value of 38% in 17 h, then slowly declined. Control experiments showed that when synthetic ^{125}I-labelled D-tyrosylvaline amide was incubated in the same conditions it was slowly degraded. Thus the formation of the dipeptide amide by the pituitary enzyme is followed by its descruction by other enzymes present in the pituitary extract. The reaction product, D-tyrosylvaline amide, was identified by co-elution with ^{131}I-labelled synthetic D-Tyr-Val amide; and in further experiments co-chromatography was demonstrated with D-Tyr-^{3}H-valine amide formed from D-Tyr-^{3}H-valylglycine with the corresponding synthetic dipeptide amide. The identity of the D-Tyr-Val-$CONH_2$ generated by the pituitary enzyme was further confirmed by its isolation in sufficient quantity for amino acid analysis. The incubation was performed using chemical amounts

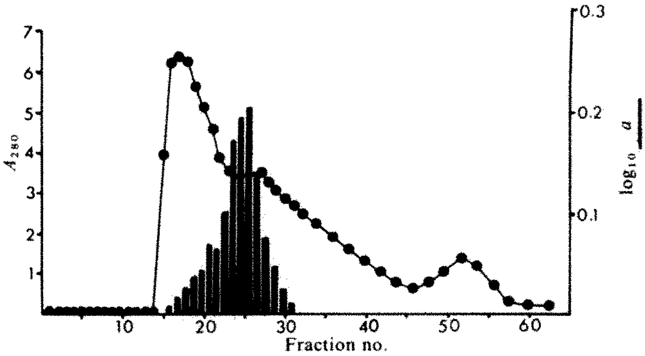

Fig. 3 Purification of amidating enzyme from porcine pituitary by gel filtration on Sephadex G100. The soluble enzyme obtained from the secretory granule fraction of porcine pituitary (50 g) was concentrated by vacuum dialysis and chromatographed on a column (60 × 1.5 cm) of Sephadex G100 eluted in 200 mM sodium chloride and 50 mM sodium phosphate at *p*H 7; fraction size was 2.5 ml. The enzyme was assayed by incubating 50-μl portions of each fraction with ^{125}I-D-Tyr-Val-Gly (20 pmol, 2 × 10^5 c.p.m.) at *p*H 7 for 5 h at 37 °C. The yields of dipeptide amide formed were determined as described in Fig. 1 legend.

0028–0836/82/320686—03$01.00

of D-Tyr-Val-Gly (100 nmol containing 2 μCi of ^{3}H-labelled peptide) in 10 ml of 200 mM sodium chloride, 50 mM sodium phosphate, *p*H 7.0, at 37°C for 10 h in the presence of enzyme purified on Sephadex G100. The resulting dipeptide amide was isolated in homogeneous form by gel filtration on Sephadex G25 to remove higher molecular weight material, by ion exchange chromatography as in Fig. 1 and by reverse-phase HPLC (Fig. 2). The reaction product (6 nmol) gave an amino acid composition of Tyr, 1.0; Val, 0.9; Gly, <0.1; NH_3, 1.1 residue.

The amidating enzyme was shown to be present in the secretory granule fraction of porcine pituitary. The granules, prepared from 50 g porcine pituitary by differential centrifugation[7], were solubilized by repeated sonication in 10 mM sodium phosphate at *p*H 7.0. The extracted enzyme was concentrated by dialysis under reduced pressure and purified by chromatography on Sephadex G100 (Fig. 3). The amidating activity emerged in a broad fraction, indicating that the minimum apparent molecular weight of the enzyme was ~60,000. Significant amidating activity could also be demonstrated, however, in the fractions corresponding to a molecular weight greater than 100,000 but further gel filtration of the higher molecular weight material gave a similar elution pattern to the initial granule extract, suggesting that the enzyme can undergo reversible aggregation. The yields of dipeptide amide obtained with the purified enzyme were ~40%, which is an order of magnitude greater than could be obtained with unfractionated pituitary homogenates.

To investigate the mechanism of amidation, the reaction was carried out with isotopically labelled tripeptides. D-Tyrosylvalylglycine was synthesized using both ^{14}N-glycine and ^{15}N-glycine and the corresponding D-tyrosylvaline amides were isolated after incubation with the purified pituitary enzyme. The molecular structures of the products were confirmed by high- and low-resolution mass spectrometric analysis of the trifluoracetyl derivatives (Fig. 4) prepared by reaction of the peptide amides with trifluoracetic anhydride in anhydrous conditions[8]. The low resolution mass spectra obtained from the enzymatically derived dipeptide amides were compared with those obtained from the corresponding synthetic dipeptide amides (Fig. 5). Three of the ions obtained showed the single mass unit increment expected from the incorporation of the ^{15}N isotope. High-resolution mass measurements of the molecular ions at 549 and 550 AMU (atomic mass units) and the base peaks of the spectra at 346 and 347 AMU gave unequivocal evidence for the empirical formulae of these compounds (Table 1), proving that the ^{15}N isotope from the glycine residue was retained in the peptide amide. This finding rules

Table 1 Mass measurements of the ions in the spectra of products formed enzymatically from D-Tyr-Val-^{14}N-Gly (a) and D-Tyr-Val-^{15}N-Gly (b)

Nominal mass	Empirical formula	Calculated mass	Measured mass	Error
346(a)	$C_{11}H_{10}O_3N_3F_6$	346.0624	346.0612	−0.0012

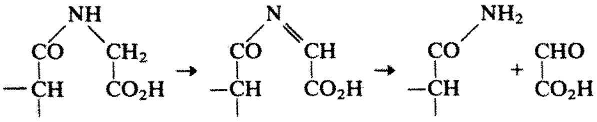
out the possibility that the amide group might arise from ammonia, either by direct amidation of the valine carboxyl group[9] or by transamidation of the valylglycine peptide bond[10]. The data obtained support a mechanism involving removal of hydrogen from the C-terminal glycine and spontaneous hydrolysis of the resulting imino linkage:



Consistent with this oxidative mechanism, it was found that when the incubation was performed with D-Tyr-Val-Gly synthesized with ^{14}C-glycine, the isotope was incorporated into glyoxylate. Furthermore, the amidation reaction was not affected by the presence of 1 mM ammonium ion, glutamine or asparagine at similar concentrations. The proposed mechanism is also consistent with previous suggestions that unsaturated peptides may be formed transiently during the biosynthesis of C-terminal amides[11,12].

The substrate specificity of the amidating enzyme was examined with a range of synthetic tripeptides. It was found that glycine was a mandatory amino acid in the C-terminal position of the tripeptide D-Tyr-Val-Gly; substrates containing leucine, alanine, sarcosine, lysine or glutamic acid in place of the glycine did not give rise to a detectable amount of dipeptide amide. Thus no amidation would be expected to take place with D-Tyr-Val-COOH as substrate, and none was observed. It can be concluded that the dipeptide carboxylate is not an intermediate in the formation of D-Tyr-Val amide from D-Tyr-Val-Gly. That C-terminal glycine should act as a signal for amidation is consistent with recent reports that the sequence of vasopressin is followed by glycine in the prohormone of vasopressin[13] and that glycine is present immediately after the C-termainal residue of calcitonin in the sequence of its biosynthetic precursor[14].

Amidation of the tripeptide D-Tyr-Val-Gly was found to take place when the valine in position 2 was replaced by phenylalanine or glycine but not when it was replaced by D-alanine, lysine or aspartic acid. This suggests that the pituitary enzyme can catalyse the formation of the amide group from the precursors of gastrin, choleocystokinin, oxytocin or vasopressin, hormones that terminate in phenylalanine or glycine amide. Furthermore, as the pituitary enzyme can form amides only with neutral amino acids in position 2 of the tripeptide substrates, and all known hormone amides appear to contain a neutral amino acid in the C-terminal position, it is clear that the pituitary enzyme has similar properties to the enzymes involved in the amidation of hormones in other tissues. The amidating enzyme in porcine pituitary may prove to be common to all tissues that biosynthesize the C-terminal carboxamide group.

We thank D. M. Carter for performing high-resolution mass measurements and product spectra. The Mass Spectrometry Unit is supported by grants from the Wellcome Trust.

Effect of an allozyme polymorphism on regulation of cell volume

Thomas J. Hilbish, Lewis E. Deaton & Richard K. Koehn

Department of Ecology and Evolution, State University of
New York, Stony Brook, New York 11794, USA

Biochemical differences have been described among allozymes[1–4], but the physiological consequences (that is, physiological phenotypes) of such differences have only rarely been demonstrated[5–7]. Such a relationship is necessary both to the argument that natural selection maintains allozymic diversity in natural populations and for understanding biochemical mechanisms of adaptation[8]. We report here a genotype-dependent difference in the rate of cellular free amino acid accumulation during adjustment to hyperosmotic conditions in the mussel *Mytilus edulis*. The product of the *Lap* locus in *M. edulis* is the lysosomal enzyme aminopeptidase-I (AM-I; E.C.3.4.11.-) which hydrolyses oligopeptides to their constituent amino acids[9]. Total AM-I activity is positively correlated with salinity; a 120% increase in salinity increases AM-I activity twofold[10–13]. Adjustment to hyperosmotic stress in osmoconforming marine bivalves, including *M. edulis*, involves rapid accumulation of cellular free amino acids[14,15]. The biochemical properties of AM-I, and its activation by salinity changes, suggest that it is important for providing cellular free amino acid pools during adjustment to hyperosmotic stress[11]. We show that individuals carrying the allele for high catalytic efficiency (k_{cat}) accumulated cellular amino acids more rapidly than other genotypes. The difference in accumulation rate was also demonstrated by an interruption of hyperosmotic adjustment, which resulted in genotype-dependent rates of amino acid excretion. These results demonstrate the role of AM-I in the physiological processes that regulate cell volume. Thus, differing catalytic properties of allozymes are manifested as phenotypic differences at the physiological level and provide a mechanism for the known selective mortality of mussels in natural populations[7].

Allozymes of AM-I have different catalytic properties; genotypes with the Lap^{94} allele (in either the homozygous or heterozygous condition) exhibit about 20% greater activity per unit enzyme protein, due to the higher k_{cat} of this allele[2]. This difference in specific activity, together with the proposed function of the enzyme in cell volume regulation, dictates that: first, on exposure to hyperosmotic stress, individuals with the Lap^{94} allele should accumulate cellular free amino acids at a greater rate. As the cellular response to hypo-osmotic stress consists of the release of amino acids to the haemolymph, some of which

Table 1 Tissue-specific levels of amino acids (ninhydrin-positive substances) as a function of AM-I genotype

	Adductor	Mantle	Digestive gland
Control	539 ± 15.0 (10)	566 ± 27.8 (10)	439 ± 7.3 (9)
Lap^{94}	681 ± 12.7 (29)	680 ± 21.8 (28)	617 ± 6.4 (29)
Non-Lap^{94}	664 ± 15.8 (11)*	655 ± 25.2 (15)*	570 ± 14.7 (16)†

All measurements were made 70 h after transfer of individuals from 15 p.p.t. to 30 p.p.t. salinity. Lap^{94} indicates those genotypes with the allele and non-Lap^{94} refers to all other genotypes. All values are mean ± s.e. in nmol per mg dry weight. Sample size is in parentheses.

* Difference between the two non-control groups not significant at $P < 0.05$; one-tailed t-test.

† Significant difference ($P < 0.005$).

are ultimately excreted[16], differences among animals in the size of the amino acid pool should result from different rates of amino acid excretion. Therefore, a second prediction is that during adjustment to hyperosmotic stress, transfer to hypo-osmotic conditions will produce a greater rate of excretion of amino acids by Lap^{94} individuals.

To test these predictions, animals were acclimated in 15 parts per trillion (p.p.t.) salinity for 2 weeks, then transferred to 30 p.p.t. and the concentration of cellular free amino acids observed during hyperosmotic adjustment. In the digestive gland, there was an increase in ninhydrin-positive substances (NPS; that is, principally free amino acids) of ~160 nmol per mg dry weight. Ten individuals maintained at 15 p.p.t. were taken at each sample period as controls, to demonstrate significant NPS accumulation in high salinity treatments. While the controls were heterogeneous ($P<0.025$; analysis of variance), the variance was due to an elevated mean of the 48-h sample; variation among controls will not affect the tests for relative differences among genotypes. All control variates were combined to give an overall mean and standard error (Fig. 1). The increase in NPS was clearly genotype-dependent (Fig. 1; Table 1); after 48 h at 30 p.p.t. the differences between Lap^{94} and other genotypes approached significance ($P<0.1$; one-tailed *t*-test) and after 70 h at 30 p.p.t., Lap^{94} genotypes had a 24% greater net increase in NPS ($P<0.005$) than other genotypes. One-tailed comparisons were dictated by the *a priori* prediction of greater NPS accumulation in Lap^{94} genotypes because of the higher catalytic efficiency of individuals carrying this allele.

The digestive gland has the greatest AM-I activity of any tissue; mantle and adductor tissues have maximally 50% and 5%, respectively, of the activity found in the digestive gland[13,17]. There were no significant contributions of genotype to the rates of accumulation of NPS in either mantle or adductor tissues, even after 70 h of hyperosmotic adjustment, although the results suggested greater rates of NPS accumulation for genotypes containing Lap^{94} (Table 1). We interpret the lack of genotype-dependent differences in mantle and adductor tissues as being due to the low AM-I activity in these tissues.

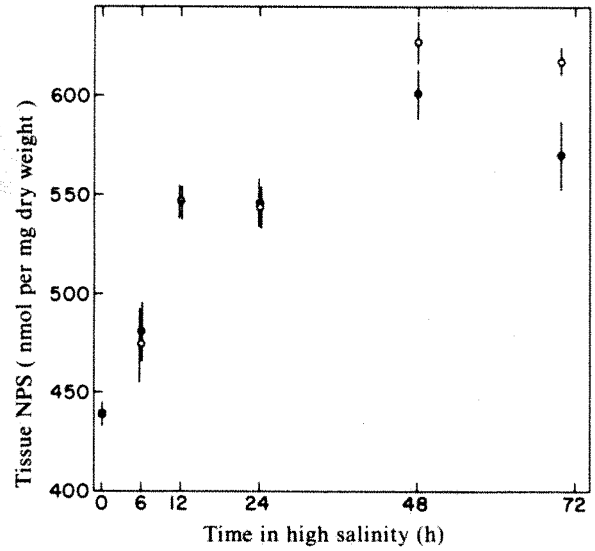

Fig. 1 Accumulation of ninhydrin-positive substances (NPS, nmol per mg dry tissue weight) in digestive gland of *Mytilus edulis* after transfer from 15 p.p.t. to 30 p.p.t. salinity. ○, Genotypes containing Lap^{94}; ●, genotypes without Lap^{94}; ■, overall mean for controls. The determination of NPS was modified for small samples[19]. *Lap* genotypes were determined by starch gel electrophoresis[20].

Table 2 Genotype-specific rates of amino acid excretion during hypo-osmotic stress

	24 h	48 h	70 h
Lap^{94}	304 ± 103 (17)	150 ± 38 (25)	497 ± 75.0 (31)
Non-Lap^{94}	296 ± 78.1 (9)*	183 ± 49.3 (16)*	271 ± 55.5 (15)†

Animals were acclimated to 15 p.p.t. salinity, 15 °C for 2 weeks before transfer to 30 p.p.t. After 24–70 h, animals were returned to 15 p.p.t. for 2 h. They were then placed in 150 ml of 15 p.p.t. filtered (0.45 μm pores) artificial seawater for 2.5 h. The amino acid concentration of duplicate 1-ml samples was determined using the fluorimetric method[18]. Results are expressed as nmol of glycine equivalents per g dry weight per h.

* Difference between genotypic groups not significant at $P<0.05$.

† Significant difference ($P<0.01$; one-tailed *t*-test) assuming inequality of variances.

In animals returned to 15 p.p.t. salinity after 70 h at 30 p.p.t., amino acid excretion reflected the genotype-dependent accumulation differences (Table 2). Genotypes with the Lap^{94} allele showed almost twice the excretion rate of genotypes without the allele. There was a notable concordance between genotype-dependent differences in accumulation during hyperosmotic adjustment and genotype-dependent excretion during hypo-osmotic stress; there were no significant differences in excretion rates until sufficient time had elapsed for significant differences in NPS accumulation to occur (Table 2).

Thus we have demonstrated that known catalytic differences among allozymes have predictable and measurable physiological consequences. In natural situations of diminished or fluctuating salinity, there is a direct ecological 'cost' to possessing the Lap^{94} allele. Our results provide a possible mechanism for the demonstrated selective mortality of Lap^{94} genotypes among natural populations experiencing differing salinities[7]. In a situation of natural environmental variation, an imbalance between accumulation and excretion of amino acids may lead to differential and excessive loss of nitrogenous resources by Lap^{94} genotypes. Specific studies of nitrogen balance in field populations are presently underway.

ANNOUNCEMENTS

Awards

The eighth Marconi Fellowship for Communications, Science and Technology has been awarded to **Arthur C. Clarke** for his contributions to the invention of the communications satellite. Most of the $35,000 grant will be used at the proposed Centre for Third World Communication, Energy and Space Technologies, at the University of Moratuwa, near Columbo, Sri Lanka, of which he is chancellor.

The World Academy of Art and Science has awarded the II Stuart Mudd Award to **Professor Leonardo J. Mata** (Institute of Research in Health, University of Costa Rica) for his pioneer work on intestinal microecology of poor and traditional populations of Central America living in different ecosystems.

The trustees of the Lady Tata Memorial Trust have made international awards for research in leukaemia to **H. Abrams** (USA), **H.J. Allen** (UK), **D.W. Anderson** (USA) (renewed awards); **R.J. Baer** (USA), **A.P. Gee** (USA), and **A.R. Venkitaraman** (India) (new awards).

Sir Alastair Pilkington has been awarded the Messel Medal of the Society of Chemical Industry for 1982. The Medal is the premier award of the Society and is awarded every second year.

The Royal Society of Chemistry presented its annual film prize on 8 June to the producers of the German film *Juncture* which describes work at the BASF chemical plant at Ludwigshafen.

The Royal Society of Chemistry has awarded the Meldola Medal and Prize jointly to **Dr D.C. Clary** (UMIST), for contributions to the theory of molecular energy transfer and chemical reactions, and to **Dr A. Dilks** (Xerox Corporation in Rochester, New York), for work on the characterization and plasma modifications of polymer surfaces.

The Meldola Medal, now accompanied by a prize of £100, will next be awarded in 1983 to the chemist who, being a British subject and under 30 years of age at 31 December 1982, shows the most promise as indicated by published chemical work. Applications, by 31 December 1982, to The President, The Royal Society of Chemistry, Burlington House, London W1, UK, the envelope being marked Meldola Medal.

An award of SF5,000 and a silver medal is available every three years, for the best paper or report devoted to significant work pertaining to coal tar products, plant or processes. Full details and conditions from BTIA, 132/135 Sloane Street, London SW1, UK.

The Beilby Awards, which consists of a medal and a prize of £250, are made to British investigators in science in recognition of original work of exceptional merit which has led to advances of practical significance. This work should have involved the development and application of scientific principles in chemical engineering, fuel technology or metallurgy. The awards are intended as an encouragement to younger men and women, normally under the age of 40. Applications, by 31 December 1982, to The Convener of the Administrators, Sir George Beilby Memorial Fund, The Royal Society of Chemistry, Burlington House, London W1, UK.

The W.K. Kellogg Foundation of America is providing $3 million to enable Oxford University to develop a major centre for continuing education. The Rewley House site in Wellington Square, part of which was acquired and converted into a residential centre for adult students with considerable financial help from the Foundation in 1963, will be redeveloped. Its new conference facilities will include a large lecture theatre, eight fully-equipped seminar rooms, a library and an administrative block. Existing residential accommodation will be upgraded, and catering facilities enlarged.

Appointments

Dr Lewis M. Branscomb has been re-elected chairman and **Dr Mary L. Good** vice chairman of the National Science Board, the governing body of the National Science Foundation.

Dr George Bugliarello (President of the Polytechnic Institute of New York) is the new Council Secretary of the Marconi International Fellowship Council following the retirement of Dr Walter Orr Roberts.

Prof. Alvin M. Kaye, has been named as the first incumbent of the Joseph Moss Chair in Molecular Endocrinology, established at the Weizmann Institute of Science.

Prof. R.J. Berry (University College, London) has been elected president of the Linnean Society for the next three years, succeeding Prof. W.T. Stearn. **Dr Colin Patterson** was elected as editorial secretary and the other officers were re-elected.

The Zoological Society of London has elected **Professor John Phillips** (Director of the Wolfson Institute in the University of Hull) as its next Secretary.

Prof. Janet V. Watson (Geology, Imperial College of Science and Technology) has been elected president of the Geological Society.

Prof. David G. Harnden (Department of Cancer Studies, University of Birmingham) has been appointed Director Designate of the Paterson Laboratories, Christie Hospital and Holt Radium Institute at the University of Manchester, to succeed the present Director, Professor L.G. Lajtha on his retirement in June 1983.

Meetings

1-3 September, **International Hepatitis Workshop,** Stirling (Miss E.K.S. Grant, Nuclear Enterprises Ltd, Sighthill, Edinburgh, UK).

1-3 September, **Annual Symposium Uranium Institute,** London (Mrs C. Scott Barrett, Conference Associates UIS, 34 Stanford Rd, London W8, UK).

1-3 September, **Fast Reactions in Solution,** Leuven (Dr A. Persoons, Dept of Chemistry, University of Leuven, Leuven, Belgium).

1-3 September, **The International Environment and Safety Exhibition and Conference,** Wembley (Labmate Ltd, Sandpit Lane, St Albans, Herts, UK).

3-9 September, **Science and Technology in the Service of Conservation,** Washington DC (IIC American Meeting, 1511 K Street NW, Suite 725, Washington DC 20005, USA).

5-9 September, **Protein Metabolism and Nutrition**, Clermont-Ferrand (4ème SIMNA, INRA-Theix, Laboratoire d'Etude de Metabolisme Azoté, 63110 Beaumont, France).

5-11 September, **World Congress on Medical Physics and Biomedical Engineering,** Hamburg (Hamburg Messr, Congress Organisation, D-2000 Hamburg 36, PO Box 30 23 60, FRG).

5-15 September, **Charles Coulson Summer School in Theoretical Chemistry,** Oxford (Dr P.J. Grout, Theoretical Chemistry Dept, 1 South Parks Rd, Oxford, UK).

6-8 September, **Charged Particles Management of Electrostatic Hazards and Problems,** Southampton (Miss L. Claff, Scientific and Technical Studies, Oyez IBC Ltd, 11-13 Norwich St, London EC4, UK).

6-8 September, **Modern Aspects of Heterocyclic Chemistry,** Sussex (Miss L. Hart, Royal Society of Chemistry, 30 Russell Square, London WC1, UK).

6-9 September, **Distillation,** Geneva (The Center for Professional Advancement, Postbus 19865, 1000 GW Amsterdam, The Netherlands).

6-10 September, **Annual Meeting, British Association for the Advancement of Science,** Liverpool (Ms U. Laver, BAAS, Fortress House, 23 Savile Row, London W1, UK).

6-10 September, **Linear Programming and Operational Planning in the Petroleum Chemical and Process Industries,** Edinburgh (Education Secretary, Institution of Chemical Engineers, 12 Gayfere St, London SW1, UK).

BOOK REVIEWS

The vision of David Marr

Stuart Sutherland

IN 1973 David Marr, then 28 years old, moved from Cambridge, England, to Cambridge, Massachusetts; seven years later he died of leukaemia. During this period he formulated a new approach to the theory of vision and published his results in a series of papers of great depth. Much of Marr's originality lay in his insistence that one must have a rigorous theory of how a particular task is performed before proceeding to construct a computer model of how the brain carries it out. *Vision,* posthumously published, presents a survey of his own work and that of the group of exceptionally clever young scientists whom he inspired with his ideas.

Despite his originality, Marr's papers were often flawed. Many were poorly written and unnecessarily opaque. Moreover, each paper tackled a particular aspect of vision and it was sometimes hard to see the connections. Marr's book overcomes both problems. It is written in a lively style and is for the most part lucid and free from technicalities. In addition, it has a clear structure that integrates the different aspects of his research.

Marr believed that there are three main levels of visual processing, at each of which a separate representation of the world is formed. At the lowest level is "the primal sketch", a representation of the retinal image that makes explicit the size and disposition of the intensity changes present. The primal sketch itself contains several levels of representation. At its highest levels it represents boundaries formed by grouping lower level elements. Such a boundary may be formed, for example, by a change in the density or size of a set of circles present in the retinal image. The purpose of the primal sketch is to deliver to higher level processes an explicit description of the boundaries that exist in the image and to enable these processes to determine whether the boundaries found are caused by a change in reflectance, a change in light intensity, an occluding contour or an edge at which two visible surfaces of a body meet.

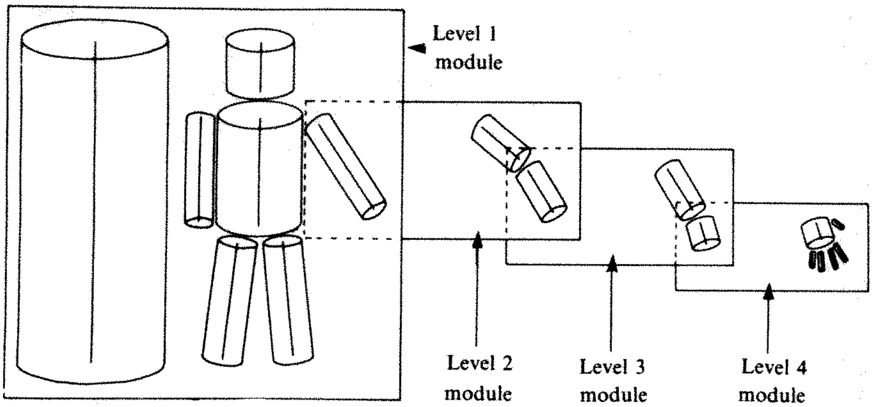
Much the longest section of Marr's book is devoted to the processes that operate on the primal sketch in order to recover a 3-dimensional representation of the world. Amongst these processes are stereopsis, and those that use shading, texture, occluding contours and various aspects of motion. From these cues the second level of representation, the "2½-D sketch", is constructed: this is a representation of the scene based on viewer-centred coordinates, which makes explicit the slope relative to the viewer at each point on all visible surfaces. For the purpose of recognizing objects, a 3-D model, the highest level of representation, is formed from the 2½-D sketch. This model represents objects in object-centred coordinates (based either on the direction of elongation of the object or on its symmetry) and it makes explicit the volumetric structure of the object by representing its parts as generalized cones (the volume swept out by moving a cross section of a particular shape along an axis).

Vision: A Computational Investigation into the Human Representation and Processing of Visual Information. By David Marr. Pp.397. ISBN 0-7167-1284-9. (W.H. Freeman: 1982.) £22.50, $39.95.

Not only does *Vision* have a clear structure, it also gives an integrated treatment of each stage of processing, based on Marr's philosophy of the nature of explanation in psychology. He distinguishes three levels of explanation. At the highest level is a *computational theory,* that is a theory of how a task can be performed. At the next level is a *representation* and an *algorithm* to achieve that representation. At the lowest level lies the question of how the algorithm is actually implemented in the *hardware* of the system.

Marr's originality and much of the depth of his own thinking stems from his emphasis on the top level type of explanation, which few had previously even considered. The computational theory for a given stage in processing should, according to Marr, specify what is being computed, and why this is a useful thing to compute. It should in addition specify the ways in which the image is related to the world, that is to say, the constraints on how the image can be interpreted. It is only the existence of these constraints that makes it possible to recover from the image the properties of the scene. Thus, in recovering the shape of a rotating body from successive views of it, it is necessary to assume that the body is rigid, since otherwise there is an infinite number of possible interpretations. The assumption will normally hold true; where it does not, no solution to recovering a body's 3-D shape from its motion will emerge. Again, stereopsis depends on the constraints that in general one and only one point on one retina receives light from the same source as a single point on the other, and that local changes in disparity will be small. Both constraints have exceptions — in parts of the visual field there will be objects or parts of objects that are seen by one eye but not the other, and where one object occludes another there will be sudden changes in disparity. But for the most part the constraints hold, because the world is largely made up of surfaces that are comparatively smooth. Only by using these constraints is it possible to decide which point in the image on one retina corresponds to a given point in the image on the other.

The computational theory of a given task not only constrains the nature of the algorithm, it also constrains the nature of the representation of the results of a given stage of processing. Thus, Marr justifies the primitives used in the primal sketch (for example, segments of lines and edges formed by brightness changes, and higher level boundaries) by noting that it is just this sort of information that is needed to recover at the level of the 2½-D sketch the



Hierarchical organization of a 3-D model: the visual object (here a person) is decomposed into parts, and each part is decomposed into successively finer and finer detail — in this case whole body, arm, forearm and hand. Each part is represented by its central axis and a generalized cone that corresponds to the volumetric shape of its surface. This method of representation preserves gross similarities between objects whilst making explicit variations in detail.

local orientation of surfaces and their reflectance. Again, in deciding how to represent the 3-D model of an object, Marr is guided by a computational theory of the process of recognition. First, the representation has to be accessible, that is, it must be possible to compute it economically from the image. Second, it should have a wide scope in that it must be possible to represent any object that can be recognized. Third, it must provide a unique description of a given object, otherwise different descriptions would be formed on different occasions and hence recognition would fail. Fourth, the representation should reflect the similarity between similar objects, but should also make explicit small differences: we can both see the similarity between different people and can also recognize individuals. Marr's method of representing 3-D objects meets all these constraints. Thus, the last constraint is satisfied by organizing the representation hierarchically so that the coarse shape of an object is represented in one module with other modules representing successively finer and finer detail (see diagram p.693).

There is a further way in which Marr's work is superior to that of most of his contemporaries. Other vision programs have usually taken no account of psychological or neurophysiological findings. In deciding what algorithm to employ, Marr makes use of both kinds of evidence where relevant results exist. For example, having proposed a simple and elegant model of stereopsis, he abandoned it because it did not fit the psychophysical findings. He put forward a second model, which although considerably more complex is consistent with the psychophysical results. In essence it begins by matching large features in the two images and allows for the use of eye-movements to reduce disparities in matching finer detail. Again, in his account of motion perception, he suggests that Y-cells may subtract a measure of the brightness at time $t+60$ msec from the same measure at time t: hence a cell will fire only if an edge is moving with the lighter part leading. He makes out a case that this idea is consistent with the known physiological properties of Y-cells. This is an ingenious idea for motion detection, but there is so much confusion amongst neurophysiologists about the role of X- and Y-cells that it may be premature.

Vision has two faults. First, despite Marr's emphasis on the importance of implementing algorithms as computer programs to make sure they work, it is often unclear whether he has actually written and tested a computer program to perform a particular task. Moreover, even when he claims to have implemented an algorithm, he rarely discusses how successful the program is and he gives no clear indication of the range of scenes on which it succeeds and those on which it fails. This nonchalant approach to computer modelling is unfortunately typical of the Artificial Intelligence community. Second, he is sometimes unduly dismissive of the research of others. For example, he scorns the work of Waltz and Mackworth, who wrote programs to recover depth from polyhedra, on the grounds that they were dealing with "mini-worlds". His allegation is correct, but it remains true that people can readily see depth in line-drawings of such objects and Marr provides no alternative account of how this task is performed. Both Waltz and Mackworth in fact succeeded (at different levels) in working out the constraints that enable this task to be carried out and to that extent they were amongst the few of Marr's predecessors who had a computational theory of the task they simulated.

Marr begins his preface by writing "This book is meant to be enjoyed": his intention will be fulfilled. The book is not only enjoyable, it is exciting and contains many stimulating ideas. For example, he gives good reasons for supposing that the brain cannot use iterative processes unless they converge very fast. *Vision* is perhaps the most important book on the subject to appear since Helmholtz's *Physiological Optics* was published over a hundred years ago. Marr's untimely death was a grievous loss to psychology. □

NMR of biopolymers

Alfred G. Redfield

NMR in Molecular Biology. By Oleg Jardetzky and G. C. K. Roberts. Pp.681. ISBN 0-12-380580-5. (Academic: 1982.) $59, £39.

ALTHOUGH nuclear magnetic resonance does not occupy the central role in the biological sciences that it has in analytical organic chemistry, there is hardly a branch of biochemistry or biology to which it has not been applied in recent years. The physical basis for these biological applications is the same as for organic chemistry, but the goals and general methodology differ significantly. While no unusually subtle new ideas are used, biologically relevant NMR is often complicated and controversial in its interpretation, owing to the complexity of the systems involved, and it forms a new and flourishing sub-discipline. Most current research is directed toward fine-grained local structural studies, and the determination of dynamic behaviour which only NMR can provide.

The authors of this treatise were among the innovators, and continue to be active, in this field. Their book is a thorough treatment of the most mature application of NMR to biological problems, namely the study of small molecules and macromolecules in solution, alone and in interaction with each other. Topics such as *in vivo* metabolism and NMR imaging are omitted, as is a comprehensive treatment of NMR of partly immobilized or frozen structures (commonly called "solid state NMR") except for a brief description of its application to membranes and related problems. The emphasis is therefore on proteins, especially enzymes, reflecting both the majority of current applications and the experience of the authors. Restricting the content of the book in this way was wise, since the areas not covered were in early stages of development at the time (early 1981) when the book was completed, and because the treatment of solution-state NMR could then be comprehensive in a book of reasonable length.

There are short introductory sections on fundamentals and instrumentation, and also descriptions of theories of relaxation, both paramagnetic and diamagnetic. Most

Climate and history

Nineteen eighty two seems to be the year for books on climate and history. In addition to the two volumes reviewed by Stephen Schneider (*Nature* **298**, 499) are *Climatic Change in Later Prehistory*, edited by Anthony Harding and published by Edinburgh University Press, and *Food-Climate Interactions* with Wilfrid Bach *et al.* as editors and Reidel as publisher. Both books are the records of meetings. Prices are (EUP) pbk £9.75, (Reidel) hbk Dfl. 135, $58; pbk Dfl. 65, $28.50.

of the book is devoted to a descriptive, often case-history, treatment of individual problems and their attempted solution. Nearly half the text covers applications to enzymes and proteins, and it concludes with chapters on nucleic acids and on membranes. There are approximately 1,500 references (out of, we are told, a possible 6,000 on the subject) and a significant number of them are discussed at least briefly.

The style is refreshingly critical, with the inevitable result that every experienced reader will find points of disagreement with certain statements or with the emphasis. For example, I felt that the treatment of nuclear spin relaxation as a tool for studies of protein dynamics overemphasizes the methods used by Professor Jardetzky and his colleagues. The novice should be warned that nearly every topic in this field is subject to dispute but for the most part the authors do present both sides of complex issues, in references if not in their discussions. Unavoidably, certain areas are developing so rapidly that the text can provide only a useful indication of very recent advances: examples of such areas are studies of nucleic acids and of the conformation of small proteins by two-dimensional NMR.

Jardetzky and Roberts have written the most thorough treatment of the subject now available, and the first such treatise to appear in some time. Their book will be extremely useful to both experienced NMR research workers and novices alike. □

Alfred G. Redfield is Professor of Biochemistry and Physics at Brandeis University.

Tackling the bugaboos of solar flares

Robert Rosner

Solar Flare Magnetohydrodynamics. Edited by E.R. Priest. Pp.563. ISBN 0-677-05530-7. (Gordon & Breach: 1982.) $89.50.

SOLAR flares have long been an enigma. Along with such problems as how the solar corona is heated, and where the "missing" solar neutrinos are, the solar flare puzzle has been a persistent reminder to astrophysicists that the gap between observation and theory is still uncomfortably large whenever the data are of sufficient quality to rigorously test the details of theoretical models.

In the case of solar flares, the difficulties may be attributed both to the classic bugaboo of theoreticians, namely phenomena in which nonlinear effects dominate (in the present case, derived from the non-linear equations of magnetohydrodynamics); and to the virtual certainty that much of the crucial physics takes place on spatial scales which are not likely to be observable in the forseeable future (hence theory in this respect remains unconstrained by data). Given the complexity of the subject, it is welcome news that *Solar Flare Magnetohydrodynamics* does a commendable job of reviewing much of the theory relevant to present-day solar flare research.

The book is largely complementary to the recent NASA monograph on solar flares, *Proceedings of the Skylab Workshop on Solar Flares* edited by P.A. Sturrock (Colorado Associated University Press, 1980) and, if read in conjunction with this second tome, the student of solar flares will have in hand a full account of research prior to the recent flight of the Solar Maximum Mission (SMM) satellite. As such, the book should be of interest to all concerned with time-dependent (magneto-)hydrodynamics and plasma physics in astrophysics. The material is written at a fairly advanced level, but is not so esoteric as to be inaccessible to students.

With the exception of Z. Svestka's brief chapter which reviews observations (a topic covered far better in the NASA/Skylab monograph), the book is true to its title and gives a systematic exposition of the physics of flaring plasmas, from equilibrium to possible instability, and along the way treats the associated microphysics leading to explosive heating and particle acceleration. Chapters are written by active, prominent researchers in the field, and generally convey a good sense of the current status of work in this area. Particularly noteworthy and complete are the discussions of current sheet dynamics by E. Priest, time-dependent hydrodynamics (I. Craig), evolution of post-flare plasma (G. Pneuman) and flare particle acceleration processes (J. Heyvaerts).

With the exception of J. Birn and K. Schindler's discussion of magnetic field equilibria, the chapters are well-integrated; this exceptional case, though competent in content, has a rather formal style, with virtually no attempt to mesh theory with observation.

A pleasant surprise is Priest's superb overview in the introduction, in which a précis of the entire book is given; this chapter not only ties the various contributions together, but also gives a nice perspective of the solar flare problem as a whole. The overall result is a monograph of great value; it is a must for solar physicists, and for all interested in sudden magnetic energy release and its consequences in astrophysics. □

Robert Rosner is an Assistant Professor of Astronomy at Harvard University.

Energy and life

Robert M. Macnab

Biological Energy Transduction: The Uroboros. By Ronald F. Fox. Pp.279. ISBN 0-471-09026-3. (Wiley: 1982.) £24.50, $43.80.

THE dual purpose of this book is given in its preface: first, it is intended to be an introduction, for physical scientists, to advances that have taken place in molecular biology in the past few decades; second, a description of biology from the viewpoint of energetics, suitable for senior undergraduates or graduates. These would seem to be rather distinct aims, and it is unclear why they should be pursued in a single volume — or, for that matter, why physical scientists require a special exposition of molecular biology.

An emphasis on energetic considerations in biology and their use as a unifying concept is what the title of the book leads one to expect, and, in general, the author has been successful in presenting this point of view. His style is clear and entertaining, and the major topics of interest in bioenergetics (e.g. control of metabolic pathways, storage of energy across membranes, chemi-osmosis, energetics of macromolecular synthesis) are treated well, provided one does not examine too closely the factual details presented.

In this latter regard, the book is flawed. Sometimes the error (e.g. that the bacterial flagellum is a triple helix) is incidental to the argument, but it is irritating nonetheless and one wonders how it came about. In other instances, the errors are more serious. I will cite two examples. First, on p.203, an erroneously high value for the cytoplasmic *p*H of bacteria is given, and then used in subsequent bioenergetic calculations. The author comments that

> Many microbiologists and biochemists will be surprised to read that for bacteria grown in a medium of *p*H 7 the internal *p*H is as high as 9.

Indeed they will — did he ever ask them? (Typical experimental values are around 7.5.) Second, the choice of standard state for H_2O in conventional tabulations of free energy changes, redox potentials and so on, is incorrectly believed by the author (p.62) to be 1 M; based on this belief, he proceeds to make adjustments to 55.6 M, which of course was the standard state chosen in the original tabulations. A variety of conclusions regarding the energetics of electron transport and oxidative phosphorylation are then based on these adjusted values, and the rest of the scientific community is taken to task (p.211) for failing to make these "corrections". It is unfortunate that the author apparently did not discuss these questions with physical chemists or biochemists before codifying his viewpoint in a textbook.

The final part of the book is devoted to a

Similarities in Physics

John N Shive and Robert L Weber

A new educational text stressing the similarities between apparently quite different areas of physics. The authors' unusual mission is best summarised by these extracts from their preface, addressed to the student reader:
The edifice of physics is not nearly as complicated as it often appears. The purpose of this book is to tie similar phenomena together, wherever they may appear, in mechanics, acoustics, optics, electricity, heat, or theoretical physics, and to call your attention to the similarities between them. Physics may be simpler than you think; nature is marvellously regular in its behaviour; analogies helpfully link what is being studied with what is already understood . . . Sharpen your ability by being alert to similarities. That's the keynote of this book!

A Handbook of Public Speaking for Scientists and Engineers

Peter Kenny

The only handbook offering guidance to scientists and engineers called upon to speak in public on technical matters. Peter Kenny aims to give every person in a technical or specialist field the opportunity of becoming a competent speaker. In his own words:
This book will show you how best to prepare your paper for presentation at a technical conference, how to put your case at your next committee meeting, and how to make a good impression on those visitors you will be talking to tomorrow. Not only does the book deal with specific events, but it also provides you with the techniques that will make you a more effective speaker whether presenting papers, answering questions, or speaking 'off-the-cuff'.
The book is intended for quick and easy reference, and also for more detailed study.

consideration of the evolution of the "uroboros", defined as an interlocking and at least partially self-sustaining macromolecular assembly of considerable complexity. It is suggested that, after several pre-biotic steps, an RNA polymer (generated under hygroscopic conditions) placed some selectivity on self amino-acylations; these eventually resulted, via "ur-" (= primitive) t-RNAs and ur-ribosomes, in a selectivity of linkage of the amino acids to each other. How closely the description approaches the actual process by which cells evolved is of course difficult to ascertain, but earnest attempts such as this to construct models, which are at least plausible in terms of the properties of biomolecules, help to take the question of the origin of life out of the realm of the utterly mysterious.

Overall, I found this to be an interesting and instructive book but, in light of the factual errors it contains, it cannot be recommended as a textbook. ☐

Robert M. Macnab is an Associate Professor of Molecular Biophysics and Biochemistry at Yale University.

From terrestrial processes to martian features

Lionel Wilson

The Channels of Mars. By Victor R. Baker. Pp.198. US ISBN 0-292-71068-2; UK ISBN 0-85274-467-6 (University of Texas Press/Adam Hilger: 1982.) £22.50, $39.95.

AMONG all the bodies of the Solar System yet explored in detail, Mars appears to be the only one which has had an evolutionary history sufficiently like that of the Earth to make extensive comparisons readily possible, and, at the same time, sufficiently different to make the comparisons profitable in the study of both planets.

The least-readily understood surface features of the planet are the several varieties of channel and valley showing many of the characteristics which would be associated on Earth with fluvial, glacial or permafrost processes. Present-day surface temperature and atmospheric pressure conditions on Mars preclude the existence of liquid water for other than very short periods unless large volumes of water are involved. Thus, any model of the channel-forming process which requires protracted periods of gentle water action has profound implications for the environmental conditions prevailing at the time the channels were formed. It is clearly vital to establish the duration of the channel-forming events and the times in martian history at which they occurred.

Victor Baker has been associated with the study of the martian channels since their discovery. In this welcome survey, he succeeds in presenting a generally well-balanced review of the classification systems and morphological features of the channels and of ideas on their origins, appealing widely to Earth analogues. The overall picture which emerges is one of very slow, periglacial activity alternating with brief periods of catastrophic water release. The morphological evidence for the proposed ice-related mechanisms is strong and the physical models for the processes involving ground ice migration seem well founded.

Much of the book is devoted to those aspects of the larger channels which appear to demand catastrophic flooding by large and rapidly-released volumes of water. An extensive comparison is made between the martian features and the landforms developed in the Channeled Scabland of the north-western United States as a result of abrupt and massive water release from glacial lakes after failure of their ice dams. The morphological comparison is supported by calculation of a number of the fluid dynamic parameters associated with both martian and terrestrial floods. While the evidence for the formation of the martian channel forms by water flooding is compelling, the author is at pains to point out that we are not yet sure of the mechanisms whereby huge quantities of water are released abruptly from within the martian crust — though he does review a number of the suggestions which have appeared in print.

The style of Baker's presentation is such that it is hard to read individual chapters of this book in isolation: appreciation of the complete story requires reading the entire book. The work seems to be pitched at the undergraduate/postgraduate level, though the lay reader will have little difficulty in following the arguments and the large collection of references will be of value to the planetary science specialist. A notable feature of the book is the high quality of the many black-and-white photographs. The few typographical errors are almost all associated with numbers and equations and will be readily detected by the attentive reader. As much as anything else, the book whets one's appetite for further advances in this field. ☐

Lionel Wilson is a Lecturer in Planetary Sciences with the Department of Environmental Sciences, University of Lancaster.

Nuclear LUAnacy or sensible choice?

The policy of launch under nuclear attack seems to be finding increasing favour in unexpected quarters. But can we rely on machines to push the button?

Long derided as highly dangerous, the policy of launch under attack (LUA), in which one superpower would launch its land-based nuclear missiles on certification of a nuclear attack by the other, is enjoying new respectability in Washington and Moscow. This heightened interest is important because LUA has been regarded as so crazy for so long by so many and because it may well be the way in which President Reagan and Mr Caspar Weinberger, the US Secretary of Defense, end up solving the problem of how to protect the US land-based missile force. Indeed, in the future, LUA may be a more reasonable strategic option than it is now or has been — but the Department of Defense and the arms control community should study it carefully before deciding to proceed down that path.

At present the United States does not tell the Soviet Union outright whether it would launch upon warning of attack or not. And in light of the number of errors which the warning and command system could produce, and the consequent difficulty the President would have in making rapid decisions, a US policy of LUA hardly seems practical. On the other hand, the annual defence posture statements setting out US military policy, during the term of former Secretary of Defense Harold Brown, contained explicit references to the possibility that the Soviet Union must consider the likelihood of LUA before deciding to attack the United States. These hints were doubtless read with interest in Moscow.

Now, however, the issue is shifting away from official verbal hints and the obvious problems of the present system towards a discussion of future US goals. The new issue is whether, in future, the United States could build a warning and command system it could rely on to execute LUA policy, not merely preserving LUA as an option.

The interest is coming from some surprising quarters. In early July, Soviet defence minister Dmitri F. Ustinov suggested — without using those exact words — that the Soviet Union might move to an LUA policy. Ustinov was echoing what another Soviet analyst had told a group of visiting Americans. Last year, the Office of Technology Assessment of the US Congress offered a surprisingly bright view of LUA as a possible alternative to mobile basing of the MX missile. Finally, Dr Richard L. Garwin, a well known defence expert for IBM, advocates LUA. Among other LUA advocates is Harold Agnew, former director of Los Alamos National Laboratory, who is now president of the General Atomic Company. But Mr Weinberger, although continuing to mention the possibility of LUA in his posture statements, has not shown any real interest in such a policy.

Ustinov and the other Soviet official who hinted at a possible Soviet LUA policy were apparently intending to counter US nuclear weapons modernization. If you get a hair-trigger ability against us with your MX and other programmes, they seemed to say, we will be forced to respond rapidly, with LUA. Another interpretation, offered recently by Paul Bracken of the Yale School of Organization and Management, is that the Soviet Union feels it was backed in a corner by President Jimmy Carter's Presidential Decision Memorandum 59, which in 1980 shifted US policy towards fighting out a nuclear war through the macabre idea of "limited nuclear war". If the United States makes a target of Soviet command authorities rather than Soviet cities, the Soviet Union has to consider launching its missiles early while it can still command them before the US missiles could reach the target.

There is, in fact, a debate about whether the Soviets could execute a LUA policy, no matter what they say. Soviet rockets are liquid fuelled, and cannot be kept ready to be fired at a moment's notice, unlike US rockets which are solid-fuelled. Nor is Soviet command and control on a high state of alert, normally, (partly, it is said, to prevent Soviet generals from commandeering their nuclear weapons as part of some coup). On the other hand, since any nuclear attack is likely to start during a period of general high tension, these drawbacks may not obtain, and the Soviet Union may have some chance, it is argued, of bringing off an LUA. Clearly a Soviet LUA policy, if only a declaratory one, should worry US leaders: among other things it would make Western Europe even more impressed by the Soviet bear.

The possibility of a US policy of LUA is more interesting, because a practical LUA capability is for the United States only several years and billions of dollars away (while the MX with its basing system would cost tens of billions of dollars). This was the conclusion, at least, of the OTA panel under Harry Woolf, director of the Institute for Advanced Study in Princeton. In a remarkable chapter on LUA, it said, in effect, that technology is not an obstacle to achieving some sort of meaningful LUA capability. "Doctrine and procedures — issues of national policy, not technology — more than anything else . . . determine the architecture of an LUA system," it said. The overall report, of course, did not favour any particular MX basing mode, or LUA. It merely presented several of the options to Congress.

This view contradicts the conventional view, based on past and present capabilities, that there are too many ways in which warning and communications could be disrupted or go wrong or simply be ambiguous. The President cannot, it has been said, have enough reliable information to make the cosmic decision in the 30 minutes afforded by an intercontinental ballistic missile (ICBM) attack or the 5–15 minutes in the case of a submarine-launched ballistic missile (SLBM) attack. Early warning satellites could be blinded by preemptive nuclear explosions in space, or mistake the signature of the missiles, or be so delicate as to trigger a false alert internally: and the government has revealed that the existing system triggers many such errors each year. Futhermore, SLBM's computer accessory equipment can set off false alarms: the DEW line radars have "seen" an attack when they were only looking at a flight of geese or the rising Moon.

The OTA report suggested that future systems could overcome many of these defects — although it made no claim that a system could be invulnerable. Early warning satellites could be moved out of crowded, geosynchronous orbit where a Soviet "space mine" could attack them. Instead they could be placed by themselves, further out, in unique deep orbits chosen at random, so there would be reason to suspect the innocence of any unidentified object that approached them. Since non-synchronous orbits would be used, there would have to be many warning satellites to assure that at any given time, one would be "watching" Soviet territory. If the satellites were high enough it would take a long

0028-0836/82/330695 02$01.00

time — as much as 18 hours — for a ground-launched missile to reach them and knock them out.

The peculiar and varying orbits, and the use of "dormant" satellites as reserves, could make it very difficult for a Soviet anti-satellite system to knock them all out. In short, the warning system itself would contribute to security, by buying leaders more time.

The report also suggested that communications links could be maintained in a variety of ways: satellite communications could use millimetre wavelengths to avoid ionospheric disturbances due to high-altitude nuclear explosions. Rocket-launched reconstitution satellites could be on ready alert; existing communications satellites could be prepared to serve as back-ups. An LUA communications net would have an advantage over the alternative communications nets for other MX options, in that its most crucial period of use would be before the atmosphere was disrupted by nuclear attack.

In sum, the OTA report foresaw a future LUA system resilient enough to warn of a major attack — such as the lightning bolt-from-the-blue that the MX is meant to counter. The report implies that the President would not be faced with only a few minutes to think, panicked generals and blinking machines, but a relatively well ordered set of options: knowledge through early-warning of anti-satellite efforts, time to use the "hot line", and sure information about the attack itself. The report went so far as to suggest a series of automatic LUA programmes for response, that might not need the President's decision, in case he was incapacitated or unavailable.

Garwin takes this one step farther. If the United States had an announced, self-evident and reliable capability for LUA, the Soviet Union should be deterred from ever attempting to attack, he says. In attacking, the Soviet Union would have to launch its missiles all at once to minimize US foreknowledge. Thus, submarine-launched missiles would start hitting US bomber bases and US submarines in port 5 to 15 minutes after the launch, when the long-range ICBMs still had 15 minutes or more to go before reaching their targets.

All the President needs to be able to do, Garwin argues, is to certify that this attack is under way, based on information his machines can surely provide. He would then authorize a pre-planned launch of the US land-based ICBMs, his only surviving force. If the Soviet Union realized how automatic and surely this retaliation would come, Garwin says, it would be deterred from attacking in the first place, even against the vulnerable force of US land-based ICBMs. Thus for Garwin, LUA is the solution to the problem of Minuteman vulnerability.

Garwin's proposed LUA policy, with its elements of automatic response and certainty of destruction of the attacking side thus has much in common with MAD — the 1960s doctrine of "mutual assured destruction" under which the United States (which then had less accurate weapons than it does now) pledged to destroy Soviet industry and society if it were ever attacked. One way to look at a possible LUA policy, therefore, is as a high-precision version of MAD.

Is all this technological hubris of the first order? What sane president, or sane society, would entrust the decision about its likely end almost entirely to machines? If the warning could not be made reliable, LUA could make a mockery of human judgement and morality.

But if technology has evolved to the point where the machinery could be made reliable we must think again. Should we decline to upgrade strategic warning, and decide not to give leaders the best information they can get? What sane president, faced with a possible nuclear attack, would want to turn the calculations over to rows of men with abacuses to make sure the "human element" was not lost in the final decision? Every day, jetliners carry innocent passengers across oceans and continents on automatic pilot systems, yet this is not morally outrageous, so long as the pilot is there to back up the machines.

A society that has already delegated so much to technology, ought, when it comes to make a final choice, to consider technology an ally, too.

An almighty crash

AEG brought about its own collapse, but there are lessons for all to learn

The collapse last week of the West German corporation AEG-Telefunken has been on the cards for more than a decade, but is none the less to be mourned on that account. The seventh largest corporation in West Germany, AEG-Telefunken is a monument to the optimism of the 1950s and 1960s, so that its decision to appeal to the courts for relief from three-fifths of its still unspecified debts marks the passing of an era. For much of the past twenty years, AEG-Telefunken had around its neck the albatross of its 40 per cent share in Kraftwerk-Union, the nuclear construction consortium — until Siemens obligingly bought it out in 1978. During the same period, but especially at the beginning of it, AEG seems accurately to have appreciated that high technology was waiting around every corner and to have determined to be strongly represented in them all. So was it just bad luck that it was not then possible to guess how high would be the cost of development in most of these new fields; or that technological conglomerates would become unfashionable; and that they would prove to be so hard to manage?

Hardly. Compared with Siemens, the obvious analogue, AEG has been run by accountants rather than by technologists. They have been skilled at raising extra capital — no less than DM1,000 million in 1979 from the West German banks, for example — but apparently less skilled at matching their technical ambitions to reality. Even so, the efforts they have made in the past three years to sell off parts of the business, and to form joint ventures with other corporations (as with Bosch over telecommunications) have been insufficient. The most obvious difficulty has been that AEG has not been technically outstanding in any of the fields in which it has taken an interest. The moral, for other corporations, should be familiar. A technically based conglomerate, however large, can survive in the long run only by technical excellence.

To many outside West Germany, it has been a surprise that one of the impediments to the reconstruction of AEG has been the resistance of the labour unions to the threat of redundancy, one of the reasons why the British General Electric Company last week pulled out of negotiations about a partnership with AEG in the manufacture of heavy electrical machinery. Despite the record of harmonious industrial relations in West Germany since the Second World War, it should be no surprise that unions are less compliant with their employers' needs on the downturn than they were during the economic miracle. But the prospect now is that AEG will have to shed at least 40,000 of the 100,000 people it employs in West Germany and perhaps an even larger proportion of its 20,000 employees elsewhere. It is almost too much to ask that flesh and blood should stomach redundancies on such a scale. Represented as they are by law on the supervisory board of AEG, the unions have behaved predictability. Elsewhere governments have stepped in to avoid trouble of this kind (as at Chrysler and British Leyland).

So what will be the consequences of the decline of AEG? Those who will lose their jobs, like those who have lost a large part of their investment in the company, will be more than merely inconvenienced. So too in the short run will be the host of smaller companies working as suppliers for AEG. Its competitors will now find the market for their goods more buoyant and more easily attacked. The business that AEG is forced to shed will in due course be picked up by others, with the result that some of those now destined to lose their jobs will be re-employed. In the long run, there will be two conspicuous losers. First, the legend of West German industrial cleverness will be permanently tarnished. Second, Chancellor Helmut Schmidt's coalition government, which has steadfastly declined to intervene on AEG's behalf (and which was politically and economically powerless to intervene) will be unfairly blamed by its opponents for not having lifted a finger and for having created the economic climate that brought AEG to its knees.

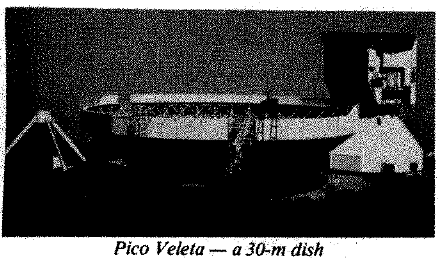
Japan reaches for the stars

Radio-dish looks set to excel

Japan is now poised to take a world lead in millimetre-wave radioastronomy — the study of molecular clouds and star-formation regions — thanks to a far-sighted decision by the Japanese Ministry of Education more than a decade ago to support the plans of Tokyo Observatory.

For while American molecular astronomers smart under the effective abandonment of their own country's plans for a large (25-metre) dish to operate in this wavelength range (see *Nature* 12 August, p.596), Professor Kenji Akabane of the Tokyo Obervatory will announce this week at the International Astronomical Union meeting at Patras, Greece, his first observations with a 45-metre dish and a 5 × 10-metre-dish interferometer — a combination which is likely to outclass the millimetre-wave equipment of other nations for a number of years.



Pico Veleta — a 30-m dish

This telescope complex, which took 13 years to construct and cost £20 million, is now in operation at Nobeyama, 200 km north of Tokyo.

There is only one doubt about the telescopes — that they are sited in Japan. There they are limited by a relatively humid atmosphere, which absorbs low wavelengths. Thus, said a British millimetre-wave radioastronomer this week, Japan may be restricted to measurements at wavelengths not much shorter than 1 cm, which in molecular terms means a limitation to the observations of relatively rare long molecules. Studies of isotopic abundances in the Universe — an important project for millimetre-wave astronomy — need shorter wavelengths. The Tokyo observatory, however, reckons that Nobeyama will reach down to 2 mm.

If the Nobeyama telescope fails to reach down that far there is a chance that it will be suspassed within a few years by other millimetre-wave telescopes, planned or under construction.

France, Germany, and Spain will be next, with the £15-million Institut de Radioastronomie Millimetrique (IRAM). IRAM has an administrative headquarters in Grenoble and two telescope sites: one in southern Spain, on Pico Veleta near Granada, and one in the southern French Alps at the Plateau de Bure.

Pico Veleta is to have a 30-metre dish, whose steel-work is nearly complete — but the telescope is unlikely to be taking data before early 1984. According to Dr Dennis Downes, one of the IRAM team, this telescope should reach down to 1-mm wavelengths. But doubts have been expressed about that objective: the IRAM telescopes are to be open to the air and Sun, and so they will be distorted by wind and differential solar heating.

The exact shape of the dish must be maintained to within a wavelength of the radiation being studied — in other words 1 mm. To achieve this, the steelwork of the Pico Veleta telescope is to be heated to a uniform temperature; and the Plateau de Bure 15-metre dishes (of which there will be three making a T-shaped interferometer) will be stiffened with carbon fibre, cost allowing. Whether these untried methods will achieve the necessary accuracy is yet to be seen. Moreover the interferometer, will take some time to construct.

Besides IRAM, Britain, together with The Netherlands, plan to build a £7-million, 15-metre dish in Hawaii. These plans require environmental approval by the Hawaii State legislature, expected towards the end of this year. The British–Dutch dish, protected by a dome transparent to the radiation, should reach down almost to the edge of the millimetre-wave atmospheric "window" at 0.35 mm. But observations are not expected there before 1986.

Thus Japan is likely to enjoy a substantial lead in this branch of astronomy, possibly the first basic science in which it might take a world lead, at least until 1984.

Robert Walgate and Alun Anderson

Remote sensing for all at UN

Vienna

Remote sensing capabilities are emerging as a keynote of Unispace-82, the Second United Nations Conference on the Peaceful Exploration and Utilization of Outer Space, now taking place in Vienna. Virtually every national delegation expressed its committment to, and hopes for, remote sensing, and although some delegates privately expressed the views that remote sensing was still a solution in search of a problem, such sentiments were kept strictly outside of the official proceedings.

Remote sensing, for example, is to be the mainstay of the United States "global habitability" programme which is expected, during the 1980s, to develop into an umbrella for the research scheduled for the US space platform. "Global habitability" is intended to open up the entire land mass of the Earth to human habitation.

Yet the use of such techniques to survey another country contains the seeds of international tension. One of the problems to which remote sensing is repeatedly urged as a solution is the more rational use of land resources. But such techniques inevitably cut across traditional concepts of national and even personal privacy. The Soviet Union is a strong supporter of new international legislation to outlaw the improper use of data gained by satellite. As Dr Andrei P. Kapitsa, director of the Soviet stand at the exhibition associated with Unispace-82 pointed out, the publication in the Western press of predicted shortfalls in the Soviet harvest (based on satellite data) immediately raised world wheat prices, causing an extra drain on Soviet hard currency reserves.

Significantly, one of the most fervent pleas for the establishment of international principles on the use of satellite data came from Brazil, a country frequently quoted as a classic case where only remote sensing can provide adequate survey facilities. President Joao Baptista de Oliveira Figueiredo spoke of remote sensing as an "instrument both valuable and dangerous" since it "impinges on the sovereignty of states over their natural resources".

The problem becomes even more complex with marine resources. One of the greatest advantages which Cuba derived from participation in the manned "Interkosmos" programme, according the Cuban cosmonaut Arnaldo Tamayo Mendez, was the discovery of new fishing grounds. However, although one of the purposes of Unispace-82 was to show third world countries what space techniques are available, and although the European Space Agency has recently offered African states experimental facilities aboard Spacelab some 25 per cent of the nations represented in the United Nations have not yet reached a level of development where participation of any kind in a remote sensing survey is an economic possibility. The use of satellites to determine fishshoals in international waters could mean that those shoals fail to reach the traditional fishing grounds of the disadvantaged nations.

To obviate such inequities, some speakers at the forum of non-governmental organizations (NGOs), which took place in parallel to the main sessions, urged that the third world should strive for its own launch capability, but without clearly suggesting how this might be achieved. More practical would be the creation of an international pool of land-resource data as part of the United Nations committment to space. The two space superpowers already have a data-pooling

0028-0836/82/330697-02$01.00

programme, which is apparently continuing, although, as the administrator of the National Aeronautics and Space Administration, James M. Beggs, made it clear there can be no resumption of joint US–USSR experiments or missions until the international political climate improves considerably.

Several countries including India, France and the host country, Austria, have already established their own cooperation programmes with both the capitalist and the socialist worlds. Yet it was occasionally difficult to pin down the delegates from these countries on the advantages their countries have derived from such cooperation. And the Polish cosmonaut, Miroslat Hermaszewski, expertly fielded the question of what benefits Poland had derived from participating in the Comecon space programme — although, only a few metres away, the Polish Institute of Cartography had on display an excellent series of maps, which synthesized data from both the Interkosmos and the Landsat programmes.

Vera Rich

Remote sensing satellites

French plans for spot satellites

The French national space agency, the Centre National d'Etudes Spatiales (CNES), believes there is money to be made by remote sensing from space. Sales of data recorded by the two Spot satellites, France's first national remote sensing satellites due for launch in 1984 and 1986, are expected to offset the capital cost of the satellites' development and running costs in about ten years. Responsibility for earning the revenue will rest with Spot-Image, the independent company created early last month to market Spot data worldwide.

CNES's approach to the commercialization of remote sensing data differs markedly from that in the United States. The US National Aeronautics and Space Administration (NASA), like CNES chiefly a research and development agency, has been an unwilling operator of the service forced upon it when data from the early Landsat satellites proved commercially attractive. Potential users have complained that NASA was sometimes insensitive to their needs.

NASA will indeed be administering the distribution of data from Landsat-D, the latest satellite in the series launched last month, and from Landsat-D′, its successor, but beyond 1987 the Reagan Administration has insisted that NASA will have to get out of commerce so that the operational service will have to be taken up by private industry. Thus the fortunes of Spot-Image will be keenly watched in the United States as well as by the European Space Agency, now debating how to make available data from its planned remote sensing satellite ERS1, and the British government, which is contemplating a major effort in remote sensing.

Spot-Image's main shareholders are CNES with a 34 per cent holding, three French government agencies each with 10 per cent — the Institut Cartographique Nationale, the Institut Français du Petrole and the Bureau de Recherche Géologique des Minières — and two companies, Matra and Societé Européen de Propulsion, with 7.5 per cent each. Organizations from Sweden and Belgium which have collaborated to some extent on Spot, will also have small sharehodings. Spot-Image will buy data from CNES and sell them.

NASA's early experience in selling remote sensing data, however, seems not to augur well for Spot-Image. Although there has been great interest in Landsat data, there has been no prospect that fees would match development costs. But, according to Gérard Brachet, director-general of Spot-Image, the market for data from the second generation of remote sensing satellites should grow by leaps and bounds — he reckons that Spot should earn about $900 million, to cover development and running costs, within ten years.

The chief advantages of Spot and Landsat-D over earlier generations of remote sensing satellites is their increased resolution and number of spectral bands. Spot, for example, whose chief instrument is a multilinear array, will observe in three bands in the infrared and visible regions of the spectrum with a ground resolution of 20 m and in a broad band with 10 m resolution. Stereoscopic images are also available.

Spot data will be received and interpreted in Europe at ground stations in Toulouse (France) and Kiruna (Sweden). Spot-Image plans to turn round data within 48 hours for dispatch to users. The charge for one scene in digital form is expected to be about $1,000, but the fee for a photographic image has yet to be worked out, although it will be less. Brachet is confident that prices will compare favourably with those for images generated by the multi-spectra scanner aboard Landsat-D although comparisons with the thematic mapper, Landsat-D's most innovative instrument, are more uncertain.

Spot-Image is negotiating with some countries to receive Spot data direct via their own Earth stations, in which case there will be a copyright fee of only about FF220 ($40) per scene, less than the cost of images bought from Toulouse or Kiruna. The apparent discrepancy is explained, according to Brachet, by the prospective loss of about 70 per cent of potential images due to cloud as well as the cost of processing images.

Judy Redfearn

South African funds

The UK Science and Engineering Research Council (SERC), is reviewing its future commitment to the South African Observatory (SAO), because of financial pressures. South African astronomers currently take up 65 per cent of the viewing time of SAO, and SERC "buys" the rest for UK astronomers; has been suggested that this proportion be decreased. A recent questionnaire, however, revealed a strong desire within the UK astronomical community for this level of involvement to continue.

In terms of technical sophistication and size, the telescopes of the SAO (near Capetown) are outranked by others available to British astronomers in the Southern Hemisphere, particularly the Anglo-Australian and UK Schmidt telescopes in Australia. Paradoxically, SAO's usefulness is increased because its telescopes are not so advanced as to be oversubscribed in demand and yet are sufficiently powerful to do valuable work. In particular, SAO is heavily used for optical and infrared photometry with such objects as the brighter active galaxies and also cataclysmic variable and Cepheid-variable stars.

Earlier this year, while reviewing its plans for the financial year 1983–84 and the following three years, the Astronomy, Space and Radio Board of SERC set up a working group to ascertain the need for continuing use of SAO. The group circulated a questionnaire, to which it received replies from 60 or so groups in the United Kingdom. SERC says the working group reported to the board in July that there was a strong user demand for SAO.

The position of the board is that the decision will depend on scientific and financial considerations and that political issues are not relevant. According to SERC, however, a handful of the questionnaires raised political reasons for discontinuing the use of SAO. One astronomer, Dr Michael Rowan-Robinson, who has just completed a period of service on the SERC committee responsible for SAO, feels particularly strongly: "I seem to be in a minority in feeling that SERC should not maintain an official link of this kind with the South African government. Use of the telescope should be left more to the consciences of individual astronomers."

SERC is due soon to start negotiating its next contract with SAO, to which it now pays about £240,000 a year (about 25 per cent of the annual budget of the observatory) for 35 per cent of the total observing time. The British astronomical community will have a chance to review its use of all observatories in the Southern Hemisphere at the Anglo-Australian Telescope symposium to be held next month.

Philip Campbell

0028-0836/82/330698-01$01.00

French Comité National

Democracy, confusion abounds

One of the major and unique institutions of French scientific democracy, the Comité National, a king of scientific parliament with effective power over the work and careers of thousands of French researchers, is to be transformed.

That fact alone would lead to a great deal of heat, given the generally polemical French nature. But the fire has been stoked even higher by the decree, just published, which describes the transformation. It leaves so many loose ends that many French scientists remain unclear whether they can vote for candidates to the new parliament or not.

This is important, because of the potential power invested in the Comité National: if a scientist can vote for a candidate, at least he or she is assured of some kind of representation.

The Comité is the 1,200-strong board of assessment of the Centre National de la Recherche Scientifique (CNRS). CNRS is only one of the principal French research organizations, but it is the biggest and arguably the most important — at least for basic science; this year CNRS controls a budget of more than FF 6,000 million (over £500 million), and supports 9,322 scientists and 14,514 engineers, technicians and administrators. In general, the best of the university laboratories are at least "associated" with (or partly supported by) CNRS. And within this organization the Comité National plays a role by giving its advice (which is usually accepted) to the CNRS research directors on such matters as the hiring and firing of staff, opening and closing laboratories, and the awarding of grants.

The Comité National may appear to be no more than a collection of peer review committees — and it certainly does function in that way, divided into 45 sections each of 25 people according to subject or research. But the Comité is unique because it is an *elected* body, with a French electorate now totalling perhaps 20,000 people; and the key to the squabbles over the Comité is the question of what groups will be represented and to what extent?

Jean-Pierre Chevènement, minister for science and industry, was unhappy with the Comité that he inherited (the last election to the Comité National was in 1980; President Mitterrand came to power in mid-1981) for two main reasons — its subject structure was out of date, and it lacked representation from the technicians and administrators.

The new decree for the Comité sorts out these matters, and others besides. Chevènement has slightly increased the number of Comité seats that he can name himself, on advice from the CNRS directorate. He can now name eight rather than nine of the 25 members of each Comité (the rest being elected); and four seats per section are now reserved for election by engineers, technicians and administrators. The remaining 12 seats per section (just under half) are to be determined by election by scientists. But how is a scientist to be defined in that context? It is here that the new decree is unclear, and it is here that there will be plenty of discussion and acrimony before the next elections to the Comité National, planned for early 1983.

For the new decree actually decreases the right of certain university researchers to an automatic vote. Previously any researcher could vote; now only researchers with a "link" (the word is deliberately ambiguous) to CNRS may vote. This may be quite reasonable — after all, the Comité directly affects only CNRS employees — but CNRS is so important that researchers were pleased to have their little right to "meddle" in CNRS affairs.

Now that right seems to have gone. Or has it? According to the decree, scientific institutions that are not part of the CNRS may still appoint certain of their staff to vote for the Comité. Among those institutions could be universities. So there may yet be a back door to a voting right. And certain other categories of people do not have an automatic vote, but may receive one if they themselves apply to CNRS for the right.

What this means in effect is that almost every scientist and technician in France will have some way of getting a vote for the Comité; but for some a vote will come more easily than for others. It seems the ministry hopes that this solution will reduce political argument about rights to vote, but at the same time it will be a hard winter for the CNRS elector committee which, between now and January, will have to decide exactly who can vote and why. This process alone will take fully six months, CNRS estimates.

Robert Walgate

US computer industry

Paying the price

Washington

Federal Judge Harold H. Greene has raised the price that American Telephone and Telegraph Company (AT&T) will have to pay for the privilege of entering the data processing and computer game.

Ruling on 11 August on the proposed anti-trust settlement between AT&T and the Justice Department, Judge Greene said he would accept the basic deal, under which AT&T gives up its local telephone companies in exchange for the right to enter the unregulated computer market. But he insisted on certain modifications. The local telephone companies should be allowed to keep publishing the Yellow Pages directories, which are a big money-maker; they should also be permitted to market, but not manufacture, telephone equipment, he said. Under the original settlement, both of these options would be reserved for the parent AT&T company.

The judge also insisted that AT&T be barred from entering the "electronic publishing" field for at least seven years. This excludes AT&T for the time being from a variety of electronic information and news services; newspaper publishers have been especially worried that AT&T's grip on the country's communication system would give it an unfair advantage in this fledgling industry. Under Judge Greene's proposal, AT&T apparently could still supply transmission lines and terminal equipment for such ventures, but could not do the actual collection and compilation of information.

The anti-trust law limits the judge to making suggestions; he cannot order changes in the settlement. He can, however, reject it, and Judge Greene did not mince words: if the parties do not agree to his "suggestions", he will throw out the settlement and reopen the anti-trust case — which has already dragged on for eight years.

AT&T's vice-president and general counsel, William Keefauver, said "AT&T has a strong incentive to accept a decree and free ourselves from the business restrictions of the 1956 decree". (The 1956 settlement barred AT&T from entering the unregulated computer market. It resulted from earlier charges that AT&T was using revenues from its monopoly telephone business to subsidize its competitive ventures.) Failure to accept Judge Greene's terms means that those barriers remain. Keefauver said that the judge's suggested modifications "don't dramatically impact the thrust of the decree".

The Justice Department is less certain to go along with the changes. It had demanded that local companies should not market telephone equipment — a competitive business — while operating as regulated monopolies. The judge ruled that this was merely "theoretical consistency", when in fact allowing the companies to market equipment would increase competition — and at the same time keep rates down.

AT&T and the Justice Department have 15 days to respond to the judge. Earlier this year, Representative Timothy Wirth (Democrat, Colorado) introduced legislation to stiffen the terms of the anti-trust settlement; he later withdrew it in the face of heavy lobbying by AT&T.

The judge's suggested changes appear to incorporate a substantial portion of the Wirth plan, in particular letting the local companies keep the Yellow Pages and the right to market equipment. But, significantly, the judge did not recommend the other major point in Wirth's package: breaking off Long Lines (AT&T's long-distance network, which holds a virtual monopoly on interstate communications) from the more competitive divisions of the company. AT&T would thus retain Long Lines, Western Electric (which manufactures communications equipment), American Bell (the new subsidiary entering the computer market), and Bell Labs without restrictions on how research and development funds are allocated.

Stephen Budiansky

US biotechnology

Re-entry plans

Washington

E.F. Hutton, the large US financial company, is making its second entry into the potentially lucrative field of founding and backing fledgling biotechnology companies. In September, Hutton will begin offering investors limited partnerships in California Biotechnology Inc., a new company organized around the talents of three prominent university researchers. Hutton has already grossed $5.4 million in startup capital for the firm, which is now building a laboratory in Mountain View, in the San Francisco area.

Cal Biotech, as the firm is called, will have as director of research Professor Brian J. McCarthy on leave of absence from his position at the University of California, at Irvine. John Baxter of the University of California at San Francisco, has agreed to consult exclusively for Cal Biotech, although he will retain his professorship at the university. The third star is to be John Shine of Australia National University at Canberra. Shine will also consult exclusively for Cal Biotech, and work for the company under contract at his lab in Canberra, according to Hutton official Zsolt Harsanyi.

The company plans to use DNA techniques to develop pharmaceutical drugs, which could be tested and marketed by major pharmaceutical firms. Cal Biotech's role will be limited to development and ownership of the drugs themselves. Initially, the group plans to pursue development of human pharmaceuticals including those useful for cardiovascular diseases and anti-inflammatory purposes. However, Baxter and Shine have developed a way to produce beta-endorphin, the patent for which is held by the University of California. Baxter's laboratory has also cloned human and bovine growth hormone gene, so the company's work could proceed in those areas as well.

"What makes our company different from other biotechnology companies" says the firm's president Alfred G. Scheid, a long term consultant and former Hutton employee who makes rather a speciality of founding new companies, "is the combination of top scientists and access to a continuing flow of capital." Besides sponsoring the company financially, Hutton has also lent one of its executive vice presidents, William G. Baker, to be chairman of the board. Hutton itself invested an undisclosed amount as part of the $5.4 million fundraising.

Harsanyi says that come September, investors can put up a minimum of $5,000 to become limited partners in Cal Biotech. Using a little-noted provision in the tax law (that has been available for research and developments partnerships since the mid-1970s), they will be able to deduct perhaps as much as 99 per cent of the money they invest if the company spends the money in that year. Thus, the attractiveness of the investment depends on Cal Biotech's financial planning, which may explain why Hutton is taking such a deep interest in its management. Besides the tax writeoff, investors will receive a share of any instant royalties and profits the company earns from drugs that are sold, which could start as early as 1988, Harsanyi says. The company itself will be the general partner, splitting profits and royalties with the group of limited partners.

The approach of forming a company around a group of researchers and limiting its scope to their research is a major switch for E.F. Hutton following its failure with an alternative approach. In February 1981 Hutton raised $40 million to start DNA Science, a company planned to sponsor biotechnology research in many institutions around the world. Most of the initial investment was to go to the Weizmann Institute in Rehovot, Israel, to support work directed by Christian B. Anfinsen who had moved there after retiring from his post at the US National Institutes of Health. Baxter's laboratory in California was also due for support.

Research funding by DNA Science was mixed up with possible marketing rights granted to two major firms, and the whole cabbodle was to be managed by a businessman, E. Russell Eggers, with two Hutton officials, Harsanyi and Nelson Schneider, as vice presidents. But the structure of the company was too unwieldy and the 1981 tax law cancelled out some of the expected tax benefits from investment. So on 4 August 1981, the investors got their money back.

The lesson of DNA Science, Harsanyi says, is that investors in biotechnology are attracted by key people, such as Anfinsen and Baxter. The most promising approach, therefore, is to structure a company around these people, not expecting them to do management and marketing but assuring their access to capital for research and development. Whether Cal Biotech can develop a group of important products, to see them through the hurdles of trials and testing, and bring its investors golden returns, remains to be seen.

Deborah Shapley

Biotechnology centre

Links between industry and biotechnology research are thriving at the University of Leicester. Four companies are putting up approximately £1 million between them to establish a new biotechnology centre at the university. And the Science and Engineering Research Council (SERC) has promised the new centre £180,000 for capital equipment.

Industry's interest in Leicester is particularly timely. The University Grants Committee (UGC) recently awarded the university £50,000 of its grant earmarked for biotechnology to create three new lectureships. The university is now hoping to persuade the grants committee that one of those posts, for a yeast specialist, should be created within the new biocentre. The others are reserved for a plant biotechnologist and a mammalian geneticist within the university proper.

The companies prepared to put their money into research at Leicester are Whitbread, the brewers, Gallaher, the tobacco company, Dalgety-Spillers, the food manufactures and John Brown Engineers and Constructors whose main claim to biotechnical fame is the construction of the Pruteen plant for ICI. They have guaranteed support to the new centre for five years and have already agreed a programme of research. The centre will be concerned primarily with recombinant DNA technology, although questions of scale-up may be considered later. The research programme will consider plasmid DNA regulation and protein secretion in yeasts and the analysis and structure of genes in higher plants.

Money from the four companies should be sufficient to keep about eight researchers employed for five years, but the centre will also be trying to build up a sound contract research business. Patents resulting from work carried out under the core programme will be shared between the four companies and the university. The share of revenue will depend on how the patent is licensed. Ultimately, the centre hopes to build up a contract research business, the profits from which will be ploughed back into the centre. Precisely how much the university will earn from its association with the centre remains uncertain.

Even if the university has little to gain financially, it is intended to benefit from the small teaching commitment that the centre will take on. Training is also to be provided for employees seconded from industry. Initially, the centre will be housed in a suite of laboratories in the university's pre-clinical medical sciences building (for which it may pay no rent), but it may later build its own accommodation if cash can be raised.

New sights for Land

Washington

Dr Edwin H. Land, a legendary figure in US industrial history for his invention of the instant camera and for founding the Polaroid Corporation, announced on 27 July that he would resign as a director and chairman of the board of the company. When a remaining role as a consultant expires at the end of the year, Land will have relinquished all direct responsibility for the company identified with his name. Since 1975, he has been gradually breaking his links with the corporation in order to devote himself to research on colour vision and related fields. He is now 73.

Freedom ideal

As an inventor, however, Land has surprised no one in inventing an entirely new setting for his new career as a full-time scientist. Earlier this month, he gave me an exclusive tour of the Rowland Institute, a luxurious new building of brick, slate and oak that he has built and endowed on the banks of the Charles River in Cambridge, Massachusetts, only a few blocks from his old centre of operations at Polaroid.

At present, only 25 of the 80 people expected to work at the institute have been engaged, but Land is in no hurry to fill it up quickly, he explained, as he mounted, two steps at a time, a circular stairway carved in poplar wood leading to a large two-storey atrium housing a Japanese style garden and off which lay two storeys of eight double-laboratories.

Land's favourite word to describe the idea of the institute is freedom. Here, he and colleagues will be free from the pressures of writing government funding proposals or the demands of industry — or, perhaps, the burden of running Polaroid, which has had its troubles in recent years. To ensure this freedom, Land has endowed the institute with $20 million. "This is an experiment to see what will happen if a group of competent, intelligent and bright people were pursuing the substance of science itself for its own sake, without thought of product or profit", he says.

Some of the basic work to be undertaken, such as the study of light-induced heat transfer across molecular surfaces, is not far from work done at Polaroid, which was famous for exploring the frontiers of the science that underlay its projects. "We were very proud of the basic work we did at Polaroid. But while we were doing it we carried a very different and very proud burden.

"It was a joy to make new films, new dyes and new cameras" said the holder of 533 patents, who is a member of the US Inventors Hall of Fame, along with Thomas Alva Edison and others. "It is a different kind of joy if the product is deep insight into natural phenomena from which there may be by-products internally". The institute, like any other non-profit group, will be eligible to apply for patents and to accept royalties. But, Land stresses, basic science will be the product, with any inventions that transpire the by-product — not the other way around. Perhaps the Rowland Institute is Polaroid in reverse.

The institute aims to be collegial in style, explains James Foley, an organic chemist from Polaroid whom Land hired nine months ago. "Each of us is a sun on our own project, with the others as satellites, and I will be a satellite on Jim's project" says Land. Projects at present contemplated range from Land's own work on the physics of colour vision to an examination of the structure of biologically important molecules.

Edwin Land, new perspectives

For all its newness, its large, quiet library, Mexican grey pebbles and whisper-perfect auditorium, the institute is avoiding stocking up on fancy equipment (although each scientist may have a computer terminal in his office). Nor is Land hiring "teams" of people to work on a single project. He is opposed to both as too likely to drag researchers away from pursuing a clear, logical line of enquiry. Once you have a big machine, he says, you tend to work on problems the machine can do, rather than those that are most important or interesting.

The enormous darkroom in the basement, for example, has only a few items in it. There, Land happily shows off a phenomenon he discovered only the day before, in which the eye, after exposure to a certain kind of light, sees the fan-shaped spokes on a wheel become narrower. "We're going to look at one thing, then the next, and the next, without trying to explain too much at first. In a sense, we're returning to an older style of doing science. This was how Faraday worked."

Base of success

Back at Polaroid, the reins of power are now firmly in the hands of William J. McCune Jr who has been with the company since 1939, and whom Land made president in 1975, chief executive officer in 1980, and who now becomes chairman of the board too. McCune, who is 67, is an independent Polaroid power in his own right. One story has it that he recently rebuffed two would-be kidnappers in a local parking lot. Most discussions of Polaroid's health and future tend to show McCune and the board of directors seeing things differently from Land, although there is no indication of an outright break being the cause of Land's present departure.

Indeed, Polaroid, while highly successful with sales of $1,400 million, has had several things to disagree about internally. The film manufacturers have been hard hit by the rising price of silver in the late 1970s. In addition, the amateur camera market, which accounts for 80 per cent of Polaroid's business, levelled in those years in response to the recession, at a time when Polaroid had doubled its camera and film-making capacity in what proved to be a mistaken expectation of continued growth. Both US sales and sales in Europe, which had grown spectacularly, tailed off. The company workforce, which numbered 20,000 in 1979, now stands at approximately 15,000, and a number of high executives have been offered generous terms to leave to reduce management too.

Finally, the company has gone on introducing the kind of spectacular, unique inventions for which Land was famous — such as Time Zero film, an improvement on the SX-70 film first introduced in 1972. But it has also recently experienced its first real failure: Polavision, an instant movie camera and film system introduced in 1977 and withdrawn in 1979. The system came just when video products were coming along, and cost more than a comparable video system; the company had to write off an estimated $68 million and opinions vary over the extent to which Land bears the blame. McCune is seen as strongly favouring the company's decision, in recent years, to expand out of the volatile amateur camera market and into commerical, industrial and scientific products. Polaroid now offers cameras for computer graphics to industry and cameras for medical purposes, including nuclear medicine for example.

Will Polaroid go on being inventive after Land? He says "One of my functions was — innocently — to insulate the company from many of the conventional criteria by which companies are judged on a monthly or quarterly basis.

"If with my insulation removed, the company becomes susceptible to these judgements . . . this will lead to a basic conflict between two different approaches: first, the long-term, imaginative approach of sensing an unmet human need and bringing it, by way of science, to fulfillment; and second, responding to a chorus of external contemporary voices." What will be Polaroid's next big invention? Land laughs, but won't say. "I hope they guess what I hope it will be", he replies.

CORRESPONDENCE

Coal in reserve

Sir — Robert Olby's article "Britain's resources of coal and spent uranium fuel" (*Nature* 29 April; **296** 797-801) puts into sharp perspective the opposing arguments about fossil fuels versus nuclear fuels.

For the first time, the previously murky distinctions between the different classes of coal reserves have been made fairly clear. Previous attempts to do this have usually been obscured by the question of the future of coal versus other forms of energy. For example, those who believe that limited government resources should not be invested in the coal industry have tended to use the most restricting definitions of coal reserves, coupled with the lowest figures of percentage extraction, in order to suggest that coal has no future. As Olby points out, referring to A.M. Clarke, the future of coal is hardly unaffected by government policy. However, Olby himself is impartial in the matter of policy; he is simply clarifying the distinctions between different classes of coal reserves.

His brief account of Jevons's much misunderstood work of 1865 is also impressive. Jevons's point is just as valid today and, apparently, just as misunderstood. The finite extent of our recoverable fuel reserves does not define the period of time for which we can exist as we are before we run out of fuel. It defines the *much shorter period* for which we can continue to expand for the same production-to-fuel consumption ratio. A statement such as "At present rates of consumption, we have enough coal for 300 years" is thus meaningless.

Mr A.M. Clarke, ex-Chief Geologist of the National Coal Board, has probably done more than anyone else in Britain to stir up thought on these issues. It is good to see that his work is acknowledged in your pages, despite the continuing efforts both inside and outside the National Coal Board to denigrate his achievements.

Ball of fire?

Sir — On Tuesday, 3 August, shortly after 4.00 p.m., the Cavendish Laboratory and the surroundings were struck by lightning several times during an exceptionally intense storm. No structural damage ensued, but immediately after one of the discharges a ball of light was seen by a number of observers. Their descriptions are not entirely consistent but certain features are agreed upon well enough to enable a broad description to be given. The discharge apparently responsible struck near the centre of the Bragg Building, which runs east-west. An observer on the ground floor of the Mott Building, whose back was to the window, saw his room momentarily lit as if by a very bright object moving past rapidly towards the west, between the Bragg and Mott buildings. Another observer on the first floor saw the space between the buildings filled with a luminous haze at least to the first floor level, and on looking to the west noticed a blue-white light that he thought at first was a warning light on a distant tower. He apparently noticed no motion, but his companion in the same room must have seen it an instant earlier for she had the impression that it was moving past and away, and possibly expanding as it went, being about the size of a grapefruit when first seen. Three people who saw it after that, as it moved over the ground to the west, agreed it looked about the size of the moon, was blue-white in colour, very bright, and was visible for some 4-5 seconds before suddenly vanishing.

To this reasonably well attested observation must be added that while an assistant in the duplicating room, on the ground floor, was closing a small window she was startled by a noise that made her think the window had been knocked in; a bright sparkling object, resembling the lights thrown out by expensive rockets, entered by her head, rebounded from a machine and left as it came. The window was in fact undamaged, and when examined next morning entirely unmarked. Both assistants who were there at the time are convinced something came into the room.

Badgers still snared

Sir — I understand that the Royal Society for Nature Conservation, while welcoming the ending of the gassing of badgers by the Ministry of Agriculture (*Nature* 22 July, p.317) because of its inhumanity, is adamant that only badgers that are positively found to be infected with tuberculosis should be destroyed. We learn, however, that snaring of badgers is to continue (which is surely as inhumane if not more so than their gassing) which makes it impossible to test for infection before killing.

Gwendolen Barter

Margate, Kent, UK

Nuclear risks

Sir — I find the claims of Martin Fodor concerning the dangers of nuclear power (*Nature* 22 July, p.320) both confusing and inconsistent with the available evidence. Studies in a number of countries have compared the number of fatalities from the routine operations of the complete fuel cycle for nuclear, coal-fired and oil-fired generation. They all show that nuclear generation is at least as safe, and probably a good deal safer, per unit output than using coal or oil. Martin Fodor is quite wrong to imply otherwise.

These evaluations include the contribution from uranium mining to the hazards of nuclear generation. I am not aware of any studies showing 50-100 per cent occupational mortality among uranium miners, but it has been known since the fifteenth century that underground metalliferous mines give rise to enhanced mortality from lung disease among the workforce. Modern radiation safety standards based on the recommendations of the International Commission for Radiological Protection (ICRP) are designed to ensure that working with radiation safety ensures that the main occupational hazard in uranium mining is the physical risk.

Comparative estimates of the routine risks from the alternative energy sources are not so reliably established as for nuclear and fossil fuels. However, such information as is available suggests that the risk per unit generation is within the range of the other fuels. Professor Fremlin has pointed out that the idyllic village millpond has only to account for one drowning every 200 years to be classified as the most hazardous energy source, and generating electricity from wavepower, the renewable resource with which the United Kingdom is most generously endowed, is likely to involve substantial risks.

Rare major accidents invariably give rise to a much smaller death rate than the routine operational risks for all technologies. Despite this, they are of particular concern because of society's abhorrence of multiple fatality accidents. Nuclear electricity generation is particularly well protected against such events: not a single death from radiation has been recorded from any accident during the 25 years such plants have been operating. Whilst the probability of nuclear power accidents is certainly not zero, all the evidence indicates that the risk is much smaller than for many other accepted activities. Anyone concerned about accidents which may kill large numbers of people should worry about technologies other than nuclear power which are over 100 times more likely to cause such accidents.

The overall conclusion can only be that no practicable method of electricity generation is particularly hazardous, nor is any so safe as to merit particular preference. Nuclear electricity generation is certainly not the most hazardous of the technologies we use, and may be one of the safer options.

Safety is only one aspect of the environmental impact of electricity generation. In other respects nuclear power has an inherent advantage because it is the most compact energy resource available. Consideration of land use, visual intrusion, water supply, transport requirements and biological effects, together with the safety aspects, gives good grounds for the view that on balance nuclear power is the least environmentally damaging of the available options for providing the electricity we need.

Oxygen treatment

Sir — In view of the recent press publicity, which we understand has embarrassed many neurologists and general practitioners, on the use of hyperbaric oxygen in the treatment of multiple sclerosis, the Multiple Sclerosis Society wishes to state that at no time has it recommended its members to seek treatment with hyperbaric oxygen.

We are awaiting with interest the results of a carefully monitored double-blind controlled study recently undertaken in America with the support of the American National Multiple Sclerosis Society. Upon receipt of the results of this trial the society's medical advisers will immediately review this matter.

John Walford

Multiple Sclerosis Society,

Mitochondrial mosaics — maturases on the move

from Leslie A. Grivell and Piet Borst

To the initiated, the idea that mitochondria have opted for unusual modes of gene expression must surely be becoming a familiar one. A paper just published in *Nature* (**298**, 628; 1982) by Dujardin *et al.* shows, however, that additional surprises may still be in store regarding the proteins that mtDNA encodes. The paper illustrates that mutations are not necessarily changes for the worse: a single amino acid substitution in an intron-encoded protein is responsible for generating a new enzymatic function, leading to the expression of a novel mRNA maturase active in splicing.

Two years ago, Lazowska *et al.*[1] showed that a protein encoded in part by the second intron in the yeast mitochondrial gene for cytochrome *b* (*cob*) is required for the splicing out of that same intron sequence from its own mRNA, one of the precursors to the mRNA for cytochrome *b*. The protein, *box3* (or bI$_2$) RNA maturase, is a chimaera, consisting of the amino-terminal half of cytochrome *b*, fused to an intron-specific sequence. Since it controls its own synthesis by destroying the mRNA which encoded it, Lazowska *et al.*[1] coined the term 'splicing homeostasis' to describe the self-regulation of RNA processing that results.

Other mitochondrial introns, both in yeast and other fungi, also contain long unassigned reading frames (URFs)[2-5] and many, if not all of them, may encode proteins with maturase action. Two series of observations support this view. First, the URFs display varying degrees of sequence conservation, suggestive of constraints on protein structure and indicating that their products have similar functions[3,6,7]. Second, *trans*-recessive mutants defective in splicing have been identified in the URFs of the other two main introns of the cytochrome *b* gene (bI$_3$ and bI$_4$)[3-10].

An unexpected complication was the finding that numerous intron mutations of the cytochrome *b* gene are pleiotropic. They prevent the synthesis not only of cytochrome *b*, but also of subunit I of cytochrome *c* oxidase[11]. This protein is also specified by a mosaic gene (*oxi3*) and the lack of expression is known to be due to a defect in the processing of the oxidase pre-mRNA[12,13]. The effect on expression works in only one direction as mutations in *oxi3*, including large deletions, have no effect on the expression of the cytochrome *b* gene[12,13]. The link is positive as deletion of all or part of the cytochrome *b* gene similarly blocks oxidase synthesis[14]. The key factor has been traced by genetic experiments to the fourth intron of the long form of the cytochrome *b* gene (bI$_4$)[15]. Several lines of evidence[9,16] now strongly suggest that the RNA maturase encoded by bI$_4$ is also involved in excision of aI$_4$, the fourth intron of the *oxi3* gene and one which is highly homologous to bI$_4$ (ref.3).

To learn more about the requirements for mitochondrial splicing and about the components involved, Slonimski and his associates have developed a general method for the selection and characterization of extragenetic suppressors of splicing-deficient mutations located in introns[17].

One of these mutations has been fully described in the recent report by Dujardin *et al.* The mutation (*mim* [*mi*tochondrial–*m*itochondrial interaction] *2-1*) is a single G→A transition in the open reading frame of aI$_4$, where it produces a glutamate to lysine substitution. In its presence, the cytochrome *b* gene and the mRNA maturase encoded by bI$_4$ are no longer required for the splicing and expression of the oxidase gene and, just as remarkable, expression of the cytochrome *b* gene in mutants with a defective bI$_4$ maturase is once again possible. Evidently, the *mim 2-1* mutation induces the synthesis of an aI$_4$ maturase with an activity different from that present in wild type. This novel maturase can presumably act as a substitute for a defective bI$_4$ maturase, using the same set of recognition sequences present in both pre-mRNAs[16]. This explanation is appealingly simple; nevertheless it raises a number of intriguing questions about the origin, evolution and function of the URFs in yeast mtDNA, some of which are addressed by Dujardin and his colleagues.

First, how is a new maturase formed from an 'inactive' one and what is the normal function of the aI$_4$ URF? Dujardin *et al.* propose that the replacement of a glutamate by lysine, which changes the overall charge of the protein by +2, may bring about a local increase in positive charge in a region of the protein that is essential for catalytic activity. The *mim2-1* change occurs in a α-helical region of 15–18 amino acids, which occupies homologous positions in the bI$_4$ and aI$_4$ URFs. The α-helix of wild-type bI$_4$ is more basic than that of wild-type aI$_4$ by two or four charges, dependent on strain polymorphism. The *mim2-1* mutation would make the aI$_4$ translation product more similar to its bI$_4$ counterpart.

What is the normal function of the aI$_4$ translation product? The aI$_4$ and bI$_4$ URFs display a high (>70 per cent) homology at the protein level and are presumably derived from a common ancestor. On this basis Dujardin *et al.* consider two scenarios. First, the aI$_4$ protein may simply be a pseudogene. A single substitution might (somewhat implausibly) still be capable of resurrecting the gene and restoring its function. Second, evolutionary divergence of aI$_4$ and bI$_4$ could have led to a diffusible protein, endowed with a pleiotropic splicing activity (bI$_4$) and to a protein with no catalytic splicing activity at all (aI$_4$). A selective pressure against the accumulation of chain-termination mutations in aI$_4$ would be provided if it had retained, or acquired, other functions, for example as a structural component of the mitochondrial splicing and/or translation apparatus. However, because of the extent and nature of sequence conservation between the two URFs, we prefer the idea that the wild-type aI$_4$ translation product fulfils a maturase function, that has so far escaped detection by mutagenesis. The main effect of the *mim 2-1* mutation may then be to alter substrate specificity.

What do maturases do and how do they do it? These are somewhat embarrassing questions, since not a single maturase has been isolated. They appear to be present in such low concentrations in wild-type yeast cells that they even escape detection by pulse-labelling. Conclusions about their structure and mode of action can, therefore, only be drawn from their DNA sequences and other indirect evidence. All URFs code for proteins which are rich in basic and hydrophobic residues and whose overall characters are suggestive of globular, non-membrane-associated proteins. Characteristics seen in similar distributions of charged residues, or residues

---

Leslie A. Grivell and Piet Borst are in the section for Medical Enzymology and Molecular Biology of the Laboratory of Biochemistry, University of Amsterdam.

0028-0836/82/330703-02$01.00

disrupting helical structure[6,7], are conserved within a central 115 amino acid stretch of each URF. This region, which is bounded by characteristic decapeptide motifs, is thus likely to play a key part in determining both protein structure and enzymatic function, as does a region immediately downstream, in which numerous *trans*-recessive mutations affecting splicing have been identified[9,10].

Two indirect observations concerning maturase function are important. First, intron mutants, with defective mitochondrial maturases, generally accumulate only high molecular weight, intron-containing pre-mRNAs[12,13]. Second, nuclear mutants defective in mitochondrial splicing reactions have been isolated and partially characterized. The defects are surprisingly specific, often involving an inability to cut or ligate the ends of a single intron in the gene for cytochrome *b* or subunit I of cytochrome *c* oxidase. In one group of cytochrome *b*-deficient mutants recently studied by Diekmann *et al.*[18], transcripts consisting of bI_4 linked to downstream exon sequences accumulated, indicating first that a nuclear gene product is required for scission of the bI_4–exon boundary and second, by implication, that the bI_4 maturase may itself be involved in the initial scission at the upstream exon-bI_4 border.

With such an intricate systems for RNA processing, it is remarkable that many individual introns and their maturases are dispensable, in that various yeast strains, either found in nature[19] or constructed in the laboratory[8,15], can lack them entirely and suffer no ill-effect. So, why have introns?

One view is that they are evolutionary relics, left over from a primitive, genes-in-pieces type of genome organization. Indeed, the high homology observed between introns in mtDNA of yeast and *Aspergillus nidulans*[4,5] indicates that at least some introns pre-date the common ancestor of these fungi. On the other hand, whatever role introns may have had in the evolution of mitochondrial genes, their continued retention in fungal mtDNAs cannot be an accident. The distribution of introns is highly non-random: two of the seven major protein-coding genes, one of the two rRNA genes and none of the tRNA genes contain introns. The maintenance of the introns requires a large number of genes involved in splicing; this complex system must be vulnerable to disruption by mutation. Nature is not without means to eliminate this costly genetic investment, because it can produce mtDNAs with fewer or no introns. The introns in the fungal mtDNAs must therefore confer a selective advantage now.

Among possible advantages, the most plausible is that additional splicing steps allow a more precise control over mitochondrial gene expression. This could permit, for example, the selective suppression of the synthesis of mitochondrial components during growth in the presence of fermentable sugars. Such an explanation may not, however, hold for all introns and all fungi. The gene for the mitochondrial large rRNA contains an intron plus URF, yet accurate splicing is possible in the absence of the URF product[20] (albeit somewhat inefficiently) and rRNA synthesis does not seem to be selectively repressible. Again, *Aspergillus* has also retained introns and their reading frames in the genes for cytochrome *b* and subunit I of cytochrome *c* oxidase, yet does not repress mitochondrial synthesis. There is obviously room for further speculation about the selective advantage of having mitochondrial introns and maturases.

Finally, where do the introns and their maturases come from? We suggested previously[21] that they might have arisen from insertion elements which lost their mobility in the course of evolution and this idea remains plausible. First, the sequence homologies found between the URFs of yeast mtDNA argue for a common origin with subsequent dispersal around the genome[7]. Second, the hypothesis correctly predicts that sequences homologous to intronic reading frames may also be found outside genes[22]. Third, all yeast URFs display codon usage which deviates markedly from the characteristic pattern observed in genes for known, major translation products[3,23]. Such usage could be the last visible trace of a separate genetic orgin of URF sequences. □

Where has that Moon been?

from Kurt Lambeck

THAT tidal forces play a most significant part in the dynamical evolution of the Earth–Moon system is beyond dispute. What is in dispute is the time scale of this evolution. One more attempt at resolving this vexing question has recently been discussed by Webb in the *Geophysical Journal of the Royal Astronomical Society* (**70**, 261; 1982).

That this ancient subject continues to draw the attention of scientists in diverse disciplines may seem curious but is a reflection of the important ramifications of tidal evolution models as well as their intellectually satisfying nature. Few other subjects require one to delve into the rigours of celestial mechanics or into the ambiguity of an observational record that includes eighteenth century telescope observations, ancient records of eclipses and the life styles of Palaeozoic corals. It requires investigations into the solid Earth's structure, into ocean tides, speculations on the evolution of the Earth and an initiation into the mysteries of lunar chemistry.

A central difficulty in modelling the past orbital and spin configurations of the Moon and Earth is to extrapolate from present-day tide models and tidal accelerations. It is inescapable that most of the tidal energy is dissipated in the oceans[1] and that this must have been so for much of the Earth's past history. Any extrapolation backwards into geological time is, therefore, only as good as the assumption that past and present tides are identical or that past tides can be characterized by some mathematically convenient law. Such extrapolations lead to the conclusion that the Moon must have been very close to the Earth some 1.5–2 billion years ago. This conclusion is unsavoury to most lunar scientists[2].

Can this close approach, so late in the Earth's history, be avoided without invalidating the orbital evolution calculations?. Is it possible to push it back into the Earth's remote past? This is the problem that Webb sets out to solve; how to compute representative tidal dissipation estimates for past epochs when the requisite detailed oceanic data are

Kurt Lambeck is Visiting Professor at the University of Paris-Sud, on leave from the Australian National University, Canberra.

0028-0836/82/330704-02$01.00

unavailable. His approach is not to consider detailed models at specific geological epochs as others have attempted[3]. Instead Webb adopts an 'average' ocean model and then investigates how dissipation may vary in response to the evolving Earth–Moon system. In particular, he investigates the dependence of dissipation on the frequency of the tide-raising force. His important result is that the rate of tidal energy dissipation has been less in the past than it is now and that the calamitous consequences of a close approach of the Moon can be readily averted.

Present rates of energy dissipation are now quite well established as about 4.0 × 10^{12} Watts (ref. 4). It is also clear that at least 90 per cent of this energy is dissipated in the oceans. What remains less obvious is the mechanism by which this dissipation takes place. Is it by bottom friction in a few shallow seas, or by a more global mechanism such as the breaking of tidal waves along shorelines or the scattering of tidal waves into internal modes? Advocates of all mechanisms can be found but it seems that the actual assumptions made have little influence on the numerical solutions or interpolations of the Laplace tidal equations. Compare, for example, the recent tidal models for the dominant lunar tide[5-8]. All solutions require that dissipation is fairly uniformly distributed through the world's oceans, and all give very comparable results once corrections for the solid tide are made where appropriate[4]. That this is so is at least partly because all solutions are either explicitly or implicitly constrained by observations of the tides. But it makes Webb's approach of considerable interest for he does not have to make assumptions about the detailed ocean geometry. Instead, he considers tides on a hemispherical ocean[9] whose orientation with respect to the Earth's rotation axis is allowed to vary through all possible values. Dissipation is introduced by requiring that the decay time of tidal energy equals the average observed value. For a given frequency of the tide — defined by the Earth–Moon distance and the Earth's spin rate — Webb averages the power estimates over all orientation angles with the acceptable rationale that the time constant for plate tectonics is much less than the age of the oceans. The variation in the ocean geometry with time is therefore accounted for in this statistical manner. At any one frequency, strong resonances are encountered as a function of the orientation but Webb finds that, when averaged, these isolated resonances are smoothed out and that any resonances in the averaged power curve occur at frequencies that are lower than present and past values: the further one goes into the past the greater becomes the separation between the forcing and resonance frequencies.

Consequentially, past rates of orbital evolution will be less than if the Q or dissipation function of the ocean had been held constant, and Webb concludes that the close approach may never have occurred at all. Quantitatively his results may not be very significant but the general trend that emerges is. Evidence for reduced dissipation in the geological past has also been found in palaeontological records of the Earth's rotation where growth rhythms in corals and bivalves point to less dissipation over the past 400 million years than occurs at present[4]. A similar conclusion was also reached from explicit model studies of past ocean tides[3].

A word of caution seems appropriate however. The resonance frequencies of the ocean basins depend on the ocean scale as well as on the ocean depth. Thus by fixing the decay time, Webb also assumes that these factors have not changed much. The approximate period of the free oscillation is given by $2L/(gh)^{1/2}$ where L is the characteristic length scale, h the average depth and g is gravity. If, on the average, L is greater than today, as when the oceans were clustered into the Pangea continent, then the driving force will have been further away from resonance than it is now. If the ocean depths were less in the past, if the present basins evolved only relatively late in the Earth's history, then the difference between the forcing and resonance frequencies also increases. Thus some cancellation of Webb's result may occur. I rather doubt that this will be significant and those who argue that the Moon formed close to the Earth can sleep in peace. ☐

From CoA to complement: thioesters as the spring in the molecular mouse trap

from John Fothergill

To most biochemists, thioesters mean coenzyme A and fatty acid metabolism. They are remarkable for their high free energy of hydrolysis and their participation as metabolic intermediates. With this background, the discovery of thioesters in proteins came as something of a surprise.

There is now good evidence that two of the complement proteins, C3 and C4, and the plasma proteinase inhibitor α_2-macroglobulin contain an internal thioester formed from the side chains of a cysteinyl and a glutamyl residue four positions apart on the polypeptide chain. In the native protein, the thioester is apparently buried, but on activation of the protein by proteolytic cleavage the thioester is exposed to the surroundings, readily generating a free thiol and an active acyl group that can react with nucleophilic amino or hydroxyl groups. This leads to covalent attachment of the thioester protein to adjacent protein or carbohydrate. Thus a single proteolytic cleavage of the protein containing the thioester leads to covalent linking of the activated protein to a nucleophilic group in its immediate environment. What are we to make of this 'molecular mouse trap'?

It has been known for a long time that complement components, once activated, adhere strongly to cell surfaces. This was explained as an interaction between a hydrophobic region on the complement component, revealed during proteolytic activation, and the cell membrane. The relatively short half life of the activated complement components was explained in terms of conformational rearrangement of this hydrophobic binding region. The first evidence[1] that the reaction could be a covalent one came from the detection of proteins in SDS-polyacrylamide gel electrophoresis that had higher molecular weights than the C3 polypeptide chains they were known to contain. Similar evidence has been obtained for the covalent binding of C4 (ref. 2) and C3 (ref. 3) to antigen–antibody aggregates. During the last two years evidence for this internal thioester has been accumulating rapidly. Publications have been overwhelmingly confirmatory, if somewhat repetitious.

Much of the evidence for the thioester in C3 has come from the work of Janatova

and Tack, and a recent paper[4] summarizes the present position. The glutamyl residue of the thioester can be labelled with radioactive methylamine producing the corresponding γ-glutamylmethylamide; the thiol group reacts with the usual reagents. Labelling studies have shown clearly that the reactive residues are in the C3d part of the C3b molecule which is known to contain the membrane-binding site. The amino acid sequence of this part of the polypeptide chain has been determined and it is obviously homologous not only to the corresponding region in C4 (ref. 5) but also to the thioester sequence in α_2-macroglobulin[6] (Fig. 1). Model-building studies have shown that the thioester cannot form if the polypeptide adopts an α-helix, β-sheet or β-turn conformation, but it is possible to arrange the atoms without undue strain in an unusually sharp bend that allows the glutamyl carboxyl and cysteinyl thiol groups to approach close enough to form the thioester.

The whole thioester story is intimately bound up with the question of conformational rearrangement during activation. Intact C3 is known to show circular dichroism spectra that are significantly different from those of a mixture of its activation products C3a and C3b (ref. 7). Treatment of C3 with methylamine or by freezing and thawing also produces evidence of conformational changes[8] and renders the C3 haemolytically inactive. Interestingly, evidence for an increase in exposed hydrophobic surface occurring concomitantly with this conformational change was also obtained[9]. Whether the biological activity of C3 and C4 depends on both covalent attachment by virtue of the thioester cleavage and hydrophobic interactions resulting from conformational rearrangement remains to be unequivocally demonstrated. It is noteworthy that the structurally homologous complement protein C5 has similar properties but no thioester.

The discovery of these thioesters has opened up many new possibilities in mechanisms of complement activation and in more general aspects of protein chemistry. The suggestion has been made that spontaneous hydrolysis of the thioester in C3 may generate C3b-like activity that could form the nucleus of a C3 convertase for the alternative pathway[10]. The implications for biosynthesis are particularly fascinating. At what stage of maturation is the thioester formed? Is there a thiokinase, with requirements for a nucleoside triphosphate, or does the folding of the nascent polypeptide chain contribute all that is necessary? Is the Lippman 'squiggle' the spring of this molecular mouse trap? ☐

Focus on filaments: embryology to pathology

from Birgitte Lane and Brian Anderton

A RECENT workshop* provided a useful summary of current research on intermediate filaments. With actin and tubulin, these filaments constitute the third fibre system of the cytoskeleton. They are morphologically well defined (as 10 nm filaments) and stable *in vitro,* and show a biochemical heterogeneity which is developmentally regulated. Each class of intermediate filament is restricted *in vivo* by tissue differentiation: vimentin to mesenchymal cells, desmin to muscle tissues, keratins to epithelia, glial fibrillary acidic protein (GFAP) to astroglia and neurofilament proteins to neurones. Given this apparently ideal experimental system, it is frustrating that so little is yet known about intermediate filament function.

However, progress is being made. Some synthesis is becoming possible regarding molecular structure, as Geisler (Max Planck Institute, Goettingen) showed in proposing a model for vimentin-like proteins, based on primary sequence data. The model molecule has three domains separated by enzyme-sensitive hinge regions: (1) a short, basic, folded head piece (about 7.5K) sensitive to proteolysis; (2) a long (38K) middle piece, helical and very acidic; and (3) a short tail piece, about 5.5 K and probably globular. The mid-piece helix has a hydrophobic edge which may stabilize the intertwining of molecules into protofilaments, while charged patches on other parts of the helix may aid association into 10 nm filaments. Mid-pieces can aggregate into filamentous and sheet-like structures, but the head and tail pieces seem to be necessary for correct assembly of filaments.

Quax (University of Nijmegen) reported the DNA sequence of a cloned hamster vimentin gene: there may only be a single gene for vimentin in mammals, in contrast to the multiple genes for keratins described by Green (Harvard Medical School). Surprisingly, keratin, and not vimentin, is the first type of intermediate filament to appear in ontogeny. The first keratins appear in the morula (Jackson, University of Geneva) as a pair of polypeptides of 53K (basic group) and 44K (acidic group). Franke (German Cancer Research Centre, Heidelberg) declared this to be the simplest keratin profile, therefore presumably the minimum required for filament formation. It was clear from many two-dimensional gels shown at the meeting that keratins can be classified as either acidic (smaller) or basic (generally larger). Presumably it is this complementarity of charge and size that restricts the major epidermal keratins to obligate heteropolymerization, as described by Steinert and colleagues some years ago.

Although some adult epithelia retain an almost embryonic simplicity of keratins, most differentiating epithelia acquire a more eleborate keratin profile, culminating in epidermal keratinocytes. Franke reported that 19 separate human keratins have now been identified. Sun (Johns Hopkins Medical Institute) suggested an ontogenic 'tree' model to help visualize the developmental complexity of the epidermis, which he demonstrated using three complementary monoclonal antibodies. Monoclonal antibodies to keratins can be used to detect non-keratinocytes in complex epithelial tissues (Lane, ICRF), and an elegant presentation by Moll (German Cancer Reserch Centre) showed how keratin microheterogeneity within a tissue or tumour could be scrutinized by two-dimensional gel electrophoresis of laser-dissected frozen sections.

Co-expression *in situ* of different types of intermediate filaments in one cell has only been reported in restricted situations, usually involving an overlap early in development between vimentin and the later-appearing tissue-specific class. Two cases of filament co-expression in adult cells were described at the meeting: astroglia, which by consensus of opinion usually contain vimentin as well as GFAP, and aortic smooth muscle, where cells may contain desmin or vimentin or both (Frank, Wistar Institute). Otherwise, the tissue specificity *in situ* of the non-vimentin filament classes remains clear-cut.

Do tumours express the filament type characteristic of the normal cell from

---

*The EMBO-sponsored workshop 'Intermediate filaments in differentiation and pathology' was held at the end of April in Gunzburg, FRG.

Birgitte Lane is at the Imperial Cancer Research Fund Laboratories, Lincoln's Inn Fields, London WC2A 2PX, and Brian Anderton is at St George's Hospital Medical School, Cranmer Terrace, London SW17 0RE.

0028-0836/82/330706-02$01.00

which they arise? The answer to this question is clearly yes — tissue specificity of intermediate filaments is retained in the tumour, and vimentin does not appear inappropriately. This was demonstrated by Osborn (Max Planck Institute, Goettingen) in the keratin-positive, vimentin-negative phenotype of intestinal cancers, and the desmin-positive, vimentin-negative phenotype of rhabdomyosarcomas.

On the other hand, tissue culture can modify filament expression, in that vimentin appears in most cultured cells. The meeting heard the first report of vimentin in epithelial cells in the body, however. Ramaekers (Catholic University of Nijmegen) observed vimentin in carcinoma cells growing as ascites, that is, in suspension, but when growing as a solid tumour these cells only expressed keratin. This may be a clue to the significance of vimentin induction.

Pathologists at the meeting agreed that intermediate filament antibodies are useful for identifying the origin of tumour metastases when standard histological methods are inconclusive. Improvements were suggested to avoid the need for frozen sections, since most intermediate filament antibodies react poorly with aldehyde-fixed material. Osborn showed high-quality immunofluorescence preparations of methanol-fixed, paraffin wax-embedded material; Coggi (University of Milan) used formalin-fixed material, but amplified sensitivity with multiple biotin-avidin complexes.

It is sometimes of immense medical value to be able to identify the origin of displaced cells. Virtanen (University of Helsinki) reported the presence of GFAP-positive (that is, astroglial) cells in amniotic fluid from anencephalic fetuses, and in many cases of spina bifida; normals were negative, since unless nervous tissue is exposed the glial cells cannot get into the aminiotic cavity.

Two examples of a pathological expression of intermediate filaments were discussed: Mallory bodies (containing keratin) of liver cells in alcoholic cirrhosis (Denk, University of Vienna) and neurofibrillary tangles of Alzheimer's senile dementia (Anderton, London, and Bignami, Havard Medical School). Anderton reported that the neurofibrillary tangles could only be stained by some of a group of neurofilament-staining monoclonal antibodies, and similar partial cross-reactivity with conventional antisera was reported by Bignami, implying that neurofibrillary tangles contain structurally altered neurofilaments.

Perhaps the most unexpected reports came from studies of mitosis. Franke and Lane independently described how keratin filaments break up into balls during mitosis in epithelial cell lines. This fact is not widely known, probably because of the preference for fibroblast models in cytoskeleton studies. Lane described how the balls, which form in prophase, may be associated with the plasma membrane, and Franke described associated 2 nm filaments, and said there was no evidence for the involvement of proteolysis. This disruption during mitosis is apparently not a tissue culture artefact, since Franke showed the effect in a human carcinoma. It was agreed that not all cell lines show the phenomenon, and Lane suggested a link with the speed of the cell cycle, such that more slowly dividing cells maintain intact filaments. Since keratins are difficult to depolymerize in non-denaturing conditions, this may be an interesting experimental system.

Thus, with some useful data on molecular structure, and the availability of systems in which the cell reorganizes its filaments *in situ*, we may soon understand how, and why, these molecules interact in the cell. Meanwhile the usefulness of filament antibodies in medical diagnosis should attract a greater commitment to this field of cell biology. □

Do steroid receptors recognize DNA sequences?

from J.R. Tata

On the twentieth anniversary of the Jensen two-step model of steroid hormonal regulation of gene expression[1] there is, at last, good evidence for one of its chief predictions. According to the model, steroid hormones interact in their target tissues with a high-affinity cytoplasmic receptor protein, and the interaction leads to a conformational change in the receptor such that the hormone–receptor complex is rapidly translocated into the nucleus. The receptor or receptor–hormone complex is then thought to interact with a variety of nuclear components in order to induce or modulate transcription of a few well specified genes. A prime nuclear target is DNA itself, but only recently has there emerged the first strong evidence to suggest sequence specificity of the interaction, at least *in vitro*.

In a recent study from Strasbourg, Mulvihill *et al.*[1] have most effectively exploited recombinant DNA technology and affinity chromatography to investigate the possible sequence specificity of interaction between the progesterone receptor and the genes of the egg-white protein that are induced by progesterone in the chicken oviduct. By adaptation of the oestrogen receptor DNA competition assay of Kallos and Hollander[2], Mulvihill *et al.* identified several cloned fragments from five chicken egg-white protein genes regulated by oestrogen and progesterone which could compete with calf thymus DNA for the progesterone receptor.

By testing deletion mutants, produced *in vitro*, of a fragment of the ovalbumin gene, Mulvihill *et al.* were able to narrow down the receptor recognition site to a region 250–300 base pairs (bp) 5′-upstream from the transcription initiation site, although recombinant fragments from other regions of all five genes (including exons and introns) were also found to be efficient competitors for the receptor. They then derived a consensus sequence of 19 nucleotides

$$\mathrm{ATC}\genfrac{}{}{0pt}{}{\mathrm{CC}}{\mathrm{TT}}\mathrm{ATT}\genfrac{}{}{0pt}{}{\mathrm{A}}{\mathrm{T}}\mathrm{TCTG}\genfrac{}{}{0pt}{}{\mathrm{G}}{\mathrm{T}}\mathrm{TTGTA}$$

not detected in a similar region of the globin gene, which is thought to be recognized by the progesterone–receptor complex.

It is interesting to compare the results of the Strasbourg group with findings from Schrader and his co-workers in Houston who have used a direct nitrocellulose DNA-binding assay[3-5]. Schrader also recently reported an A+T-rich region 135–250 bp upstream from the mRNA start site which is recognized by the progesterone receptor[6]. Photoaffinity labelling of the receptor with a synthetic analogue of progesterone (R5020) enabled this group to confirm their earlier suggestion that only one of the two subunits (A subunit) of the receptor recognizes DNA, while the other binds to chromatin (presumably to a protein component). However, the results of the two groups differ in some important respects. Whereas Mulvihill *et al.* find that the progesterone receptor specifically recognizes and binds to double-stranded DNA, the Houston group reported that the progesterone receptor acts as an unwinding or helix-destabilizing protein and has a preference for single-stranded DNA. The Strasbourg group ascribes this major inconsistency to several differences in methodology. They stress that they have used a crude cytoplasmic extract, in contrast to the highly purified preparation used in Schrader's laboratory, and that over-purification may have removed another component essential for the sequence-specific recognition of double-stranded DNA. They also point out that their assay measures the extent of competition by soluble DNA of progesterone–receptor complex to DNA already bound to cellulose, whereas the DNA filter-binding assay only gives the rate of association between the receptor and DNA.

J. R. Tata is Head of the Laboratory of Developmental Biochemistry at the National Institute for Medical Research, Mill Hill, London NW7 1AA.

0028-0836/82/330707-02$01.00

The sequence specificity of DNA binding by another steroid hormone receptor has also been reported recently. In a collaborative study between the University of California, San Francisco, and the Karolinska Institute in Stockholm, Payvar *et al.*[7] have suggested that the receptor for glucocorticoid hormones recognizes specific DNA sequences of murine mammary tumour virus (MMTV) within or neighbouring the gene, although the precise location of all possible sequences has not yet been determined. Their receptor preparation was purified 10,000-fold (that is, to about 50 per cent homogeneity) and tagged with the synthetic glucocorticoid ^{3}H-triamcinolone acetonide as the radioactive ligand. In a separate report, the San Francisco group has described how a 4.5 kilobase pair (kbp) *Eco*RI fragment of MMTV DNA cloned in plasmid pMTV2, which contains the long terminal repeats encoding the transcription start site but lacks 4.4 kbp of the rest of MMTV DNA, induced glucocorticoid-responsive transcription when introduced into cellular DNA[8]. Payvar *et al.* showed by ^{32}P end-labelling that the MMTV DNA fragment was specifically retained on nitrocellulose filters when bound to the glucocorticoid receptor preparation. Three different types of competition binding experiments demonstrated that the receptor selectively binds to at least four widely separated regions of MMTV proviral DNA. One of these binding sites was located 110–449 bp upstream of the promoter for MMTV transcription. Preliminary observations (for which experimental data have not yet been provided) revealed that at least one receptor binding site is located several kilobase pairs downstream from the start site of MMTV transcription.

How relevant are these *in vitro* receptor DNA binding studies to the physiological action of steroid hormones? Pongs and his colleagues in Bochum have provided the first direct evidence for the *in vivo* localization of a steroid hormone–receptor complex at the site of hormone-activated genes[9]. In the first of two papers, they showed that the insect metamorphic hormone β-ecdysterone can be covalently fixed by photolabelling to specific hormone-induced puffs of the polytenic chromosomes in the salivary glands of the third instar larvae of *Drosophila*. By using the 'Western' blotting technique of localization of ecdysterone antibody on cellulose nitrate filters, and two-dimensional gel electrophoresis, the second paper convincingly demonstrates that UV irradiation cross-links ecdysterone to a single protein of molecular weight 130,000 in both *Drosophila* larval salivary glands and K_c *Drosophila* tissue culture cells. This single protein exhibits all the characteristics of a steroid hormone receptor, including translocation from the cytoplasm to the nucleus.

The technical innovations in these recent studies represent a major step forwards in unravelling the role of steroid hormones in regulating gene expression, but they leave unanswered some important questions and raise a few new ones. First of all, discrepancies resulting from different techniques must be resolved. Then, there is the unresolved question of the high number of nuclear receptor molecules associated with full hormonal response. Although 42 sequences homologous to the 19 bp consensus segment were detected in the 14 kbp of known egg-white protein gene sequences, this number, even after generous extrapolation, does not explain the several thousand receptor binding sites normally found per cell nucleus. In this context, it is worth pointing out that the relative intensity of interaction between the progesterone receptor and specific 5′-upstream DNA sequence is only 10–40 times that observed with non-specific sequences such as calf thymus DNA or cloned globin genes[1,5]. Does this fact suggest that numerous other binding sites, not on DNA but on chromosomal proteins (also known as 'acceptor' sites), ribonucleoproteins, nuclear matrix and even non-nuclear sites, are required to induce alterations in overall structural conformation in order fully to maintain transcriptional activity? Will the results with progesterone receptor apply equally well to oestradiol, the major physiological regulator of egg-white gene expression?

In vivo functional tests, such as the introduction of viral sequences in a cell containing the rat glucocorticoid receptor, or the photoaffinity bonding of ecdysterone to its receptors in *Drosophila* cells, represent important approaches to be explored further. The next major advance will be the successful introduction of receptors in cells lacking these regulatory molecules and the manipulation of genes coding for the receptors. There is still some way to go before we can derive a unified concept of how hormones regulate gene activity, but what we learn along the way will be most valuable for our understanding of the multiple mechanisms of eukaryotic gene expression. □

Molecular heterogeneity and the nervous system

from Colin J. Barnstable

THE nervous system has an anatomical and physiological complexity that is considerably greater than that of other tissues and is seemingly part of a generally increased level of molecular complexity. The complexity arises both because the nervous system consists of more cell types and subtypes than other tissues and because a given neural cell seems to have a greater molecular complexity. Monoclonal antibodies are now providing an important new means of tackling this heterogeneity and of recognizing similarities and differences in neural cell types. Indeed, the use of monoclonal antibodies has grown so rapidly that two major review volumes on the fledgling subject of 'neuroimmunology' have already been published[1,2]. Two recent papers[3,4] provide good examples of the approach currently being taken by a number of laboratories.

In one paper, Hawkes *et al.*[3] used a synaptic plasma membrane fraction from rat cerebellum to immunize mice for monoclonal antibody production. In the other, Sternberger *et al.*[4] used a crude homogenate of rat hypothalamus as the immunogen.

Both papers describe antibodies that stain sections of rat brain in a manner characteristic of neurofibrillar staining. This makes it likely, though not certain, that these antibodies are staining neurofilaments, the class of intermediate filaments unique to neurones. Unlike intermediate filament types of other tissues, which consist of similarly sized polypeptide chains, neurofilaments have been isolated as a triplet of distinct polypeptides of molecular weights 200,000, 140,000 and 68,000 (ref. 5). Hawkes *et al.* found one such antibody that stained the cerebellum and reacted with a polypeptide of molecular weight 30,000. It is not yet clear whether this represents a new neurofilament polypeptide or whether it is some neurofilament-associated molecule. The staining patterns given by the other neurofibrillar antibodies were not identical, which suggests that either the neurofilament polypeptides are distributed differently between various neuronal cell types or that one or more of the neurofilament polypeptides exists in a

variety of isotypic forms. Biochemical analysis of the antigens recognized by these monoclonal antibodies should resolve this question.

An important point to emerge from these papers is that an antibody can label different subpopulations of neurones in different brain regions. An example given by Sternberger *et al.* is the antibody 02-135 which labels pyramidal cells in area CA2 but not CA1 of the hippocampus, Purkinje cells but not granule cells of the cerebellum, and stellate cells but not pyramidal cells of the cerebral cortex.

The interpretation of such results is complex. Similar results using antibodies raised against the leech nervous system were interpreted as suggesting a possible functional interaction or neural subnetwork between the labelled cells[6]. While this is indeed possible, mammalian studies suggest a different interpretation. It seems as if each antigen can be used for one class of cells in an area of the nervous system that is physiologically and anatomically separated from other regions in which the same antigen appears. Clearly further characterization of the respective antigens is required since any interpretation will depend on whether or not the same molecule is being detected in the various cells. Hawkes *et al.* have shown that some antibodies that give very distinct immunocytochemical staining can react with a number of polypeptides of different molecular weights and the general problems of cross-reaction of monoclonal antibodies have been discussed in these pages recently[7]. If we view the nervous system as having evolved by duplication and divergence of cell types or even whole neuronal networks, then the problem of cross-reactions between related molecules is going to be particularly acute.

One antibody produced by Hawkes *et al.* has been characterized more fully[8] and shown to recognize a 23,000 molecular weight polypeptide that is present in all neurones. Both anatomical studies and subcellular fractionation experiments suggest that this antigen, named MIT-23, is restricted to neuronal mitochondria. During cerebellar development this antigen appears after the final cell division or migration of the neurones. It is at present unknown whether this molecule carries out a function that only appears in postmitotic neurones or whether it is a neurone-specific isozyme of a common mitochondrial component, another isozyme of which is present in the dividing neuroblast. This latter possibility would be reminiscent of one of the first immunologically identified 'brain-specific antigens', the 14-3-2 protein, that turned out to be a brain-specific subunit of the enzyme enolase that is only expressed in postmitotic neurones[9].

Because of the different methods being used to characterize antibodies by different laboratories, and the different extents of characterization, it is often difficult to compare results in different papers. A particularly acute problem arises when some of the results are based on reactions of uncloned antibodies, as in the case above. One thing that is clear, however, is that we do not yet know the full extent of the molecular complexity of the nervous system. The challenge facing those who would like to find molecules carrying out a particular function is to identify them against what is clearly a high background of molecular complexity that may be completely incidental to those functions.

BIRPS: deep seismic reflection profiling around the British Isles

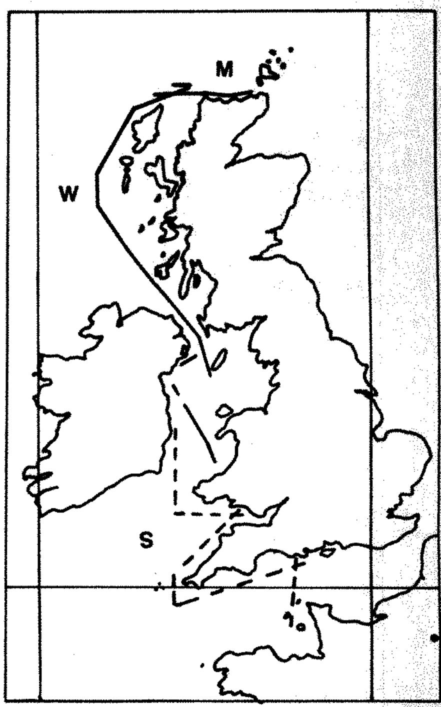
from D.H. Matthews

BIRPS* is investigating the geological structure of the lower part of the continental crust and of the underlying uppermost part of the Earth's mantle in and around the British Isles, using seismic reflection profiling techniques developed by the oil industry. The technique can be used at sea or on land and is similar to echo sounding: sound from an explosion at the surface passes down through the rock layers and is reflected back to a detector at the surface from inter-layer boundaries, across which there is a change in acoustic impedance (the product of sound velocity and density).

Two lines (MOIST and WINCH) have been shot so far — both offshore, as shown on the map (Fig. 1). The sound source was an array of air-guns which released compressed air into the sea every 50 m along the ship's track. Reflected sound was detected by a towed streamer, 3 km long, containing hydrophones arranged in 60 sections each 50 m long. By adding the returns from 30 consecutive shots recorded from sections 2, 4, 6 . . . 58, 60 and correcting for the increasing length of the raypath it was possible to add 30 reflections from a common point on the reflector (30-fold coverage). The recording equipment was run for 15 s; sufficient for the sound to travel to about 45 km beneath the surface and back again if the mean crustal sound velocity is 6 km s^{-1}.

MOIST obtained what are arguably the best deep seismic reflection data in the world[1,2] (Fig. 2). The crust–mantle boundary, the Moho, can be traced as a strong reflector along the greater part of the profile westwards from the Pentland Firth until it apparently terminates against a second strong reflector (the Flannan Thrust?) which can be followed down to 40 km depth. The Moho depth of 27 km agrees with that obtained on the LISPB refraction line where the two lines intersect[3]. Further velocity information was obtained from two-ship multichannel experiments[4]. The Outer Isles Thrust, which was reactivated as a normal fault in Mesozoic time, can be traced down as a planar reflector dipping at about 30°

Fig. 1 Outline of the British Isles with the positions of deep reflection lines: MOIST (Moine and Outer Isles Seismic Traverse, 180 km, shot 1981 by Western Geophysical), WINCH (Western Isles and North Channel Traverse, 1,000 km, shot 1982 by GECO International), SWAT (South West Approaches Traverse, planned for 1983). Meridians 0° and 10°W and parallels 50° and 60°N (the top border) are shown.



---

*BIRPS (The British Institutions Reflection Profiling Syndicate) is made up of members of university earth science departments and the Institute of Geological Sciences. The core group receives an annual grant from the Natural Environment Research Council and Shell (UK) supports a visiting scientist. Data from the first seismic reflection line shot (MOIST) are on open file at the Institute of Geological Sciences, Edinburgh, and are available for the cost of reproduction. The data from the second line (WINCH) will be available in July 1983.

From 1 October 1982 D.H. Matthews will be a senior research associate in the University of Cambridge, Director of the BIRPS core group.

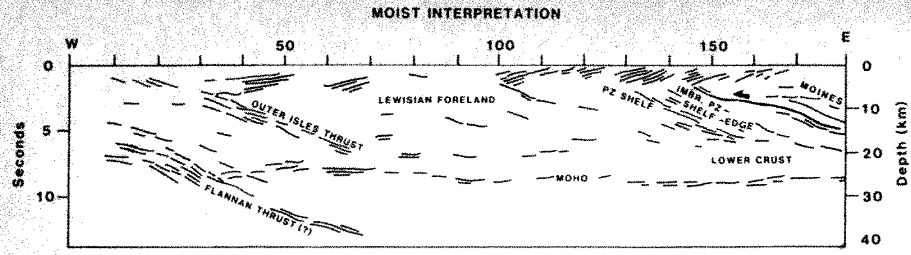

Fig. 2 Line drawing of reflection line-ups identified on MOIST (migrated data). The arrows indicate one plausible position of the Mone Thrust and the lettering in the border indicates one plausible geological interpretation[2]. Migration was done for BIRPS by Shell UK.

almost to the Moho, but the Moine Thrust is less easy to identify. At the eastern end of the profile there are easterly dipping reflectors which appear to pass up into the boundary faults of rotated blocks of Devonian sediments and are interpreted as imbricate thrusts reactivated as normal faults during a later period of stretching. There is a close parallel here with easterly dipping reflectors seen at the seaward end of COCORP profiles across the Appalachians[2,5].

WINCH was intended to elucidate the Flannan Thrust and to cross the principal faults of the Caledonides. Processing of the data has begun, as has planning for profiling in financial year 1983–84 around Cornwall and probably across the English Channel towards Guernsey to investigate Hercynian structures, the Cornubian batholith and the Brioverian basement. It is intended to work with the French ECORS group which is forming to carry out deep seismic profiling in France.

A start has thus been made on investigating the deep geological structure under the British Isles using the only technique that promises to have sufficient resolution. Also, two short deep profiles have been shot by the deep-geology unit of the Institute of Geological Sciences on land and one by the University of Leicester. The oil industry has also begun to obtain some deep profiles at sea and on land. Resolution is limited by the low frequencies of the returns from deep reflectors: a frequency of 20 Hz in rock with sound velocity $V_p = 6$ km s^{-1} implies a wavelength of 300 m and the possibility, at a depth of 30 km, of resolving two reflecting points 75 km apart vertically and 2,100 m apart horizontally. The recording parameters are chosen to look at deep features so that the resolution of shallow events is less good than that of standard industry reflection profiling which is usually run for about 5 s two-way time. For resolving details of relatively shallow sedimentary strata a wealth of data obtained by the oil industry is held by the Department of Energy.

The main objectives of BIRPS are threefold. First, structural geology, particularly to trace the attitude of major faults which are known at outcrop or subcrop to deep within the crust. Do the normal faults curve, to 'sole out' at relatively shallow depths? Are many thrust faults splays off sub-horizontal *decollement* surfaces like the Brevard zone[5] in the southern Appalachians? What is the shape of the Moho under sedimentary basins? Are all granites floored at about 6 s two-way time?

Second, continental rheology. A glance at a map of earthquake distribution is sufficient to convince that plate tectonics does not work in Eurasia: it is impossible to define aseismic plates delineated by lines of epicentres at their edges, as one can in the deep oceans, anywhere between Spain and Singapore. Is this because the hot continental lithosphere responds to stress by flowing, generating earthquakes only at shallow depths, or is it because the continents have such a long history of faulting that they can always respond to stress by reactivating some older fault surface, producing the widespread belt of earthquakes with random mechanism solutions that we observe in Eurasia. In the latter case, we should commonly find faults extending right through the crust into the upper mantle. In this context, it is likely that depth or penetration could be extended deeper than the 15 s that we have so far tried. Attenuation is low in crystalline rocks ($Q \sim 400$) and signal-to-noise ratios are still workable at the bottom of the record if reflectors are there.

Third, imaging. There is a perceived need, both in industry and in academic deep seismics, for better techniques of imaging steeply dipping reflectors. Groups of theoretical seismologists are working on this problem both in industry and at Cambridge, Princeton and Stanford. We also need to compute the reflection profiles that we would expect from model structures, for comparison with observed profiles, if we are to understand how we get apparently flat-lying reflections, albeit discontinuous, from the foliation surfaces of the high-grade metamorphic rocks that we expect to occur deep in the continental crust and which we observe exposed at outcrop on the continental shields.

BIRPS will try to contribute to all three objectives, and perhaps in the future we may be able to profile abroad in areas of active mountain building. Working deep within the crust sounds esoteric, of interest only to academic structural geologists. But, like COCORP in the USA, to whom we are deeply indebted[6], we are investigating the skeleton of the continent which supports and delimits the soft sediments of the oil basins. ☐

SCIENTIFIC EXPLORATION IN EGYPT

Now that we have embarked in a war in Egypt, it is to be hoped that steps will be taken to have a proper staff of scientific explorers attached to the army with facilities for conducting their investigations. There are periods of rest in a campaign during which soldiers and others may be usefully employed in conducting excavations at comparatively slight cost; and difficulties in the way of investigation, arising from the requirements of trade and industry, disappear in time of war. The deposits of the Delta require to be examined. The gravels of the Nile Valley have to be connected with their animal remains. Much has to be done for the earliest and best period of Egyptian art, and the Stone Age of Egypt has to be fixed with certainty.

I trust also that we shall not rob Egypt of her antiquities to any great extent. It may be useful to complete our typical series to a limited extent, but if Boulak should be happily preserved, I hope it will be preserved for Egypt and not brought home. Nothing would serve more to prove that we go there to civilise and not to rob. The means of communications are now so easy that all who are interested in Egyptology can see it there. Steam and railways have materially altered the requirements of education in this respect. Humanity, and British humanity in particular, now pours through all the great arteries of the world, and people observe and study more abroad than at home. The time has passed when antiquities should be regarded as trophies of war. It is no longer necessary for instruction to hoard up valuable specimens of foreign antiquities in European museums. So long as science has access to the materials of knowledge, that is all that it is necessary to bring away. Besides which, it should be remembered that the atmosphere of Egypt preserves antiquities in a way that no other climate can do; and when this fact hereafter becomes fully impressed upon the public mind, the time may come when subscriptions will be raised to take back obelisks and put them up again in their proper places; at any rate we have enough of them weathering and withering in smoke and damp. But the opportunity for exploration should not be lost. The French savants did their work thoroughly during their military operations in that country, and it would be shameful if, with the knowledge now at our disposal, the British expedition did not achieve more for the promotion of science than was effected by Napoleon half a century ago.

A pregalactic Population III: primordial helium and heavy elements and the microwave background

P. W. Tarbet & M. Rowan-Robinson

Department of Applied Mathematics, Queen Mary College, Mile End Road, London E1 4NS, UK

The helium, heavy elements and dark remnants produced by a pregalactic generation of stars, Population III, are discussed quantitatively for three scenarios: (1) Population III is responsible for the distortion of the microwave background spectrum measured by Woody and Richards; (2) Population III objects generate the whole of the microwave background; (3) Population III provides the oldest metals found in our Galaxy today.

A NATURAL consequence of the isothermal density fluctuation picture is the possibility of a pregalactic generation of stars, Population III, where 'stars' includes objects up to 10^6 or 10^7 solar masses. Consequences of such a population have been considered elsewhere (see ref. 1 and refs therein). Here we investigate three different roles for Population III. First, to generate the distortion of the microwave background measured by Woody and Richards[2,3], as proposed in ref. 4. Second, to produce the entire microwave background, and the observed 'primordial' helium abundance. Third, to manufacture the first metals in galaxies.

These three possibilities are explored quantitively with assumptions about the mass spectrum of the stars, the helium and heavy element yields of stars of different masses and the remnants.

Helium and metal yields of Population III

The mean mass density parameter of the Universe at the present epoch, $\Omega_0 (= 8\pi G\rho_0/3H_0^2 = (\rho_0/2\times10^{-29}\ \text{g cm}^{-3})\ (H_0/100)^{-2})$, can be considered to have three components; Ω_g, the contribution from visible matter, Ω_r, that due to dark matter, such as black holes and neutron stars, which we will assume are the remnants of Population III, and Ω_ν, from non-baryonic matter, such as neutrinos with mass $\Omega_0 = \Omega_g + \Omega_r + \Omega_\nu = \Omega_b + \Omega_\nu$, where Ω_b is the total baryonic contribution.

We assume that at some epoch in the early Universe a population of stars was born and subsequently died at a later epoch z_f (z_f is the redshift at which the objects cease to produce radiation, so in the case of black holes it is the epoch when they stop accreting at an appreciable rate).

If $Y(M)$ and $Z(M)$ are the fraction of a star's mass returned as helium and heavy elements respectively, then the fraction of visible matter in the form of helium and heavy elements is

$$Y = (1 - \Omega_{ej}/\Omega_g)Y_P + (8\pi G/3H_0^2\Omega_g)(1+z_f)^{-3}A\int_{M_1}^{M_2} Y(M)MN(M)\,dM$$

$$Z = (8\pi G/3H_0^2\Omega_g)(1+z_f)^{-3}A\int_{M_1}^{M_2} Z(M)MN(M)\,dM$$

where Y_P is the cosmic (pre-Population III) helium abundance, Ω_{ej} is the contribution to Ω_g that was cycled in pregalactic stars, H_0 is the Hubble constant and $AN(M)\,dM$ is the number-density of stars with masses in the range M to $M+dM$ at epoch z_f, having upper and lower limits of M_2 and M_1 respectively. We shall take $N(M) = M^{-\alpha}$. Similarly if $R(M)$ denotes the fraction of a star's mass left behind as dark matter, then

$$\Omega_r = (8\pi G/3H_0^2)\cdot(1+z_f)^{-3} \times A\left(\int_{M_1}^{M_b} R(M)MN(M)\,dM + (1+\mu_B)\cdot\int_{M_b}^{M_2} R(M)MN(M)\,dM\right)$$

where it is assumed that the remnant is a black hole for $M > M_b$, and μ_B is the ratio of the mass accreted by a black hole to the mass of an initial black hole.

The coefficient A of the mass function is related to the radiation output of these objects. If they enhance the background by a factor β and $\varepsilon(M)$ is the fraction of a star's mass converted into radiation, then

$$\beta a T_0^4(1+z_f)^4 = A\int_{M_1}^{M_2} \varepsilon(M)MN(M)c^2\,dM$$

$T_0(1+z_f)$ being the temperature of the primordial cosmic background at epoch z_f. If the efficiency of producing radiation in the conversion of H to He is $\varepsilon_Y(\sim 0.007)$ and from He to metals is $\varepsilon_Z(\sim 0.003)$, then

$$\varepsilon(M) = \varepsilon_Y(Y(M) + Z(M) - Y_P) + \varepsilon_Z Z(M)$$

for the nucleosynthetic contribution; and for those stars which produce black holes at their deaths, which then accrete a fraction μ_B of their initial mass with efficiency ε_B

$$\varepsilon(M) = \varepsilon_B\mu_B R(M)$$

The value of $\varepsilon_B\mu_B$ is difficult to determine as the accretion rate depends on the temperature of the material being accreted

Table 1 The effect of varying the parameters M_2, α, μ_B and H_0 on models producing the distortion of the microwave background

M_2	α	μ_B	H_0	Ω_g	Ω_b	Y_{min}	Y_P	Z
10^6	1.0	5.0	50	0.043	0.100	0.259	0.256	2.85×10^{-5}
10^6	1.25	5.0	100	0.016	0.030	0.262	0.258	1.32×10^{-4}
10^5	0.75	5.0	50	0.375	0.432	0.275	0.268	1.63×10^{-5}
10^7	1.25	5.0	50	0.021	0.078	0.256	0.254	6.63×10^{-5}
10^6	1.0	1.0	50	0.147	0.243	0.268	0.263	4.16×10^{-5}
10^6	0.75	0.5	50	0.173	0.316	0.270	0.266	1.02×10^{-5}
10^6	0.75	0.1	50	0.769	1.294	0.282	0.277	1.15×10^{-5}

Y_{min} is the minimum net helium yield given by the parameters M_2, α, μ_B, H_0 and Ω_g; the corresponding Ω_b, Y_P and Z are also shown.

0028-0836/82/330711—05$01.00

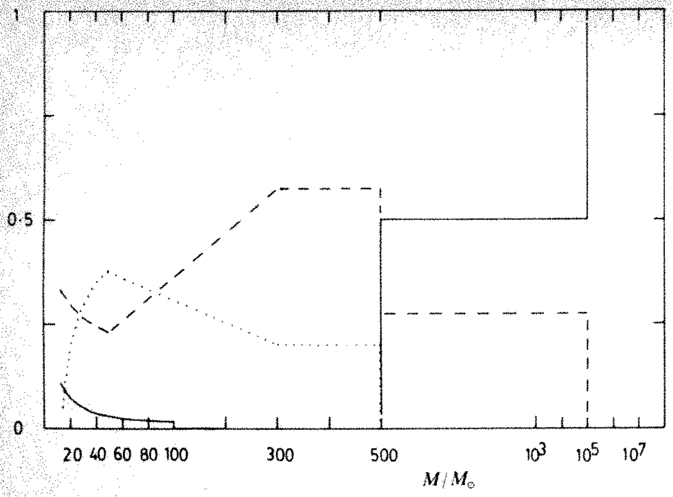

Fig. 1 The fraction of a star's mass ejected as helium ($Y(M)$, dashed curve) and heavy elements ($Z(M)$, dotted curve), and left as a remnant ($R(M)$, solid curve), as a function of the star's mass. Note that the mass scale changes at 100, 500 and $1{,}000M_\odot$.

which in turn is determined by the accretion, and the efficiency depends on the details of the flow and cooling processes[5]. The efficiency, ε_B, is of the order of 0.1 and if we consider $\varepsilon_B\mu_B = L_{ED}t/Mc^2$, where the Eddington luminosity $L_{ED} = 10^{38}(M/M_\odot)$, and $t = 10^{17.5}\Omega^{-1/2}z_f^{-3/2}$, then $\varepsilon_B\mu_B = 0.02$ for $\Omega = 0.15$ and $z_f = 200$. But it was found that in the models having $z_f = 200$, $\varepsilon_B\mu_B$ could not be much less than 0.1, (see ref. 6), to avoid excessive amounts of matter or high yields from Population III.

Schramm and Steigman[7] give $(0.9\text{–}3.5)\times10^{-3}h_0^{-1}$, where $h_0 = H_0/100$, as a firm lower limit to the nucleon density parameter, based on observations of the light producing stars in the solar neighbourhood. This is taken as the lower limit for Ω_g.

The functions $N(M)$, $Y(M)$, $Z(M)$, $R(M)$

The function $N(M)$ is assumed to have the form $M^{-\alpha}$. For the solar neighbourhood $\alpha = 2.35$, the Salpeter value[8], $M_1 = 0.01\text{–}0.1M_\odot$ and $M_2 = 60\text{–}100M_\odot$. In a zero metal abundance medium, cooling will be less efficient and fragmentation inhibited[9]. We may therefore expect M_1 to be increased (Silk[9] argues that $M_1 \sim 20M_\odot$) and α reduced. For $\alpha < 2$, M_1 is not a very important parameter; $M_1 = 13M_\odot$ was adopted. The cocoon star mechanism that limits M_2 in the solar neighbourhood[10] also does not apply in the metal-free primordial environment, and we assume that M_2 can extend up to the scale of the Jeans mass at decoupling.

In the range $12 < M/M_\odot < 100$ stars are believed to be able to burn all of their nuclear fuels through to iron without mishap[11]. The core then undergoes hydrodynamic collapse but the implosion is reversed when nuclear densities are reached and a large amplitude bounce reflects the incoming kinetic energy, blowing off all layers external to the core in a supernova explosion[12,13]. The exact details of core bounce are not yet known and the complex reaction networks of static and dynamic burning make yield determinations uncertain. Here, the helium yields of Arnett[14] (scaled for an initial helium content of Y_P) are used, the formula of Weaver and Woosley[15] is used for the metals, and the neutron star core remnants are taken to be $1.4M_\odot$.

Stars with initial mass greater than about $100M_\odot$ do not burn fuels all the way through to iron but encounter the e^+e^- pair instability and undergo core collapse[16]. The question is, can subsequent fast nuclear burning reverse this collapse or is the ultimate fate a black hole? Woosley and Weaver[17] and Bond *et al.*[18] calculate that stars having an initial mass much exceeding $300M_\odot$ (the uncertainty coming from the uncertainty in mass loss) will be unable to reverse this collapse, whilst those in the range $100\text{–}300M_\odot$ suffer complete disruption.

It has often been pointed out that massive stars ($M \gtrsim 60M_\odot$) are unstable to nuclear energized pulsations[19–21]. But studies by, for example, Appenzeller[22,23], Talbot[24,25] and Papaloizou[26] imply that these pulsations do not completely disrupt the stars. For those of initial mass $>300M_\odot$ a substantial fraction of the star may be lost on a time scale much shorter than the hydrogen burning phase, whilst those below $100M_\odot$ suffer little from this instability[23].

Talbot and Arnett[27] looked at helium production from massive stars, with no initial helium, suffering mass loss due to nuclear pulsations and concluded that 17% of the star could be shed in the form of helium with a net helium yield of about 0.5 for stars $>300M_\odot$. However, other mechanisms (radiatively driven winds) may be important and the observations of Humphreys and Davidson[28] seem to point to the possibility that mass loss severely restricts the evolution of stars with initial masses $50\text{–}60M_\odot$ to cooler regions of the H-R diagram. It has been suggested[29] that OH-IRII sources with deep silicate absorption may be the remnants of massive stars which have suffered substantial mass loss.

Considering the uncertainties in mass loss and the upper limit of complete disruption the following simple approach was taken. Stars of mass $>M_a = 300M_\odot$ are assumed to lose half their mass due to winds and so (scaling for $Y_P = 0.25$) shed 0.275 of their mass as helium. The remnant then contributes to the yield after disruption to give a total fraction of 0.575 as helium and 0.2 as metals. Those above $M_b = 500M_\odot$ (up to $10^5M_\odot$) return the 0.275 wind component but the remnants collapse to black holes. For stars in the range $50\text{–}300M_\odot$, $Y(M)$ and $Z(M)$ were interpolated linearly between the values adopted at 50 and $300M_\odot$.

Objects exceeding $10^5M_\odot$ encounter a general relativistic instability during quasi-static collapse[30] and if they contain no heavy elements, nuclear burning cannot proceed rapidly enough to prevent catastrophic collapse[31]. Thus virtually the whole star collapses to a black hole on a short time scale.

The adopted forms for $Y(M)$, $Z(M)$ and $R(M)$ are summarized in Fig. 1.

Viable scenarios of Population III

(1) The distortion of the microwave background: To produce the spectrum observed by Woody and Richards[2], Negroponte *et al.*[32] found it necessary to have z_f in the range 150–225, β in the range 0.2–0.4, and a metal abundance relative to the total mass of $2.5\text{–}7.5\times10^{-6}$ for $\Omega_0 = 1$ and $1\text{–}3\times10^{-5}$ for $\Omega_0 = 0.1$ ($H_0 = 100$), depending on the grain material. To test this type of model we take $z_f = 200$, $\beta = 0.25$ and look for values of the parameters Ω_g, H_0, M_2, α, μ_B, which give a heavy element abundance in the right range. Allowing for the uncertainties in the type of grain material and the observed distortion, we take this to be $\Omega_g Z = 5\text{–}50\times10^{-7}$ for $H_0 = 100$, and $10^{-6}\text{–}10^{-5}$ for $H_0 = 50$.

We have taken $H_0 = 50$ or 100; $\log_{10} M_2/M_\odot = 2(1)7$; $\alpha = 0.5(0.25)2.5$; $\mu_B = 1, 5$; and in each case varied Ω_g from 0.001 to 1.

Table 2 Models in which Population III stars produce all the microwave background

a	M_2	α	μ_B	H_0	Ω_g	Ω_b	Y	Z
	10^5	0.5	5.0	50	0.091	0.394	0.223	9.26×10^{-5}
	10^5	0.5	5.0	100	0.023	0.099	0.223	9.26×10^{-5}
	10^6	0.75	1.0	50	0.013	0.522	0.220	3.51×10^{-4}
	10^6	0.75	1.0	100	0.003	0.130	0.220	3.51×10^{-4}
b	10^5	0.25	5.0	50	0.091	0.394	0.223	4.56×10^{-5}
	10^5	0.25	5.0	100	0.023	0.099	0.223	4.56×10^{-5}
	10^5	0.5	5.0	100	0.023	0.099	0.223	1.69×10^{-4}
	10^6	0.5	1.0	50	0.007	0.516	0.231	1.74×10^{-4}

a, The only models producing all of the microwave background and providing enough helium without overproducing heavy elements; *b*, as *a* but with $Z(M)$ increased at the expense of $Y(M)$ in the stellar mass range $300\text{–}500M_\odot$. Y is the net helium yield given by the parameters M_2, α, μ_B, H_0 and Ω_g; Z is the corresponding net heavy element yield.

Table 3 The effect of varying the parameters α, M_1 and M_2 on initial enrichment models

α	M_1	M_2	Ω_{III}	Ω_{ej}	Ω_{r}	Y_{III}	β
2.35	20	100	3.18×10^{-5}	3.06×10^{-5}	1.19×10^{-6}	8.37×10^{-5}	3.93×10^{-4}
1.0	20	100	2.96×10^{-5}	2.87×10^{-5}	8.33×10^{-7}	7.74×10^{-5}	3.91×10^{-4}
2.35	13	100	3.90×10^{-5}	3.70×10^{-5}	1.99×10^{-6}	1.08×10^{-4}	4.11×10^{-4}
2.35	30	100	2.88×10^{-5}	2.80×10^{-5}	8.13×10^{-7}	7.30×10^{-5}	3.85×10^{-4}

2.35	20	500	3.38×10^{-5}	3.30×10^{-5}	8.04×10^{-7}	1.11×10^{-4}	4.54×10^{-4}

See text for definitions of the parameters and their functional dependence on Z, Ω_g and z_f.

Because the Jeans mass at decoupling is $\sim10^6M_\odot$ it is natural to look first for models with $M_2=10^6M_\odot$ which produce the required Ω_gZ. $M_2=10^6M_\odot$, $H_0=50$, $\alpha=1.0$ and $\mu_B=5.0$ fits the required Ω_gZ and has a minimum helium yield of $Y=0.259$ at $\Omega_g=0.043$, $\Omega_b=0.100$, $Z=2.85\times10^{-5}$ and $Y_P=0.256$. The dependence of Y (and Y_P) on Z and Ω_g for this model is shown in Fig. 2. For low values of Ω_g the net metal and helium yields from Population III are high but decrease as Ω_g increases. At higher Ω_g, and hence Ω_b, the primordial helium yield increases so Y starts to increase again. The model cited above is seen to have a net helium yield slightly higher than some recently deduced primordial values; $Y=0.216\pm0.015$ (ref. 33), $Y=0.228\pm0.014$ (ref. 34). As most of the helium comes from primordial nucleosynthesis this problem is shared by the standard model unless $\Omega_b<0.03$ (ref. 7). However, these low values are disputed by Kunth[35], who deduces $Y=0.243\pm0.010$.

We have used the work of Yang *et al.*[36] to determine Y_P, which in turn adopts the nucleosynthesis code of Wagoner[37]. As discussed by Olive *et al.*[38], Y_P (and consequently Y) could be reduced by taking a lower value for the free neutron half life, $\tau_{1/2}$. Bondarenko *et al.*[39] have determined $\tau_{1/2}=10.13\pm0.09$ min, compared with $\tau_{1/2}=10.7$ used by Wagoner and $\tau_{1/2}=10.56\pm0.09$ recommended in ref. 40. This could reduce Y_P by ~0.01. If the τ-neutrino has a mass >1 MeV/c^2, then the two-neutrino case rather than the three-neutrino case should be used in the helium nucleosynthesis calculation (see the dotted curve in Fig. 2). However, this case leads to implausibly high values of Ω_ν unless the mass of the τ-neutrino is greater than 2 GeV/c^2 and this is inconsistent with the experimental upper limit of 250 MeV/c^2 (ref. 41).

The deuterium in these models is given by

$$D=(1-\Omega_{\mathrm{ej}}/\Omega_g)D_P$$

and since, for the case cited, $\Omega_{\mathrm{ej}}=5.06\times10^{-4}$, $D=0.988D_P$, (almost identical to the standard model).

We consider the effect of varying the other parameters of our model. Changing H_0 to 100 decreases Ω_gZ by a factor of 4 whilst the required range in Ω_gZ is reduced by a factor of 2. The net effect of changing H_0 is therefore small. To recover a model giving Ω_gZ in the required range we need to increase α from 1 to 1.25 when H_0 is changed from 50 to 100. The dependence of Ω_gZ on α is more significant. Increasing α to 1.25 with other parameters unchanged still leaves Ω_gZ in the required range, but $\alpha=1.5$ gives $\Omega_gZ=5.70\times10^{-5}$ and $\alpha=0.5$ gives $\Omega_gZ=2.55\times10^{-8}$. Since the radiation is mainly from accreting black holes, the upper end of the mass spectrum, the effect of reducing M_2 is to require a lower value of α to maintain Ω_gZ in the required range. The yields are also increased as M_2 is reduced because the contribution to the radiation from objects returning processed material is higher. It was found that M_2 must exceed $10^4M_\odot$ unless $\alpha<0.5$. Lowering μ_B increases the yields from Population III and such models also require more matter (higher Ω_r to provide the required radiation), hence Y_P is increased. Table 1 illustrates the effects of varying the parameters M_2, α, μ_B and H_0.

Thus a pregalactic stellar population can provide a distortion of the microwave background as in the scheme outlined in ref. 4, but to give acceptable values of Y and Z the mass function must be flat and extend to super-massive objects, so that most of the light is generated by accreting black holes.

(2) Generation of the whole of the microwave background: As pointed out by Carr[6], if a pregalactic generation of stars could have generated 25% of the microwave background, could it not be possible for them to have generated all of it? In this case $\beta=1.0$ and we take $T_0=2.9$ K so as to give a total energy density equal to that observed by Woody and Richards[2,3]. The primordial helium yield now has to be generated entirely by Population III stars (nucleosynthesis needs to be suppressed in a cold Universe by taking the lepton-to-baryon ratio >1.3 to prevent most of the Universe being synthesized into helium and heavy elements)[42]. If we are still trying to fit the claimed distorted spectrum then the required Ω_gZ is as in the previous case, and we take $z_f=200$. We have also looked at $z_f=1{,}000$ because, in the Carr model, the extra 75% of the background radiation produced in these models has to be generated at this earlier epoch for thermalization by free–free processes to be effective. (The Rowan-Robinson *et al.*[4] scheme requires only that the radiation be produced by $z_f\sim200$. The constraints on Ω_gZ are due to the optical depth in dust back to $z_f\sim200$ required in this scheme, so are unchanged.)

The only models giving the required Ω_gZ and enough helium are given in Table 2*a*. All other models (with $\mu_B=1.0$ or 5.0) satisfying the constraints on Ω_gZ and Z, from old Population II, produced too little helium.

Models with lower μ_B were found. With $M_2=10^6M_\odot$, $\alpha=0.75$ and $\mu_B=0.5$, we found $Y=0.220$ and $Z=3.51\times10^{-4}$ with $\Omega_g=0.007h_0^{-2}$, $\Omega_b=0.197h_0^{-2}$ ($\Omega_r=0.190h_0^{-2}$), but the only two cases with acceptable yields for $\mu_B=0.1$ were $M_2=10^6M_\odot$, $\alpha=0.5$ and $M_2=10^7M_\odot$, $\alpha=0.75$ which had $\Omega_r=0.697h_0^{-2}$ and $\Omega_r=0.670h_0^{-2}$, respectively, which are rather high. We also found acceptable models with $z_f=1{,}000$ but these also required high densities ($\Omega_r>0.6h_0^{-2}$) or had <1% of the total baryonic matter in visible form today, so are rather implausible.

Note that none of these models produce any deuterium and it is therefore necessary to appeal to some *ad hoc* astrophysical mechanism for this (see ref. 43). However, as there are models that imply that the Carr scenario can simultaneously produce all of the microwave background, explain the Woody and Richards distortion with the mechanism proposed in ref. 4, and give the correct helium yield and Population II metals, it would perhaps be worthwhile to investigate the predicted background spectrum of these models in more detail, taking into account the staggered way in which the radiation from different stellar masses is generated. The capacity of free–free processes to thermalize the bulk of the radiation has been disputed by Wright[44]. He argues that for adequate thermalization at long wavelengths, needle-shaped conducting grains are required, with a length-to-width ratio of at least 210; a similar mechanism is proposed in ref. 45.

(3) Initial enrichment: The need for a non-zero initial metal content for the Galaxy has been argued by many authors (see refs 46–48) and most recently by Bond[49] who deduces a mean metal abundance of $0.0181Z_\odot$ for Population II and an initial metal content of $2.51\times10^{-3}Z_\odot$.

It has been seen that models (1) and (2) can provide this initial enrichment, but here we suppose the radiation requirement on Population III to be minimal and try to produce the required metal abundance without adding significantly to the primordial helium.

Individual galaxies are believed to condense out at about

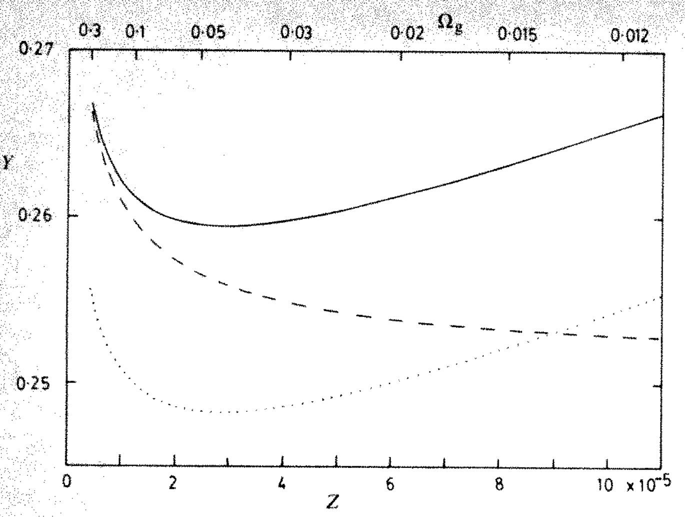

Fig. 2 The total helium abundance, Y (solid curve) and the primordial helium abundance, Y_P (broken curve), plotted as a function of the heavy element abundance, Z (lower scale). The contribution to Ω_b due to visible matter, Ω_g, is labelled on the upper scale. The dotted curve shows the two-neutrino case. Model parameters are given in the text.

redshifts 10, so z_f is relaxed to this value. However, β is not a relevant parameter in these models as we are not concerned with the effect of the stars on the microwave background. Instead we consider the fraction of the Universe that needs to go into a pregalactic stellar generation to provide the initial metals. We define Ω_{III}, the density parameter today for these objects if they had not ejected any of their mass (or accreted any).

$$\Omega_{III} = (8\pi G/3H_0^2)\cdot(1+z_t)^{-3}\mathrm{A}\int_{M_1}^{M_2} MN(M)\,\mathrm{d}M$$

First let us consider $M_1 = 20M_\odot$ (ref. 9), $\alpha = 2.35$ (the Salpeter[8] value), and $M_2 = 100M_\odot$. For this set of parameters we find $\Omega_{III} = 3.18\times10^{-5}\,(Z/10^{-4})\,(\Omega_g/0.1)$, $\Omega_{ej} = 3.06\times10^{-5}\,(Z/10^{-4})\,(\Omega_g/0.1)$, $\Omega_r = 1.19\times10^{-6}\,(Z/10^{-4})\,(\Omega_g/0.1)$, $Y_{III} = 8.37\times10^{-5}\,(Z/10^{-4})$, (where Y_{III} is the net helium yield from Population III) and $\beta = 3.93\times10^{-4}h_0^2\,(Z/10^{-4})\,(\Omega_g/0.1)\,(11/1+z_f)$.

It is therefore possible to provide the initial metal content of galaxies without resorting to a flat mass function extending to SMOs, and with only a very small amount of the Universe being cycled in pregalactic stars. Such models have a negligible effect on primordial helium and deuterium abundances and on the microwave background.

The effect on these values of variation of the parameters α, M_1 and M_2 is illustrated in Table 3.

Only for high values of M_2 and low values of α, comparable with those required in cases (1) and (2), does β, and hence the distortion of the microwave background, become significant.

Discussion

Because of uncertainties in Fig. 1 we now discuss the effects on our results of varying some of the values adopted for the yield functions.

(1) We have redone the calculations for scenarios (1) and (2) ($\mu_B = 1.0$ and 5.0, $z_f = 200$) varying the limit M_a, where a star loses half its mass due to pulsations, between 300 and $500M_\odot$, and the limit M_b, where black hole formation occurs, between 300 and $1{,}000M_\odot$. Varying these limits was found to have no qualitative effect on our previous conclusions and a negligible effect on the quantitative results.

(2) Klapp[50] has performed numerical calculations of the evolution of very massive stars and obtained yields which differ from those we have adopted (Fig. 1). We therefore consider the effects of changing $Y(M)$ and $Z(M)$ in two different ways: (i) increasing $Z(M)$ from 0.2 to 0.45 in the mass range 300–$500M_\odot$ at the expense of $Y(M)$, so more helium is cycled through to metals than assumed previously (we still linearly interpolate $Y(M)$ and $Z(M)$ between the values adopted at 50 and $300M_\odot$), and (ii) increasing $Z(M)$ from 0.0 to 0.02 in the mass range 500–$10^5M_\odot$, so a small amount of the material processed into metals is able to diffuse up to the surface of the star and is shed before the collapse to a black hole occurs (see ref. 50).

(i) The effect of increasing $Z(M)$ at the expense of $Y(M)$ over a small section of the mass spectrum is, generally, that α has to be reduced fractionally for a given model to keep Ω_gZ in the required range. However, in our case (1) above (producing the distortion of the microwave background) it was found that our best model ($M_2 = 10^6M_\odot$, $H_0 = 50$, $\alpha = 1.0$ and $\mu_B = 5.0$) is still viable and gave $Y = 0.259$ at $\Omega_g = 0.041$, $\Omega_b = 0.098$, $Z = 4.99\times10^{-5}$ and $Y_P = 0.256$. For models producing all of the microwave background (case (2)) the only cases giving Ω_gZ in the required range and enough helium, without violating the constraints on Z are given in Table 2*b*.

(ii) In this case $Z(M)$ has been increased over a large range of the mass spectrum and it is therefore necessary to reduce α more substantially than in case (i) to recover viable models. Our best model now has $\Omega_gZ = 2.13\times10^{-5}$ and is therefore invalid. Reducing α from 1.0 to 0.5, with all other parameters held constant, brings Ω_gZ back into the required range and gives $Y = 0.256$ at $\Omega_g = 0.021$, $\Omega_b = 0.078$, $Z = 2.94\times10^{-4}$ and $Y_P = 0.254$. The effect of varying the parameters of this model are again as previously discussed, but it was found that M_2 must exceed $10^5M_\odot$ unless $\alpha < 0.25$. No models were found that produced all of the microwave background and enough helium without overproducing metals. These models are much more dependent on the helium to metal production ratio of Population III than those producing only the distortion of the microwave background, because for the latter most of the helium is provided by nucleosynthesis in the fireball phase of the Universe.

We conclude that small changes in our adopted yield functions (case (1)) only affect the details of our results, not the general conclusions. But if Klapp's conclusion that even very massive stars which collapse to black holes return some of their mass in the form of heavy elements is correct, then models trying to produce all of the microwave background and the initial helium from Population III are untenable.

There are several viable and interesting roles for Population III and the best hope of testing these ideas observationally is improved measurements of the spectrum of the microwave background near the peak.

Vitrification of pure liquid water by high pressure jet freezing

Erwin Mayer & Peter Brüggeller

Institut für Anorganische und Analytische Chemie, Universität Innsbruck, A 6020 Innsbruck, Austria

The vitrification of pure liquid water by projecting a thin jet of liquid water at high speed into a liquid cryomedium is reported. The influence of the experimental parameters on the cooling rate and the devitrification of the jet-frozen vitrified material have been investigated. A structural difference between vitrified liquid water and amorphous solid water prepared from the vapour phase is inferred from a comparison of the X-ray diffraction patterns.

FINDING a method for vitrifying pure liquid water is important for several reasons. The investigation of vitrified liquid water will help to elucidate the structure of liquid water because the effects of thermal and static disorder can be largely separated[1–4]. It might help in interpreting the anomalous properties of supercooled water[5–8]. Vitrification of biological systems without cryoprotectants is another application that could enable studies to be made of morphology without freezing artefacts and of the mechanism of freezing damage[9,10]. When applied to dilute aqueous solutions complete vitrification means the simultaneous matrix isolation of dissolved species. This extends the well known matrix isolation from the gas phase[11] to nonvolatile solutes such as ionic systems or biomolecules and allows, among others, spectroscopic investigations at low temperatures in the dissolved state. Attempts to form vitreous ice by rapid cooling of liquid water have invariably led to formation of ice I_h (ref. 12). (Pryde and Jones[13] did report a heat capacity change of rapidly cooled water at 126 K which they attributed to a glass transition, but could not reproduce this result in subsequent experiments.) We have recently described the complete vitrification of liquid water and dilute aqueous solutions by jet-freezing of aqueous droplets distributed in *n*-heptane as an emulsion, where the combination of emulsification and high cooling rate was essential for vitrification[14]. We have since increased the cooling rate by orders of magnitude and report here the vitrification of pure liquid water without emulsification by injecting a thin fluid jet of liquid water at high pressures *in vacuo* into a liquid cryomedium. This is an extension of the jet-freezing method developed by Bachmann and Schmitt for freeze etching[15]. Our technique differs from that of splat-cooling on a cold metal surface by using a liquid cryomedium, and gives for liquid water and dilute aqueous solutions much higher cooling rates[14]. [It has been reported that D. R. Uhlmann has vitrified liquid water by splat-quenching (ref. 16 in our ref. 6). However, to our knowledge no report has appeared since then.]

Conditions for vitrification

We have investigated the following parameters, considered to be important for a high cooling rate, with the ESR method described previously[14]: aperture diameter from 5 to 100 μm, working pressures between 10 and 400 atm, effect of the liquid cryomedium and of stirring. Small aperture diameter together with high working pressure were found to be most important for high cooling rates. With increasing working pressures the liquid jet is broken up by air resistance closer and closer to the exit hole of the aperture and dispersed into a fine mist. Therefore vacuum is essential for working at pressures above 100 atm. Liquid ethane, propane and butene-1 were investigated as cryomedia and gave for small apertures very similar cooling rates. Figure 1*a* shows the X-ray diffraction pattern of a jet-frozen sample of liquid water using the best conditions for vitrification emerging from hundreds of experiments: jetting through a 10-μm aperture with 400 atm working pressure (the

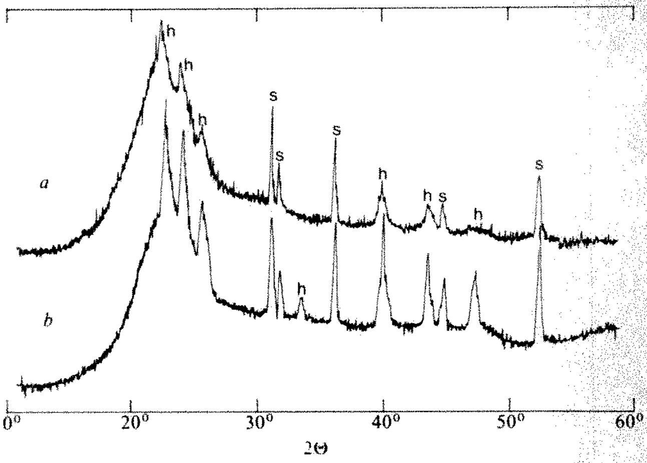

Fig. 1 X-ray diffraction patterns (CuKα, 90 K) of jet-frozen pure liquid water with: *a*, 400 atm; *b*, 100 atm working pressure (s, substrate reflexes; h, reflexes from crystalline ice). Samples were jet-frozen as follows: between 2 and 5 ml of pure liquid water were jetted through an aperture with a 10-μm opening (Balzers Union no. 16001), using working pressures of at most 400 atm, into 120 ml of vigorously stirred liquid propane cooled to 80 K. Liquid consumption at 100 atm: 0.4 ml min^{-1}, at 400 atm: 1.1 ml min^{-1}. The working pressures were generated with a hydraulic pump (type Maximator MSF 72), plugging of the 10-μm aperture was prevented by two filters (a Nupro 2-μm metal filter and a Millipore high pressure filter unit with a 0.2 μm filter). The experiment was started at normal pressure and vacuum applied as quickly as possible. Starting and stopping the jet already *in vacuo* gave identical X-ray diffraction patterns, but seemed to give apertures that clogged more easily. The suspension was filtered at liquid nitrogen temperature and the remaining mixture of frozen water and liquid cryomedium was transferred quickly with a liquid-nitrogen cooled spoon into the precooled apparatus. All operations at normal pressure were carried out under a cover of dry nitrogen gas. At liquid-nitrogen temperatures special care has to be taken to prevent accumulation of liquid oxygen in the cryomedium. The X-ray data were recorded on a Kristalloflex 4 (Siemens), using a vertical flat sample holder and samples between 0.5 and 1 mm thick.

0028-0836/82/330715-04$01.00

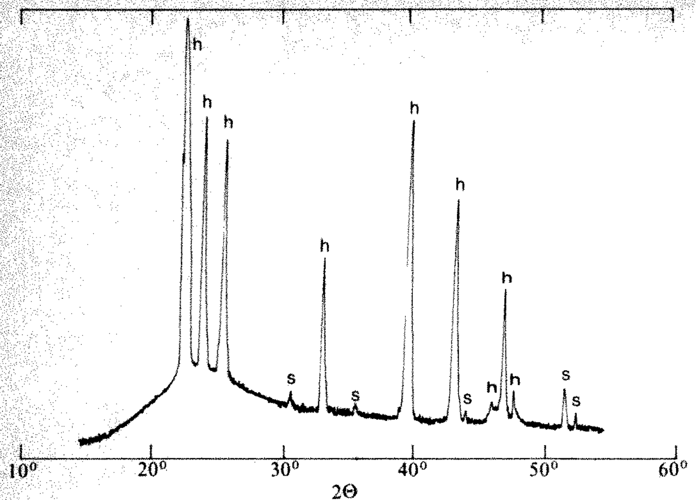

Fig. 2 X-ray diffraction pattern (CuKα, 90 K) of jet-frozen pure liquid water with 10 atm working pressure, showing the contribution of the liquid cryomedium at $2\theta = 23°$ (s, substrate reflexes; h, reflexes from ice I_h). The experimental conditions and the instrument gain were the same as conditions for Fig. 1 except for the working pressure and an aperture with a 20-μm opening. A 20-μm aperture was used because we could not start the jet through a 10-μm aperture with only 10 atm working pressure. However, from jet-freezing experiments with 50 atm we know that apertures with 10 and 20 μm openings give comparable cooling rates in this range of working pressures. With 10 atm working pressure the comparatively slow jet is not broken up by air over a long distance and thus the cooling rate is not increased by jetting *in vacuo*. The sharp reflexes are due to ice I_h, the intensity changes at small angles being caused by texture.

highest pressure used) into vigorously stirred propane at 80 K *in vacuo*. The X-ray diffraction pattern contains only a small amount of crystalline—mainly hexagonal—ice and is dominated by the broad feature characteristic of vitreous or microcrystalline substances. The effect of high working pressures is clearly seen by comparison with Fig. 1*b* where the pressure was reduced to 100 atm, using otherwise jet-freezing conditions identical with the experiment of Fig. 1*a*, and where the amount of hexagonal ice increases strongly. In several experiments we obtained nearly identical X-ray diffraction patterns with the same set of jet-freezing conditions which means that this method of vitrification is highly reproducible.

The vitrified liquid water inevitably contains some liquid cryomedium which cannot be removed without partial devitrification. The effect of the liquid cryomedium on the X-ray diffraction pattern of vitrified liquid water is demonstrated by Fig. 2, where the pattern of jet-frozen water using 10 atm working pressure only is shown with approximately the same intensity as in Fig. 1*a*, *b*: by differential thermal analysis (DTA) and by the ESR method reported previously[14] we confirmed that jet-freezing with 10 atm working pressure gives only crystalline ice. The X-ray diffraction pattern contains a broad peak centred at $2\theta = 23°$ in addition to the strong reflexes of ice I_h and is very similar to the pattern of a mixture of the liquid cryomedium with crystalline ice. The broad peak in Fig. 2 is therefore caused by the liquid cryomedium[16] and not by vitrified liquid water. The comparatively strong X-ray intensity of the liquid hydrocarbon might at first seem surprising. The small absorption coefficient for X rays of the solid water and the resulting transparency of the sample provide a simple explanation. In addition a matrix effect of the liquid cryomedium leading to strongly enhanced Compton scattering[17] and a particle size effect[18] might have a role. In any case the jet-freezing conditions for Fig. 2 are useful as a 'null-experiment', showing clearly in comparison with Fig. 1 the effect of high working pressures on the relative X-ray intensities of crystalline and amorphous material. We do not consider it useful to correct the X-ray diffraction pattern of vitrified liquid water for the effect of the cryomedium quantitatively because the amount of liquid and thus the size of the broad peak in Fig. 2 varied somewhat, and the possible additional effects considered above cannot be evaluated.

The vitrified material is definitely liquid water and not water vapour because: (1) the liquid enters the cryomedium as a continuous fluid jet of ~10 μm diameter. Typically between 2 and 5 ml of liquid water were jetted using a vacuum of 1 torr total pressure. The jetting time depends on the working pressure and the diameter of the aperture and was varied between 1 and 5 min. Therefore the amount of water vapour present during the experiment is negligible in comparison to the total amount of liquid water jetted. (2) We had tried to vitrify liquid water in the form of a very fine mist of small water droplets using working pressures of 1 to 2 atm only. The water droplets were generated by an ultrasonically vibrating 10-μm orifice similar to the aerosol generator of Berglund and Liu[19]. These experiments were carried out with a very small flow rate over considerable periods of time and therefore represent conditions where the amount of water entering the liquid cryomedium from the vapour phase becomes increasingly important. However, we have found no indication that material was vitrified using this arrangement. (3) The ESR spectra of jet-frozen 0.10 M aqueous $CuCl_2$ solutions depend strongly on the working pressures and were used as a good indicator for relative cooling rates[14]. We found that with a 200-atm working pressure the jet-frozen ESR spectrum is already nearly identical to the ESR spectrum of a perfectly vitrified 0.10 M $CuCl_2$ solution containing 50% glycerol for vitrification. While this does not prove that the jet-frozen solid has been vitrified completely, it still proves that the solute $CuCl_2$ has been matrix isolated and hence, that the liquid has experienced very high cooling rates.

Our jet-freezing conditions give a clear improvement, in terms of the amount of the vitrified material, over the previously reported vitrification of emulsified liquid water droplets[14] where we had obtained yields of ~13 and 16% for pure water and a 0.10 M $CuCl_2$ solution by DTA. These yields had been only barely noticeable in the X-ray diffraction pattern as a broadening underneath the sharp reflexes of the crystalline material between $2\theta = 20°$ and 28° (see Fig. 1*a* in ref. 14), whereas in Fig. 1*a* we have only a small amount of crystalline material on top of the broad feature. The determination of the relative amount of vitrified liquid water by DTA does not have any meaning for samples prepared as described in Fig. 1*a*, because the DTA method is not accurate enough, and the crystalline material comes mainly from condensation of water vapour during the preparation and transfer of the sample to the X-ray camera.

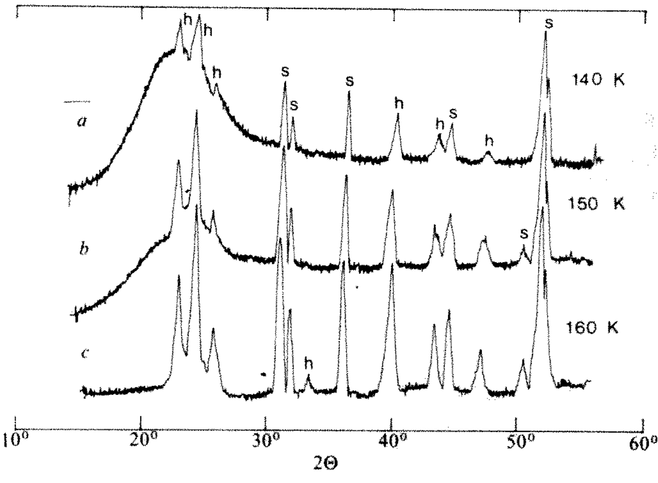

Fig. 3 X-ray diffraction patterns (CuKα) of jet-frozen pure liquid water warmed consecutively for 30 min to *a*, 140 K; *b*, 150 K; *c*, 160 K. The sampe was prepared as described in Fig. 1 with 400 atm working pressure except that liquid butene-1 was used as cryomedium at 100 K instead of propane. From 90 to 140 K the relative intensities of amorphous to crystalline reflexes were approximately constant, only the overall intensity decreased, probably due to movement of the viscous paste on the vertical sample holder with increasing temperature.

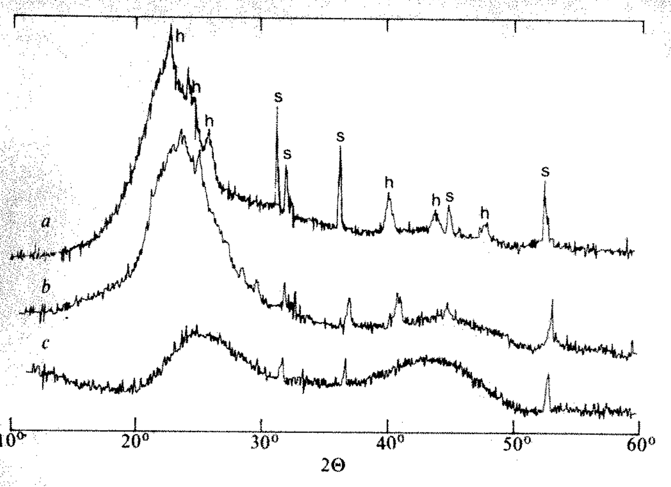

Fig. 4 X-ray diffraction patterns (CuKα, 90 K) of: *a*, jet-frozen pure liquid water prepared as described for Fig. 1*a* and thus containing some liquid propane; *b*, $(H_2O)_{as}$ mulled with liquid propane; *c*, $(H_2O)_{as}$ without propane. $(H_2O)_{as}$ was prepared as described in ref. 22 by vapour condensation at 77 K on a Cu-plate from a bath for the reservoir of water held at 210 K, using high vacuum conditions. For comparison with the pattern in Fig. 4*a* $(H_2O)_{as}$ was mixed thoroughly at 80 K with 20 ml of liquid propane, filtered and the remaining paste transferred to the precooled apparatus, using the same technique as for jet-frozen liquid water samples. As the pattern of $(H_2O)_{as}$ in Fig. 4*c* contains no reflexes of crystalline impurities, the amount of crystalline material in Fig. 4*b* represents the contamination of vitrified samples by crystalline ice due to condensation of water vapour during the experimental procedure.

We have investigated the devitrification and found that within the time scale of our X-ray measurements (30 min at every consecutive 10 K, starting at 90 K) the formation of ice I_c starts at 150 K (Fig. 3). This agrees very well with the devitrification of a vitrified 0.10 M $CuCl_2$ solution investigated previously within a similar time scale using ESR where a devitrification temperature of 153 K was deduced from signal broadening[14]. We found that the cryomedium used for vitrification affects the devitrification temperature. The sample giving the X-ray diffraction patterns in Fig. 3 had been prepared by jetting liquid water into butene-1 and therefore contained some butene-1. Vitrified liquid water containing some propane had started to devitrify already at 130 K. We think that this difference comes from the higher vapour pressure of liquid propane (1 torr at 144 K) and that devitrification is possibly induced by evaporating propane. At low temperatures the X-ray diffraction patterns of vitrified samples prepared with butene-1 or propane as cryomedia, using otherwise identical jet-freezing conditions, are very similar. The X-ray diffraction patterns of jet-frozen samples stored at 77 K for 3 months did not show any change.

Comparison with $(H_2O)_{as}$

In Fig. 4 the X-ray diffraction pattern of vitrified liquid water containing some liquid propane (Fig. 4*a*) is compared with the pattern of amorphous solid water prepared by condensation from the vapour phase (called $(H_2O)_{as}$ in accordance with Rice[1], Fig. 4*b*, *c*). Figure 4*c* shows the published X-ray diffraction pattern of $(H_2O)_{as}$ (refs 3, 20). Figure 4*b* the pattern of $(H_2O)_{as}$ mulled with liquid propane. A comparison has meaning only between the patterns of samples treated both with liquid cryomedium and has to be made between the patterns shown in Fig. 4*a*, *b*. A difference might possibly be found at high angles where the broad feature in the pattern of $(H_2O)_{as}$ centred around $2\theta = 44°$ appears to be less intense or absent in the pattern of vitrified liquid water. For further comparison we have tried to remove the cryomedium by washing the sample with liquid methane. However, this procedure leads to partial devitrification of the sample. In Fig. 5 the X-ray diffraction pattern of vitrified liquid water washed with liquid methane (Fig. 5*b*) is compared with the pattern of $(H_2O)_{as}$ treated identically (Fig. 5*a*), showing again for vitrified liquid water no clear amorphous peak at $2\theta = 44°$ underneath the sharp reflexes of crystalline ice in contrast to the pattern of $(H_2O)_{as}$. The X-ray diffraction pattern of the devitrified sample in Fig. 5*c* can be used as background of Fig. 5*b*. However, only a presentation of the X-ray data in the form of the structurally sensitive part of the scattered X-ray intensity will make a clear differentiation possible, and we cannot do this because we have not been able to compensate for the effect of the liquid cryomedium.

Discussion

The influence of high working pressures on the amount of vitrified material and thus on the cooling rate is certainly connected with the speed of the liquid jet. For 10, 100 and 400 atm working pressures approximate jet speeds of 20, 100 and 250 m s^{-1} can be calculated from the diameter of the 10-μm aperture and consumption of liquid. The effect of jet speed can be easily demonstrated by jetting at room temperature into paraffin oil with a viscosity similar to liquid propane at 80 K. With 10 atm working pressure the liquid jet hardly penetrates the surface, whereas with 100 atm working pressure penetration goes up to 20–30 mm. Therefore the liquid jet passes within a given time with increasing jet speed a larger volume of cryomedium, causing more efficient heat transfer from water to the cryomedium and giving higher cooling rates. In addition, vigorous stirring of the cryomedium enforces a circular movement onto the liquid jet, probably breaking up the jet into small droplets.

It is impossible to measure the cooling rates obtainable with high pressure jet-freezing. Fletcher[12] estimated the cooling rate necessary for vitrifying a micrometre-sized droplet of water to be $>10^{10}$ K s^{-1} from the theory of the homogeneous nucleation of freezing, whereas Uhlmann[21] calculated a cooling rate of $>10^7$ K s^{-1}. We do not know how the liquid jet breaks up in the cryomedium at high pressures, but we consider it likely that the jet breaks up into droplets of approximately the size of the jet diameter. Therefore a minimum cooling rate of 10^{10} K s^{-1} is obtained from Fletcher's value and of 10^7 K s^{-1} from Uhlmann's. As the minimum cooling rate depends strongly on droplet diameter and was calculated for 1-μm droplets[12,21] much higher cooling rates would result for larger droplet diameters. For a 10-μm droplet minimum cooling rates of 10^{13} and 10^{10} K s^{-1} follow from Fletcher's and Uhlmann's calculations. An idea about the distribution of cooling rates can be obtained from an inspection of the frozen products. We had

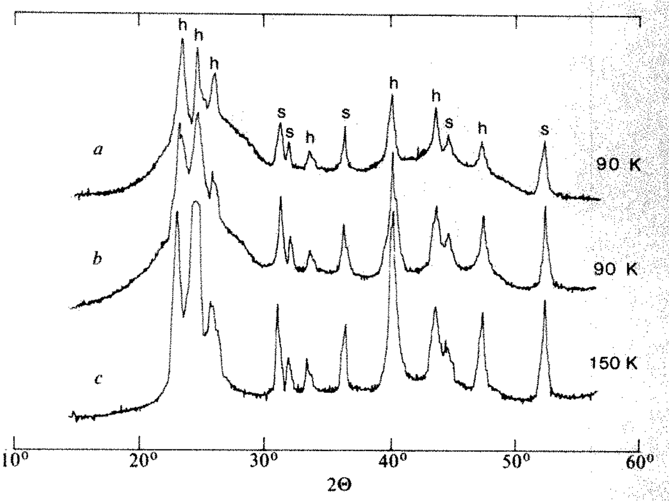

Fig. 5 X-ray diffraction patterns (CuKα) of: *a*, $(H_2O)_{as}$ from Fig. 4*b* washed with liquid methane; *b*, jet-frozen liquid water from Fig. 4*a* washed with liquid methane; *c*, the sample in *b* devitrified by warming up to 150 K. To remove liquid propane or butene-1 the samples were washed with liquid methane, filtered at ~90 K as described in Fig. 1 for propane, and the remaining methane pumped off at 77 K from the sample. This procedure leads inevitably to strong contamination and/or partial devitrification of the samples as shown by a comparison of Fig. 5*a* with Fig. 4*b* and *c*. The reflex at $2\theta = 24.3°$ in Fig. 5*c* was truncated.

expected that with increasing working pressure, increasing amounts of ice I_c and then of vitrified liquid water would be formed. This was frequently observed for the preparation of $(H_2O)_{as}$ from the vapour phase[20,22]. However, Fig. 1*b* shows that the crystalline fraction consists mainly of ice I_h in addition to the vitrified material. Thus the liquid jet apparently experiences either low cooling rates, giving ice I_h, or very high cooling rates leading to vitrified water. We believe that this is due to the vortex of the vigorously stirred cryomedium.

The thermodynamic conditions necessary for vitrifying liquid water have been discussed recently by Angell and Tucker[8]. The argument is based on the incompatibility of an extrapolated value of the glass transition temperature of vitrified liquid water with Kauzmann's entropy paradox[23] which states that a liquid can be supercooled only by a limited number of degrees before it loses all its excess entropy over the crystal, that is before its total entropy becomes equal to that of the crystal. This presents a problem, especially for liquid water, because in supercooled water a drastic increase of C_p occurs with decreasing temperature[5] among other anomalies. To resolve the entropy paradox Angell and co-workers postulated the existence of a λ-type heat capacity anomaly at 228 K associated either with some liquid state mechanical instability or with the cooperative formation of a long-range hydrogen-bonded network with decreasing temperature[6–8]. Angell and Tucker speculate that liquid water departs during cooling (assuming a rate of 10^8 K s^{-1}) from the metastable heat capacity already below the maximum observed value (which has been recorded at 235 K (refs 6, 24)) due to the 'freezing out' of the 'anomalous fluctuations' (see Fig. 5 in ref. 8). From the C_p versus temperature curve we wonder whether liquid water does not diverge at much higher temperatures—thereby avoiding the anomalous C_p increase altogether—and lose its internal equilibrium than that suggested by Angell and Tucker, considering the extreme cooling rates discussed above. In analogy to SiO_2 the vitrified solid is supposed to have different densities depending on the temperature at which internal equilibrium was established before quenching[25,26]. However, a determination of the density of vitrified liquid water is not possible at present due to the presence of the liquid cryomedium.

The similarity of structure between vitrified liquid water and $(H_2O)_{as}$ has been disputed recently. Rice[1,3,27] and Angell[8] believe that there is a continuity of state between liquid water and $(H_2O)_{as}$, that $(H_2O)_{as}$ is essentially liquid water, especially because the observed glass transition temperature of $(H_2O)_{as}$ is identical with the extrapolated value for vitrified liquid water. This hypothesis is the basis of the random network model of water recently proposed by Rice *et al.*[4,28]. In contrast Johari[29] argues on thermodynamic grounds mentioned above that a discontinuity of states exists, and that therefore "the structure of $(H_2O)_{as}$ is different from the one towards which supercooled water would tend". We have tried without success to observe a glass transition temperature in our vitrified water samples. A structural difference between vitrified liquid water and $(H_2O)_{as}$ could possibly emerge from a comparison of the X-ray diffraction patterns (see Figs 4 and 5). We do not know yet if the absence of the broad peak at $2\theta = 44°$ in vitrified liquid water is real or is only an artefact caused by the presence of the liquid cryomedium. According to Narten and Levy[30] a change of the double maximum in the structure functions of liquid water around 2.5 $Å^{-1}$ into a single peak corresponds to a disappearance of the maxima and minima between 3.5 and 8 Å in the correlation functions.

We thank Professor E. Schnell for help with the X-ray work.

Recognition by cro repressor protein of its specific DNA binding sites appears to occur via multidentate hydrogen bonds between amino acid side chains of the protein and base-pair atoms in the major groove of right-handed B-form DNA. Most of the sequence-specific interactions between cro and DNA, as well as a number of sequence-independent ones, are mediated by a two-α-helical unit which appears to be common to many proteins that regulate gene expression.

THE structures of three proteins that specifically bind to DNA have recently been determined, namely, the cro repressor protein (hereafter called 'cro') from bacteriophage λ[1], the catabolite gene activator protein (CAP) from *Escherichia coli*[2] and the amino-terminal fragment of the *c*I repressor protein (cI) from bacteriophage λ[3]. It has been proposed that these proteins bind to DNA with protruding α-helices penetrating[1,2] or partly penetrating[3] the major grooves of the DNA (in the case of CAP, the DNA has been postulated to be left-handed[2]).

In this article we propose a detailed model for the complex between cro and DNA. The model is consistent with the relative binding affinities of cro for the six operator sites within bacteriophage λ at which it binds specifically, and can also be used to rationalize known changes in binding affinity caused by mutations within these sites.

Cro is one of a number of proteins that participate in the

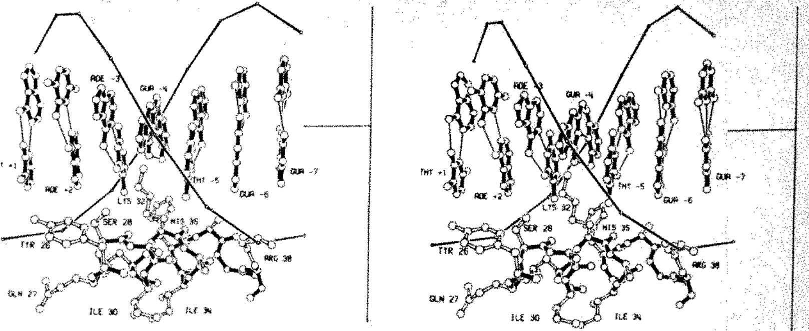

Fig. 1 Stereo drawing illustrating the initial alignment of residues 26–38 of cro repressor within the major groove of the DNA. Only the left half of the 17-base-pair binding site is shown. The vertical line at the right of the figure is the common protein and DNA twofold-symmetry axis which relates the other half of the binding site to that shown here. The horizontal line at the right coincides with the long axis of the DNA. The conformations of the individual protein side chains are those determined from the crystal structre of cro repressor protein. The base sequence is that for O_R3, with numbering as defined in the text. For clarity the details of the DNA backbone have been omitted and replaced by lines connecting the phosphates.

commitment to either the lytic or lysogenic pathway during the development of bacteriophage λ (for review see refs 4–6). Cro recognizes six binding sites on the bacteriophage genome, three within the left operator region (O_L1, O_L2 and O_L3) and three within the right operator region (O_R1, O_R2 and O_R3). Each binding site consists of 17 base pairs with approximate twofold symmetry. The base sequences of all six sites are similar but not identical[7].

Starting parameters

Coordinates for the DNA were derived from the fibre diffraction analysis of B-DNA by Arnott and colleagues (refs 8, 9 and S. Arnott, personal communication). Initially, the rise per base-pair, z, was set at 3.4 Å and the twist per base-pair, θ, was set at 34.6° (10.4 base-pairs per turn). These parameters are representative of values obtained by others[10–12].

The coordinates for cro were based on the previously reported structure determination[1]. The quality of the electron density map has been improved by a process of electron density averaging and phase extension[13] in which the final agreement between observed and electron-density-averaged structure factors was 22.3% at 2.8 Å resolution (R.G.F., D.H.O. and B.W.M., unpublished results). Also the cro structure has been partially refined, the coordinates used here being taken from the present stage of refinement, for which the crystallographic residual is 27% at 2.2 Å resolution (23% at 2.8 Å resolution) (D.H.O. and B.W.M., unpublished). The estimated error in the protein coordinates is about 0.4 Å.

The protein dimer was placed so that its twofold axis of symmetry coincided with that of the DNA[1], leaving two adjustable parameters, one the separation, d, between the protein and the DNA, and the other the rotation, τ, of the protein dimer relative to the DNA about the common protein-DNA symmetry axis. In addition to the above four parameters, z, θ, d and τ, adjustments were allowed in the radius of curvature, r, of the DNA. Because of the twofold symmetry of the protein–DNA complex, bending was constrained to occur only about points on the dyad axis.

Model building

Our general approach was to carry out model building on an MMS-X computer graphics facility[14] and to supplement this with energy minimization using the program EREF of Jack and Levitt[15]. Use of computer graphics permitted the screening of a large number of potential interactions between the protein and the DNA while energy minimization ensured that the stereochemistry of a proposed DNA–protein complex was reasonable.

The energy minimization procedure gives the calculated energy for the system under consideration, and, as such, provides an indication of the relative strength of a postulated cro:DNA complex. However, the energy minimization algorithm does not take account of solvent, and has other limitations which prevent its use for the reliable estimation of absolute interaction energies. Therefore, in attempting to optimize a given cro:DNA complex, we used energy minimization as a guide, but supplemented this with additional criteria such as the adherence of postulated hydrogen bonds to acceptable stereochemistry.

There has been considerable speculation that the free energy of stabilization of DNA:protein complexes comes primarily from relatively nonspecific interactions[16] while specificity derives largely from hydrogen bonds between protein side chains and the parts of the base pairs exposed in the grooves of the DNA[16–19]. Therefore, in model building we attempted to maximize the number of hydrogen bonds and other interactions between cro and the DNA, and assumed that each 'mispositioned' (that is, unsatisfied) hydrogen bond decreased the affinity of the DNA–protein complex, although it is understood that other factors such as shape complementary, hydrophobic and dipolar interactions and the role of solvent are also important. Since the binding constant, K, for the cro:DNA interaction is related to the free energy of the interaction, ΔG, by the formula $K = \exp(-\Delta G/RT)$, it follows that each improperly positioned hydrogen bond donor or acceptor, which reduces the free energy by about 1 kcal mol^{-1} (refs 16, 20), results in a reduction of the binding constant by a factor of approximately seven.

The presumed complexes between cro and DNA were initially subjected to energy minimization in which the protein backbone was kept rigid and only those side chains which appeared to interact with the DNA were allowed to move. A specialized version of EREF was used which allowed the explicit specification of hydrogen bonds. The five interaction parameters z, θ, d, τ and r (see above) were then systematically varied in small increments to determine which values gave the best value for the calculated energy of interaction. (This stepwise approach was necessary because EREF tends to make changes in local geometry, but not in the global interaction parameters.) In the final stages of the energy minimization, the local geometry of the DNA was allowed to vary, and, in addition, small adjustments were permitted in the protein backbone.

Interaction of cro with DNA

The initial structure determination of cro suggested that it bound to the DNA with a pair of dyad-related helices penetrating the major groove of the DNA[1]. This overall complementarity between the surface of the protein and the DNA not only suggests the approximate alignment of the protein relative to the DNA, but (short of making major conformational changes in the protein which we shall consider below), makes it sterically difficult to devise alternative interaction schemes which seem plausible.

Since both cro and the DNA binding site have approximate twofold symmetry it is, in the first instance, sufficient to consider the interaction between one monomer of cro and half of the binding site. We have numbered the base pairs within each half-site from 1 to 9 starting at the distal base pair. Bases +1 and −1 constitute a base pair, and so on. The '+' base is the one for which the inward direction of numbering is from 5′ to 3′.

The initial alignment of cro (Fig. 1) suggested that the amino acid side chains most likely to participate in interactions within the major groove of the DNA were Tyr 26, Gln 27, Ser 28, Asn 31, Lys 32, His 35 and Arg 38. Based on the framework of the potential hydrogen bonds and the cro:DNA geometry suggested by the energy calculations, it is possible to construct a set of rules which can be used to predict the hydrogen bonds

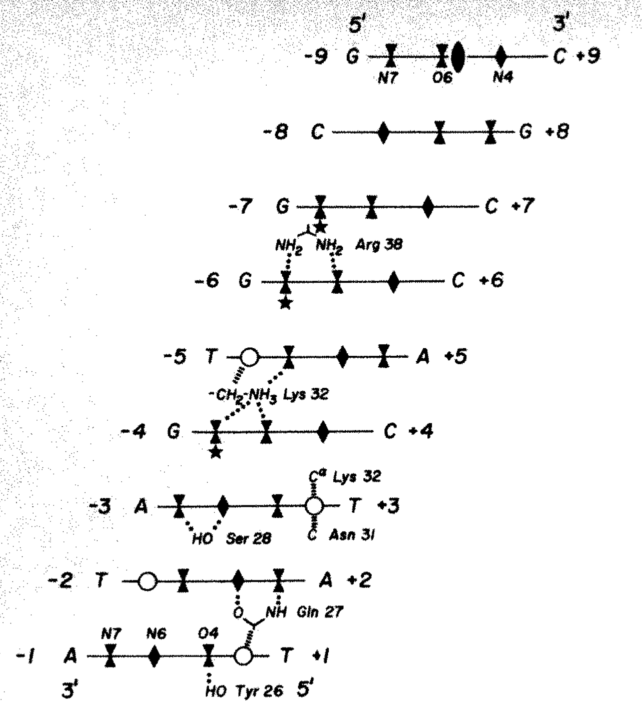

Fig. 2 Schematic representation, following Woodbury *et al.*[20], of the presumed sequence-specific interactions between cro and the parts of the base pairs exposed within the major groove of the DNA. The direction of view is imagined to be directly into the major groove of the DNA with the base-pairs seen edge-on. The dyad symbol within the topmost base pair indicates the center of the overall 17-base-pair binding region. The symbols are as follows: ⧗, hydrogen bond acceptor; ◆, hydrogen bond donor; ○, methyl group of thymine; ★, guanine N7 which is protected from methylation when cro is bound[22,23]. Presumed hydrogen bonds between cro side chains and the bases are indicated (. . . .). Apparent van der Waals contacts between cro and the thymine methyl groups are shown (||||||). Other van der Waals contacts are not shown.

expected when cro interacts with a given sequence of DNA. The proposed rules for hydrogen bonding are as follows:

(1) Arg 38 forms two hydrogen bonds to O6 and N7 of guanine −6. If base −6 is an adenine then Arg 38 makes a hydrogen bond with either the N7 of this adenine or the N7 of a purine at −7. If base −6 is a thymine then Arg 38 can make no hydrogen bonds to this base because of the blocking methyl group on C6 but can form one hydrogen bond to N7 of a purine at −7 (that is, a net loss of one hydrogen bond).

(2) Lys 32 N^{ζ} forms one hydrogen bond with either a purine N7 or an O4 of thymine at position −5. In addition, it forms a second hydrogen bond with O6 of guanine −4 and possibly a third hydrogen bond with N7 of guanine −4.

(3) Ser 28 O^{γ} forms two hydrogen bonds with N6 and N7 of adenine −3 or, alternatively, one hydrogen bond to N7 of guanine, N4 of cytosine, or O4 of thymine at −3. In the case of a thymine at position −3 there is a second hydrogen bond from the N6 of the adenine at +3 to the carbonyl oxygen of the serine.

(4) Gln 27 forms two hydrogen bonds to N6 and N7 of an adenine at +2. In all other cases it forms a single hydrogen bond.

(5) Tyr 26 O^{η} forms a hydrogen bond with either O4 of thymine +1 or N7 of a purine at +1, but cannot be placed in a stereochemically acceptable position to accept a hydrogen bond from N6 of adenine or N4 of cytosine.

As shown in Table 1, this model for the interaction between cro and DNA is consistent with the known relative affinities of cro for its six binding sites and for mutant sites as well.

The presumed sequence-specific hydrogen-bonding between cro and O_R3 is shown in Fig. 2 using a schematic representation based on that proposed by Woodbury *et al.*[20] and is shown in stereo in Fig. 3. The apparent interactions between the protein and the DNA backbone, which are not sequence-specific, and, presumbly, provide much of the overall energy of interaction, are summarized in Fig. 4. The overall conformation of cro repressor when bound to its specific binding site is illustrated in Fig. 5.

In the proposed cro:O_R3 complex, there are about 20 sequence-specific hydrogen bonds (Fig. 2) as well as many sequence-independent interactions (Fig. 4). These interactions could easily account for the observed dissociation constant of about 10^{-10} M (refs 21, 22).

Because cro is known to bind most tightly to O_R3 (refs 23–25) we used this for the initial model building and for most of the energy calculations. After refinement of the cro:O_R3 complex, the DNA had a mean z of 3.48 ± 0.09 Å with a range of 3.30 Å to 3.56 Å and a mean twist θ of $34.7 \pm 3.2°$ with a range of 26.9° to 39.8°. These values compare well with previously reported values for these parameters[10,26,27].

The optimization procedure suggests that the DNA is bent to a radius of about 75 Å. This degree of curvature is not excessive, as might at first be supposed. In the crystallized B-DNA dodecamer CGCGAATTCGCG, the DNA bends to a radius of 110 Å (ref. 28). Also, when associated with proteins in the nucleosome, DNA adopts a radius of about 45 Å (ref. 29). It can be estimated that the energy required to bend a 17 base-pair segment of DNA to a radius of 75 Å is between 0.85 and 1.7 kcal mol^{-1} (refs 30, 31), an amount of energy approximately equivalent to the formation of one hydrogen bond per monomer. As an alternative to the bending of the DNA, an essentially equivalent result could be obtained by a 'hinge-bending' motion of the two cro monomers in the vicinity of the antiparallel β-sheet strands, Glu 54–Lys 56. These residues form part of the C-terminal 'arms' (residues 52–60) which appear to be the major determinant in stabilizing the cro dimer. Other than the contacts mediated by these two arms there are only very tenuous interactions between the respective monomers, suggesting that a 'hinge-bending' motion could easily occur (Fig. 5; see also Figs 3, 4 and 6 of ref. 1).

Specific and nonspecific cro:DNA interactions

The proposed model for the complex between cro and DNA suggests that interactions occur predominantly within two regions of the protein, namely residues 15–38, that is, essentially the α_2 and α_3 helices, and residues 54–66 which include part of the third β-sheet strand and the carboxyl terminus of the molecule.

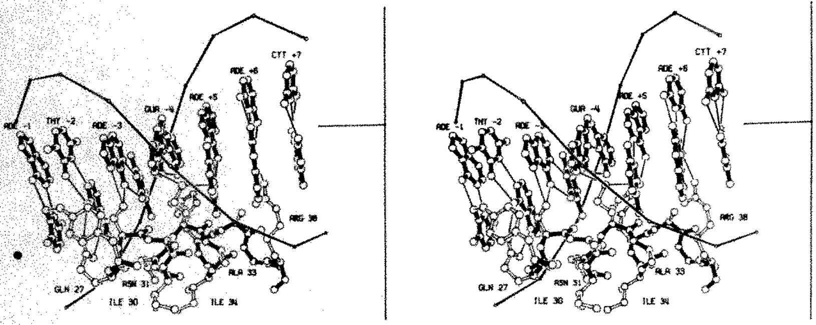

Fig. 3 Stereo drawing (Compare Fig. 1) showing the presumed hydrogen bonding of cro to base pairs in the major groove of O_R3, following model building and energy refinement.

DNA sequences and relative affinities are shown for the six 17-base pair sites to which cro binds specifically in phage λ. Mutations in these sites with known relative affinities for cro binding are also shown. (Data taken from refs 23, 24.) The relative binding affinities are to be compared with the change in the number of sequence-specific hydrogen bonds between cro and the DNA site as predicted from the model for cro binding proposed in the text. If the model is correct, and if hydrogen bonding is a major determinant in the specificity of cro: DNA recognition, then the loss of successive hydrogen bonds ought to correspond to successive reductions in the affinity of binding by about a factor of seven.

The α_3 helix (residues 27–36) penetrates the major groove of the DNA and appears to contribute most of the sequence-specific interactions (Figs 2, 3). Interactions of Lys 32 and Arg 38 with bases in positions −4, −5 and −6 account for the observed protection from methylation of guanine N7 at these positions[4,23,24]. In the presumed complex between cro and O_R3 (Figs 2, 3) there is no hydrogen bonding at the N7 of guanine −7. This is, perhaps, surprising in view of the observed protection of this nitrogen from methylation. However, the close proximity of the guanidinium group of Arg 38 to guanine −7 (Fig. 3) might sterically inhibit the access of dimethyl sulphate to this base.

The α_2 helix (residues 15–23) appears to make a number of sequence-independent interactions with the outermost part of the DNA binding site (Fig. 4). Altogether, residues in the α_2 and α_3 helices may contribute as many as five hydrogen bonds to the phosphate backbone. In the model, there are no sequence-specific interactions between cro and the central three

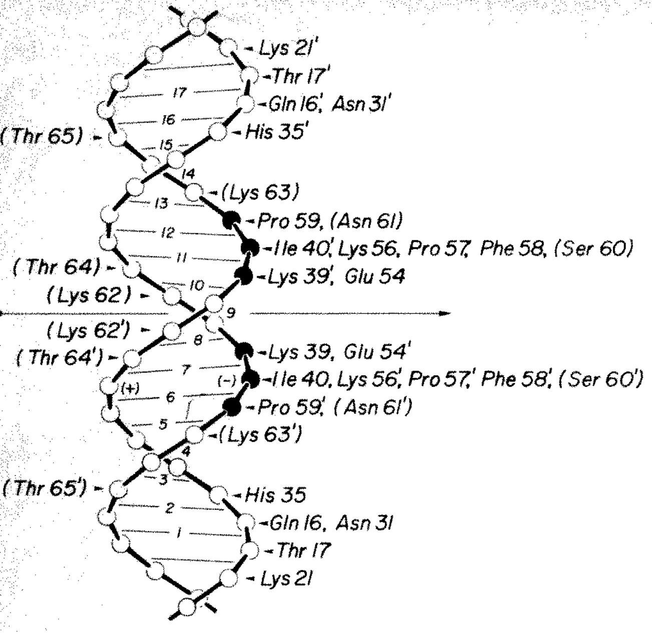

Fig. 4 Schematic representation of the contacts and interactions which are presumed to occur between cro and the phosphates in the DNA backbone. In the presumed cro: DNA complex, at least one close approach occurs between a given phosphate group and the named amino acids. Those phosphates for which ethylation interferes with cro binding[23] are drawn solid. Numbering of the base pairs and the signs (+) and (−) correspond to the identification used in the text. Amino acids belonging to 'lower' and 'upper' cro monomers related by the horizontal dyad axis are non-primed and primed, respectively. Amino acids in parentheses are those at the C-terminus of the molecule which are disordered in the crystal (residues 62–66) or for which the backbone conformation has been adjusted (residues 60, 61) to improve the contact with the DNA.

base pairs of the binding site, consistent with the observation that, for these three base-pairs, nitrogens N3 of the adenines exposed in the minor groove and N7 of the guanines exposed in the major groove are susceptible to methylation by dimethyl sulphate[4,23,24].

Residues Glu 54–Lys 56 of the third β-strand, together with the twofold-related strand in the adjacent cro monomer, are located close to the centre of the binding site and lie parallel to the minor groove, but, in part because of the bending of the DNA, do not lie within the minor groove (compare refs 1, 32). Rather, their contact with the DNA appears to be limited to interactions between the side chains and the phosphate backbone (Fig. 4). In the model for the presumed cro:DNA complex, the phosphate at position −6 (between base pairs 6 and 7 in Fig. 4) and possibly one or two solvent atoms or cations are surrounded by protein. The two neighbouring phosphates also appear to be partly 'covered' by protein (see Fig. 4), consistent with the observation that ethylation of these three phosphates interferes with the formation of the cro:DNA complex[4,23]. In the presumed cro:DNA complex, it appears that the seven C-terminal residues, including Lys 62 and Lys 63, could lie along the minor groove of the DNA with the side chains interacting with the phosphate backbone (Figs 4, 5). Since the five C-terminal residues are disordered in the crystals of the native protein[1] it has to be emphasized that the details of such interactions remain very speculative.

Inferences for protein–DNA recognition

The proposed complex between cro and DNA has a numnber of features which may be of general significance for recognition by proteins of specific sites on DNA.

The initial determination of the cro structure[1] revealed a pair of twofold-related α-helices arranged in such a way that they could be placed within successive major grooves of right-handed Watson–Crick B-form DNA. This result gave credence to previous suggestions that α-helices of proteins might bind within the major groove of B-DNA[33–36].

The present study strongly suggests that sequence-specific recognition of DNA is mediated by hydrogen bonds between protein side chains and the parts of the base pairs exposed within the grooves of the DNA as has been advocated by a number of authors[16,19,35–38]. In particular, it is of interest to note that the specificity of recognition appears to be enhanced by multiple interactions between a given side chain and appropriate hydrogen bond donors and acceptors on the base pairs. The apparent bidentate interaction of Gln 27 with nitrogens N6 and N7 of adenine +2 as well as the interaction of Arg 38 with O6 and N7 of guanine −6 (Figs 2, 3) are as anticipated[18,39]. Ser 28 and Lys 32 are also presumed to participate in multiple interactions. Such interactions had not been postulated previously, although von Hippel and colleagues[16,19] have suggested that bridging interactions could occur between atoms on successive base pairs, as seems to be the case with cro, in some instances. Also Drew and Dickerson[40] have observed a solvent molecule (molecule 66 in their numbering scheme) which forms hydrogen bonds with both the N6 and N7 nitrogens of an adenine, precisely as is proposed to occur between O^{γ} of Ser 28 and adenine −3.

In addition to the above hydrogen bonding within the major groove of the DNA, there are a number of apparent van der Waals contacts which are presumably also important in sequence-specific recognition. In particular, the C7 methyl groups of thymines +1, +3 and −5 appear to interact, respectively, with C^{δ} of Gln 27, with the carbonyl carbon of Asn 31 and the α-carbon of Lys 32 and with C^{γ} and C^{ϵ} of Lys 32 (Fig. 2). The importance of such hydrophobic interactions in the recognition of *lac* operator by lac repressor has been shown by Caruthers[41].

Another feature of the model which may be of general relevance is the combination of sequence-specific interactions, mediated by the more rigid parts of the protein structure, together with non-specific interactions that are assumed to derive, in part, from flexibility in the cro structure. Two distinct types of flexible motion seem likely. First, the C-terminal residues (62–66) are not ordered in the crystals of the native protein, and are presumably free to move in solution. Because of this freedom of motion, and also because the C-terminal residues do not seem to be involved in sequence-specific interactions, we suggest that these residues are involved in the initial binding of the protein to the DNA. The second type of flexible

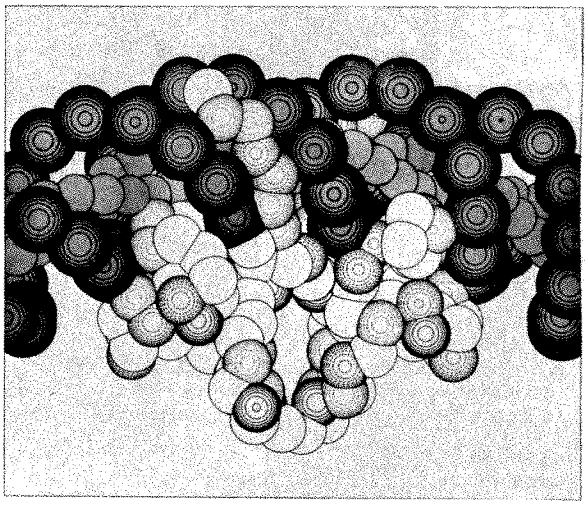

Fig. 5 Schematic drawing of the proposed sequence-specific complex of cro with DNA. For the stylized DNA (shaded) the large concentric circles indicate the positions of the phosphate groups and the smaller circles follow the bottom of the major and minor grooves. For the cro dimer, one circle is drawn for each amino acid; continuous concentric circles indicate acidic residues, broken circles indicate basic residues, dotted circles indicate non-charged hydrophilic residues and open circles show hydrophobic residues.

motion suggested by the cro structure is the 'hinge bending' motion described above. We suggest that such flexibility may be of general importance in facilitating 'sliding' along the DNA as has been proposed to occur for lac repressor[42–47]. Inspection of the structures of CAP[2] and *c*I repressor[3] indicates that 'hinge' motion seems possible for these structures as well, suggesting that this type of flexibility may be of general significance. One could imagine that a hinge motion of the protein, as well as flexibility in the DNA, would give each of the cro monomers some freedom to 'sample' adjacent base pair atoms in the major groove of the DNA. Only at the correct twofold-symmetric binding site would the full DNA-binding specificity be satisfied for both cro subunits simultaneously. Because a dimer rather than a monomer of cro binds to DNA, the overall recognition site extends over 17 base pairs (~60 Å). However, the cro:DNA complex is presumably optimized for control rather than tightness of binding so that not all of the 17 base pairs need contact the protein and, in addition, departures from exact twofold symmetry of the base sequence could be used to 'fine tune' the strength of the cro:DNA complex.

Finally, we note that in the proposed cro:DNA complex, most of the sequence-specific interactions, as well as a number of the sequence-independent ones, come from the α_2–α_3 helical unit. It has been striking to find, on the basis of recent sequence and structure comparisons, that a similar two-helical fold appears to occur in a number of other DNA-binding proteins[48–54] indicating that the principles of specific protein–DNA recognition suggested by the proposed model may be of general significance.

We thank Alan Bender for help with model-building and Dr. P. H. von Hippel for discussions. This work was supported in part by an NIH postdoctoral fellowship to D.H.O. (GM08403), a Damon Runyon-Walter Winchell Cancer Fund postdoctoral fellowship to R.G.F. (DRG-388-FT), by the MRC of Canada through the Group on Protein Structure and Function (to W.F.A.), by NIH grants to B.W.M. (GM20066) and Y.T. (GM28138) and by grants to B.W.M. from the NSF (PCM-8014311) and the M. J. Murdock Charitable Trust.

Complete nucleotide sequence and identification of membrane components of the histidine transport operon of *S. typhimurium*

C. F. Higgins*, P. D. Haag, K. Nikaido, F. Ardeshir*, G. Garcia & G. Ferro-Luzzi Ames

Department of Biochemistry, University of California, Berkeley, California 94720, USA

The nucleotide sequence of the entire histidine transport operon from Salmonella typhimurium *has been determined and is shown to consist of four genes,* hisJ, hisQ, hisM *and* hisP. *This operon provides the only example of a binding protein-dependent transport system for which the total number of protein components is known. Determination of the amino acid compositions and sequences of these four transport proteins, together with analysis of various transport mutants, allows us to propose a molecular model for binding protein-dependent transport.*

AT least five separate transport systems are involved in the uptake of histidine by *Salmonella typhimurium*[1]. One of these, the high-affinity histidine permease, has been extensively characterized and is among the best understood of all bacterial transport systems. This permease belongs to a broad group of 'shock-sensitive' transport systems that require for function specific substrate-binding proteins that are located in the periplasmic space and released by osmotic shock[2]. Such periplasmic binding proteins are also involved in chemotaxis. Shock-sensi-

0028–0836/82/330723—05$01.00

tive transport systems usually involve multiple components, in contrast to shock-resistant systems which require only a single, membrane-bound component (such as the lactose permease[3]). Previous studies of the high-affinity histidine permease have identified three essential genes, *hisJ*, *hisQ* and *hisP*, which together with a regulatory locus, *dhuA*, form a single operon located at 48.5 minutes on the *S. typhimurium* chromosomal map[4] (Fig. 1). The *hisJ* gene encodes the periplasmic histidine-binding protein, J, which has been purified and characterized[5]. The *hisP* gene encodes a basic protein, P, which is located in the inner cytoplasmic membrane[6]. The previously defined *hisQ* gene is here shown to consist of two separate cistrons, *hisQ* and *hisM*. Thus, four protein components are required for high-affinity histidine transport.

The periplasmic protein J and the membrane-bound protein P interact with each other during histidine transport[7]. Complementation studies suggest that Q, M and P also interact with each other[6], possibly existing as a multicomponent complex located in the cytoplasmic membrane. The Q, M and P proteins, but not the J protein, are also essential for an arginine transport system that requires an alternative periplasmic component, the lysine–arginine–ornithine-binding protein, LAO[8,9]. The amino acid sequences of LAO and J are 70% homologous and the two proteins are believed to interact with the same site on the membrane-bound P protein during arginine or histidine transport, respectively[10]. Thus, the P protein provides a common membrane-bound receptor for two independent binding proteins. LAO is encoded by the *argT* gene which is located immediately upstream (Fig. 1) and is transcribed independently of the histidine transport operon[11].

Nucleotide sequence

The entire histidine transport operon has been cloned as a 12.4-kilobase (kb) *Eco*RI fragment in the phage vector λgt4 (ref. 12). The precise locations of the transport genes on this fragment were determined by correlating accurately a restriction map with the genetic map of the histidine transport operon[13]. The various genes of the operon were sequenced by subcloning appropriate restriction fragments into the plasmid vectors pBR322 and pBR322-SVa[13]. Figure 1 shows schematically the histidine transport operon and the restriction fragments used in our study, while the complete nucleotide sequence of the histidine transport operon, a total of 3,700 base pairs (bp), is presented in Fig. 2.

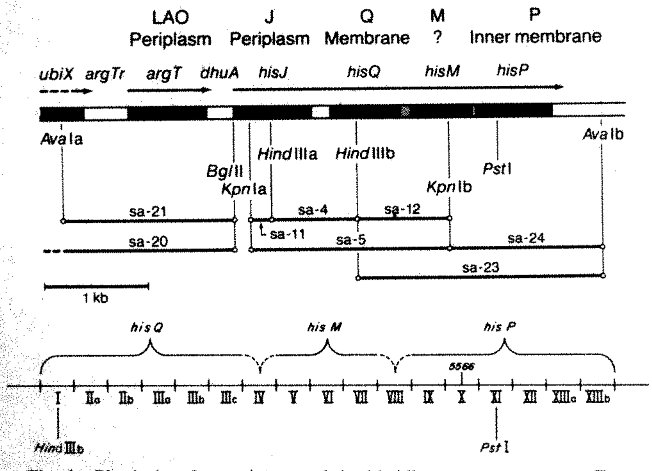

Fig. 1 Physical and genetic map of the histidine transport operon. Top: the structural genes (solid bars) and the intercistronic and regulatory regions (open bars) are all drawn to scale and include the *argTr*/*argT* operon. The dashed bar indicates uncertainty about the initiation site for *hisM* (see text). Arrows above the genes indicate length and direction of transcripts, as deduced from the sequences. The transcription terminator sequence for the histidine transport operon is located 0.11 kb 3′ to the end of *hisP*. The horizontal lines below the chromosome indicate specific restriction fragments subcloned for sequencing purposes. All are derived from the original clone of the entire region sa-1 (a 12.4-kb *Eco*RI fragment[13]). Bottom: genetic regions within the *hisQ*, *hisM* and *hisP* genes. These regions (in roman numerals) were defined by deletion mapping and biochemical analysis of mutants (refs 4, 6 and unpublished data).

Identification of the coding sequences

hisJ. The reading frame between bases 1 and 780 has previously been shown[10] to be the coding sequence for *hisJ*. The amino acid sequence deduced from this nucleotide sequence corresponds with the known amino acid sequence of the J protein[14]. Salient features of the amino acid sequence of J and its relation to the LAO protein have been discussed elsewhere[10].

hisP. All *hisP* mutations are located within eight genetic regions (IX–XIIIb; see Fig. 1)[4,6] (unpublished results). The structural gene encoding the P protein (as opposed to a possible regulatory region) must begin in or before region X because two-dimensional gel electrophoresis[6] shows that one mutant mapping in this region (*hisP5566*, Fig. 1) results in a P protein with an altered mobility. As the *Pst*I site is located in region XI[13], the coding sequence for the P protein must include this site. The only open reading frame of any length spanning the *Pst*I site is from position 2,367 to 3,140. This reading frame encodes a basic protein with a calculated molecular weight (M_r) of 28,738. The P protein has been confirmed experimentally to be basic and of ~24,000 M_r on SDS gels[6]: a discrepancy between the calculated molecular weight and the molecular weight determined on SDS gel is not unusual (see, for example, ref. 15). We confirmed that this reading frame encodes the P protein by purifying P protein, double-labelled with ^{35}S-methionine and ^{3}H-leucine, from several two-dimensional gels and analysing the first 12 amino acids on a sequenator. ^{3}H-leucine appeared in steps 5 and 10 (data not presented), and a very small amount of ^{35}S-methionine appeared in steps 1 and 2. These results are consistent with the predicted P sequence at the NH_2-terminus if we assume that most of the molecules have both N-terminal methionines removed post-translationally, but a few have only one or none of them removed.

hisQ. The region between *hisJ* and *hisP* has previously been defined genetically as *hisQ* and divided into regions (I–VIII)[6]. The sequence (1,586 bp) between the termination codon of the J protein (position 781) and the initiation codon of the P protein (position 2,367) could potentially encode a single polypeptide of M_r 53,000. However, examination of the nucleotide sequence does not reveal a reading frame covering this entire region. We have identified a protein, which we call Q, by non-equilibrium two-dimensional gel electrophoresis[16] either of whole cells or UV-irradiated cells[17] following infection with λ phages carrying the cloned transport operon[12] (data not shown). It is a basic protein, of apparent M_r 21,000, located in the membrane, and present in extremely small amounts (10–100 times less than J; we have been unable to determine its NH_2-terminal amino acids). The Q protein is absent from mutants in regions I–IV, but present in mutants in regions V–VIII. Thus, the *hisQ* gene proper does not extend beyond region IV. Region I of *hisQ* contains the *Hind*III site b (Fig. 1)[13]: therefore, the *hisQ* coding sequence must start 5′ to this restriction site. Of all the potential initiation codons (ATG, GTG and TTG[18]) between the end of *hisJ* and *Hind*III site b, only one, at position 966, could initiate a peptide of more than a few amino acids. This initiation codon is preceded by a strong ribosome-binding site and would initiate a basic protein of 24,573 M_r. Both the molecular weight and basicity of this protein are consistent with those of the Q protein. Therefore, we conclude that base pairs 966–1,649 are indeed the coding sequence for the Q protein and we re-define the *hisQ* gene as comprising this coding sequence only. Regions V–VIII (and part of IV) must code for one or more additional structural genes, or may comprise an extensive intercistronic region.

hisM. Between the termination codon for *hisQ* (position 1,650) and the beginning of *hisP* (position 2,367) is a sequence of position 717 which must correspond to regions V–VIII of the previously defined *hisQ* gene[6]. Mutants mapping in these regions are indistinguishable phenotypically from *hisP* and *hisQ*

Fig. 2 Nucleotide sequence of the histidine transport operon and amino acid sequence of the gene products. The sequence presented (nonsense strand) begins immediately after the termination codon of the *argT* gene (see Fig. 1) and is numbered with base 1 being the first base of the *hisJ* gene; bases 5′ to this initiation codon are numbered negatively. The amino acid sequences have been determined (J protein[14]) or predicted (all others); the P protein amino terminus has been confirmed by sequencing (see text). The promoter region in *dhuA* is marked by two solid bars above the −10 and −35 regions, joined by a line. The vertical arrow at position 66 indicates the site of processing of the J protein precursor. Horizontal arrows at bases 3,254–3,266 indicate the region of dyad symmetry which is the presumed transription terminator signal for the transport operon. The horizontal arrows at −200 to −177 indicate a presumed transcription terminator signal for the *argT* gene which is immediately upstream from *dhuA*. Horizontal arrows at bases 831–902 indicate a region of dyad symmetry which is believed to serve a regulatory function[20]. The *hisM* gene is assumed to start with the GTG at position 1,649, although initiation may be at the in-phase ATG at position 1,754 (see text). The entire nucleotide sequence was obtained by the method of Maxam and Gilbert[44], both strands being sequenced at least once in their entirety. All restriction sites were sequenced over. The sequences of *dhuA* and *hisJ* have been published previously[10,11], but are presented here for completeness.

mutants and produce normal levels of unaltered P protein, indicating that this region is not regulatory and encodes at least one additional polypeptide. The nucleotide sequence of this region contains only one open reading frame of any length, beginning with either the GTG at position 1,649 or the ATG at 1,754. Each of these initiation codons is preceded by a ribosome-binding site. We call this sequence, between the GTG at 1,649 and the TAA translation termination codon at 2,353, *hisM*. This sequence encodes a basic protein of M_r 26,404, which we refer to as the M protein. This protein has not been identified, probably because of its hydrophobicity, strongly basic character and probable low level.

Noncoding regions

The region 240 bp 5' to the *hisJ* structural gene comprises the regulatory region for the histidine transport operon, *dhuA*. This region has previously been defined as the noncoding region between the termination codon of *argT* (position -240), the structural gene immediately upstream from the histidine transport operon, and the initiation codon (+1) of *hisJ*[10]. The promoter for the histidine transport operon occurs within the region -55 to -84 as indicated in Fig. 2. Features of the nucleotide sequence of *dhuA* important in regulating expression of the histidine transport operon have been discussed elsewhere[11].

Between *hisJ* and *hisQ* there is an intergenic region of 183 bp which contains an exceptionally long inverted repeat that, when transcribed, could form a very stable stem-loop structure ($\Delta G = -54$ kcal mol^{-1})[19]. As *hisJ* is expressed at a level at least 10 times that of *hisQ*, *hisM* and *hisP*, it seems probable that this intergenic element has a regulatory role in reducing the expression of the distal genes of the operon. The function of this element is discussed in the accompanying article[20].

There is no untranslated intergenic region between *hisQ* and *hisM* if the M protein starts with the GTG codon at position 1,649, as the first codon of *hisM* overlaps the termination codon of *hisQ*. However, if the initiation codon is the ATG at 1,754, the *hisQ–hisM* intergenic region consists of 101 bp: no inverted repeats or other features of potential regulatory interest have been found in this region. The third intergenic region, *hisM–hisP*, is only a few base pairs long. Such short intergenic regions, as seen for *hisQ–hisM* and *hisM–hisP*, are typical of multicistronic operons where the flanking genes are expressed to approximately the same extent[21,22].

Preceding each of the four genes of the histidine transport operon are presumed ribosome-binding sites, sequences homologous to the 3' end of 16S rRNA[23].

We have shown that the 5.4-kb *Ava*I fragment (Fig. 1) contains all the genes required for normal high-affinity histidine transport (data not presented). Every transport mutation we have isolated maps within this fragment[13]. Thus, if any histidine transport genes are located downstream from the *hisP* gene, they cannot be any larger than ~400 bp, this value being determined by *Ava*I site b (Fig. 1). However, no open reading frame of any length is found between the end of *hisP* and *Ava*I site b. A typical transcription termination signal (a G+C-rich dyad symmetry followed by several Ts; ref. 24) is found following *hisP* at positions 3,254–3,270. Thus, it is clear that we have identified all the genes required for high-affinity histidine transport.

Amino acid compositions of the histidine transport proteins

Figure 2 gives the predicted amino acid sequences of the four histidine transport proteins. The sequence of the J protein matches the determined amino acid sequence[10,14].

Of the four genes of the operon, only that for *hisJ*, the periplasmic histidine-binding protein, encodes a typical signal peptide (see examples in ref. 25), consisting of 22 mostly hydrophobic residues with two lysines located close to the NH_2-terminus. We have shown that the J protein is synthesized as a precursor, which is processed by removal of the signal peptide, presumably during secretion into the periplasm (G.F.-L.A. and K.N., unpublished data). All other known periplasmic and outer-membrane proteins (including the *tra* proteins; E. G. Minkley, personal communication) are synthesized as precursors with a signal peptide.

The other three proteins of the operon do not have a typical NH_2-terminal signal peptide and indeed, for P we have shown that the NH_2-terminal sequence of the mature protein is the same as that predicted by the nucleotide sequence. We have previously shown P to be located in the inner (cytoplasmic) membrane; as it interacts with the J protein[7], it is presumably exposed on the outside of the membrane. The Q protein is also located in either the inner or outer membrane (see above). It seems likely that the M protein also is located in the inner membrane because it is hydrophobic and the complementation pattern for mutants in these genes[6] implies that all three proteins, P, Q and M, interact with each other. Thus, although an NH_2-terminal signal peptide seems to be essential for a protein to pass through the inner membrane, it is not required for insertion of proteins into the membrane. This is consistent with results obtained for several other inner membrane proteins whose genes have been sequenced and which also lack a typical NH_2-terminal signal peptide[18,26]. However, there do seem to be certain exceptions to this general difference between inner membrane and outer membrane/periplasmic proteins. For example, the integral membrane protein bacteriohodopsin from *Halobacterium halobium* is apparently synthesized as a precursor which is processed, although its structural gene does not code for a typical signal peptide[27,28]; penicillin-binding proteins from *Escherichia coli* are also synthesized as precursors, though in this case it is not known whether their genes encode a typical signal peptide or whether processing occurs at the amino terminus[29]. The lactose permease gene codes for what might possibly be a signal peptide, although no processing occurs[3,30]. It is possible that in cases such as *hisM*, *hisQ* and *hisP* where no processing occurs, an internal hydrophobic region functions as a signal sequence, such as is found for the eukaryotic ovalbumin gene[31].

Consideration of the amino acid composition of the four transport proteins shows that the Q, M and P proteins are basic, in contrast to the J protein and the bulk (~90%) of the bacterial cell proteins, which have pI values of about 7 or less (as estimated by two-dimensional gel electrophoresis of total cell protein[32]). Two other inner membrane proteins, the lactose permease[3] and NADH dehydrogenase[18], are also basic, their basic character possibly being related to their need to interact with the negatively charged phospholipids of the membrane. Calculation of the hydrophobicity index[33] shows that proteins

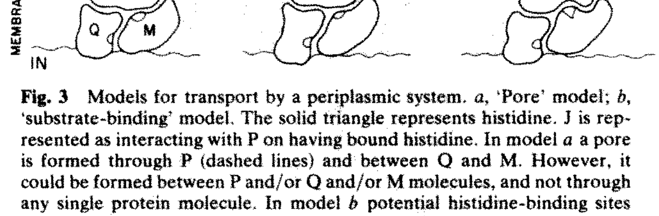

Fig. 3 Models for transport by a periplasmic system. *a*, 'Pore' model; *b*, 'substrate-binding' model. The solid triangle represents histidine. J is represented as interacting with P on having bound histidine. In model *a* a pore is formed through P (dashed lines) and between Q and M. However, it could be formed between P and/or Q and/or M molecules, and not through any single protein molecule. In model *b* potential histidine-binding sites on the membrane components are represented by hemispherical identations which are sequentially 'activated' to functional sites (indicated by triangles). Only the initial transfer of histidine from J to P, with the concomitant conformational changes, is illustrated. The transfer of histidine from P to M and from M to Q can be imagined to occur by a similar series of events. See text for discussion of these models.

Q and M have several uncharged stretches of 10 or more amino acids (residues 62–80, 92–109 and 190–215 in Q; 20–47, 57–66, 68–85, 192–221 in M) which are more hydrophobic than water-soluble proteins[33]. However, the P protein has no significantly hydrophobic stretches and in this respect is comparable with the water-soluble hydrophilic J protein. The percentage of charged amino acids in each of these proteins parallels the hydrophobicity calculations. The unusually low hydrophobicity of the membrane-bound P protein presumably reflects the fact that this protein interacts with the J protein[7] and may therefore protrude extensively into the periplasm. Notably, histidine is found in all four transport proteins and is particularly abundant in the P protein (11 histidines). The predicted sequences of two histidine biosynthetic proteins, HisG and HisD, show that they also contain histidine (W. Barnes, personal communication). Thus, despite the fact that all these proteins serve to supply histidine to the cell, they also require histidine for their own synthesis. An analysis of codon usage in the four histidine transport genes shows clearly that codon usage is non-random, condons recognized by the major iso-accepting species of tRNA being most frequently used.

Mechanisms of transport

We have shown that the high-affinity histidine transport system requires the function of four separate proteins. One of these, the histidine-binding protein, J, is located in the periplasmic space. Of the other proteins, at least two (Q and P), and probably all three, are associated with the membrane. This provides the only example of a shock-sensitive, binding protein-dependent transport system for which the total number of essential components is known. However, all other binding protein-dependent systems which have been studied in detail also seem to require other components in addition to a binding protein[34–41]. This multiplicity of components is in marked contrast to the lower-affinity, shock-resistant, binding protein-independent systems, such as the lactose permease (*lacY*), where only a single, membrane-bound component seems to be required.

The present determination of the number and location of the proteins required for transport, together with studies of transport mutants described previously and below, now allow us to begin to understand the molecular events involved in transport by a binding protein-dependent system (Fig. 3). The periplasmic protein J binds histidine[5], inducing a conformational change (such a change has been shown to occur; ref. 42 and S. Zukin, personal communication), which then allows the J–histidine complex to interact with the membrane-bound protein P[7]. Proteins P, Q and M form a cytoplasmic membrane-bound complex[6], with P exposed at the periplasmic face of the membrane. The membrane-bound complex of P, Q and M could promote the passage of histidine through the membrane either by forming a simple diffusion pore through the membrane, or they might possess specific binding sites for the transported substrate. These two possibilities are shown schematically in Fig. 3*a* and *b*, respectively. As P, Q and M do not mediate transport to any significant extent in the absence of J, the interaction of the J–histidine complex with P must induce a conformational change in the membrane complex. In Fig. 3*a* the 'pore' model (modified from ref. 43) indicates that the J–histidine complex, on interaction with P, induces a conformational change allowing P, Q and M to form an open pore through which histidine can diffuse into the cell interior. In Fig. 3*b*, the 'binding site' model indicates that one or more of the three membrane-bound proteins has a histidine-binding site[6,7]. These sites are 'activated' in a cascade-like manner, with histidine passing from one protein to the next, thus being carried across the membrane. It is also possible to envisage models which combine features from each of the two models described. In both models an energy-coupling step is presumably involved, although the mechanism by which this is achieved remains unknown.

The existence of certain classes of histidine transport mutant could help us distinguish between the two models. The wild-type histidine permease transports L-histidine efficiently; it also transports D-histidine and the histidine analogue HIPA with lower affinity. The isolation of mutants in *hisQ*, *hisM* or *hisP*, which differentially transport these substrates, suggests that the corresponding proteins have a substrate-binding site rather than being strictly part of a diffusion pore. We have found two types of such mutants: (1) *hisQ6699* transports L-histidine normally (K_m within 10% of normal) but does not transport D-histidine or HIPA at all within the limits of our measurements; (2) some *hisM* mutants (the 'odd group'[4]) result in the loss of transport of L- and D-histidine, and of HIPA, but also in an improved ability to transport L-histidinol. Both types of mutant can best be explained by an alteration in a substrate-binding site in a membrane-bound protein. This evidence supports the 'substrate-binding' model: isolation and characterization of additional mutants is required for confirmation. It has also been suggested that a membrane-bound component of the maltose permease may have a substrate-binding site (H. Shuman, personal communication).

The membrane-bound components of the histidine transport system are only present in very small amounts in the cell, and hence are extremely difficult to purify. The cloning and characterization of the genes encoding transport proteins thus provide the most powerful technique available for studying such systems. Given the many similarities between the histidine and other binding protein-dependent permeases, it seems likely that the model presented here can be generalized to most, if not all, such transport systems.

This work was supported by NIH grant AM12121 to G.F.-L.A., C.F.H. was supported by a NATO/SRC fellowship. P.D.H. was partially supported by a NSF predoctoral fellowship. We thank Dr R. Tjian and members of his laboratory for advice and for supplying us with ^{32}P-ATP, D. Cole and J. Sample for help with the sequenator experiment and W. Barnes for showing us DNA sequences of the histidine biosynthetic operon before their publication.

Character of 'prolate' galaxies

Douglas O. Richstone & Michael D. Potter

Department of Astronomy, University of Michigan, Ann Arbor, Michigan 48109, USA

It is still not known whether elliptical galaxies are oblate, prolate or triaxial. The prototype 'prolate' galaxy NGC2685 has a rapid observed stellar rotation rate around the projected minor axis. We show here that a steady figure, exactly prolate model can have no such rotation, and that a nearly prolate model fails by a factor of 7. We suggest that the galaxy is oblate and that the gas disk is the wreck of a dwarf companion.

There has recently been much interest over the determination of the three-dimensional figure of elliptical galaxies. This interest can be classified into four areas—statistical studies of surface brightness[1-3], theoretical models[4,5], detailed surface photometry[6-8] and the study of the distribution of embedded gas[9]. The last approach is distinguished by its potential ability to make statements about individual galaxies.

In the absence of figure rotation (for example, the tumbling of a bar) a gaseous disk is thought to settle into the fundamental plane of a biaxial galaxy in a time scale given by

$$\tau \approx T\left(6J_2\cos\theta\left|\frac{\mathrm{d}\ln T}{\mathrm{d}\ln r}\right|\frac{\Delta r}{r}\right)^{-1} \qquad (1)$$

where τ is the settling time, T is the orbital time, J_2 is the quadrupole moment of the gravitational potential, θ is the angle between the disk plane and the fundamental plane of the galaxy, r is the disk radius and Δr is the characteristic excursion in radius of gas clouds in the disk[10]. That excursion can be related to the peculiar velocity Δv of the gas clouds through $\Delta r = \Delta v/K$ where K is the epicycle frequency. Specializing now to a logarithmic potential (flat rotation curve), we can use $K = \sqrt{2}v_c/r$ (where v_c is the circular velocity) to write

$$\tau \approx T\left(3\sqrt{2}J_2\cos\theta\frac{\Delta v}{v_c}\right)^{-1} \qquad (2)$$

Noting that J_2 is <0.5 even for very flat galaxies and that $\Delta v/v_c \approx 0.1$ (a reasonable assumption), we see that the settling time from an inclination of 60° or more is always $>\tau_0 \sim 9T$.

The fact that the characteristic settling time is less than the age of the Universe has been used to argue that NGC2685[11] is, in fact, a prolate object with a small pattern speed[12].

The next step is to construct a prolate stellar dynamical model for NGC2685 which is consistent with the observed stellar rotation. We attempted such a construction as part of a systematic study of prolate stellar systems using Schwarzschild's[4] self-consistent field method. That method chooses a specific potential, follows stellar orbits in that potential and finally adds up the time averaged stellar orbits to produce a density distribution corresponding to the original potential. We used a logarithmic potential with a flattening corresponding to an E5 galaxy[5].

Such a model must reproduce the large observed rotation rate about the projected minor axis. The observed rotation parameter v/σ is ~ 1 (ref. 13), while σ is $\sim 100\ \mathrm{km\ s^{-1}}$. (This dimensionless rotation rate is 3–10 times the normal observed value for an elliptical, and is much more consistent with an S0 disk). There is some evidence also for minor axis notation. If this is true, it would suggest that the galaxy is triaxial.

Because the figure is fixed, the observed rotation must be derived from orbits which stream through the figure. Such an orbit is shown in Fig. 1*a*. Maximizing the polar streaming velocity (using linear programming techniques) permits a maximum streaming velocity—corresponding to an observed v/σ of only 0.075 on the projected major axis. Moreover, this large streaming velocity can only be obtained if the y component l_y of the total angular momentum of each orbit is >0 for all $l_z = 0$ orbits (no orbit circulates in the opposite sense). Because these orbits are only neutrally stable against perturbations which cause rapid precession about the z axis, this configuration is implausible. Even if the orbits were stable, the model's v/σ completely fails to reproduce the observed one of unity.

A model more consistent with the observations can be constructed with a slightly triaxial figure. The orbit of Fig. 1*a* can easily be followed in a gravitational potential of the form

$$\Phi = \frac{1}{2}\ln\left(x^2+\frac{y^2}{p^2}+\frac{z^2}{q^2}\right) \qquad (3)$$

If $p < 1$ the orbit is stable but l_z is no longer conserved and the orbit is no longer required to reach $z = 0$ frequently (see Fig. 1*b*). Therefore a larger number of these orbits can be incorporated into the model. A nearly prolate model was constructed maximizing the influence of these streaming orbits with $p = 0.9$. Viewed from the x axis (edge on) its $v/\sigma = 0.1$. The maximum v/σ was achieved from $\sim 30°$ from the x axis in the x–z plane. From that vantage point $v/\sigma = 0.14$. Thus we cannot construct a nearly prolate model with no figure motion and large v/σ. We emphasize that this method maximizes v/σ within the set of all self-similar solutions of this general form.

The failure to construct a figure fixed prolate model with large v/σ indicates that the galaxy is not prolate. An alternative explanation for the gas ring is that it is the wreck of a dwarf

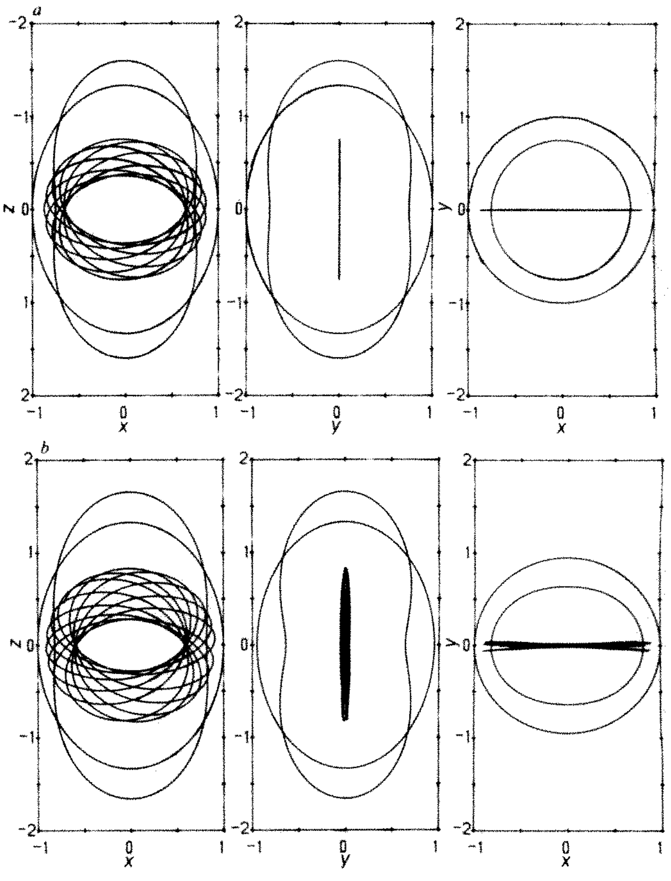

Fig. 1 *a*, Three orthogonal views of an orbit in a fixed biaxial prolate potential (with $p = 1$, $q = 1.333$, see equation (3)). The envelopes are cuts through the equipotential and equal-density surfaces. Note that the orbit streams through the galaxy maintaining a well defined circulation in the x–z plane. This orbit has no z angular momentum and is only neutrally stable. *b*, As *a* but with a triaxial potential with $p = 0.95$ and $q = 1.333$. This orbit also streams. It is a stable orbit with fluctuating z angular momentum.

0028–0836/82/330728—02$01.00

companion, which has not yet decayed to the fundamental plane of the galaxy.

Such a scenario does not, by itself, constrain the age of this gas disk. The disk is very inclined, and equation (2) suggests that for exact polar alignment ($\theta = 90°$), the disk lifetime is infinite.

In fact, equation (2) for the settling time also provides the means to calculate the time independent (or ensemble average) distribution of ring angles. From equation (2), $d\mu/dt \propto \mu^2$ where $\mu = \cos\theta$ is the cosine of the tilt angle ($\mu = 0$ for a polar ring). Because rings are inserted at some angle and then decay to the plane, they obey a continuity equation of the form

$$\frac{\partial n}{\partial t} + \frac{\partial}{\partial \mu}\left(\frac{d\mu}{dt} n\right) = \left(\frac{\partial n}{\partial t}\right)_i \tag{4}$$

where $n = n(\mu, t)$ is the chance of finding a disk at inclination μ at time t, and $(\partial n/\partial t)_i$ is the insertion rate. In steady state, $\partial n/\partial t = 0$. For insertion in strictly polar orbits it is easy to show that $n \propto \mu^{-2}$, while for an insertion rate independent of μ, $n \propto \mu^{-1}$ (to verify these results it is necessary to apply the appropriate boundary conditions at $\mu = 0$).

Note that the above results indicate a preference for disks in non-steady state but relatively long-lived nearly polar configurations regardless of the injection rate. The number of inclined disks will, however, be set by the ratio of the injection rate to the decay rate. Since the latter is $\approx \tau_0 \approx 10T$ ($\approx 10^9$ yr), a frequent incidence of tilted disks is required to demand an insertion time scale much shorter than the age of galaxies. However, these objects may be more common than we realize judging from a flurry of recent discoveries (ref. 14 and P. Schechter, unpublished data). Note that our Galaxy may be about to acquire such rings as the Magellanic clouds come apart[15].

Although we have presented a strong case for the view that this particular galaxy is axisymmetric with two long axes, we have not explicitly ruled out a slowly tumbling bar.

There is, however, an argument which suggests that slow figure motion does not alter the small values of v/σ derived above. Schwarzschild[16] and Miller and Smith[17] have constructed models of tumbling triaxial and biaxial prolate galaxies of very different rotation rates. In both studies the observable rotational velocity is never more than 1.5 times the pattern speed at any radius. Because the pattern speed must be small to avoid disrupting the polar rings in the galaxy under consideration if it is a tumbling bar[12], these models also indicate a small value of v/σ.

We conclude that it is easy to model NGC2685 as an oblate galaxy with polar rings of gas which are the wreck of a dwarf companion. It is impossible to construct a fixed figure prolate model which reproduces the observed stellar rotation rate. It is doubtful that a tumbling prolate model would resolve the discrepancy. It may be that a number of galaxies which have been identified as prolate objects because of embedded disks are in fact oblate objects.

We thank G. Lake, S. Tremaine, M. Schwarzschild and P. Schechter for advice and encouragement. This research was partially supported by NSF grant AST 82-02930 and by NASA grant NGR 23-005464.

Composition-dependent glass-transition temperatures and copolymers

P. R. Couchman

Department of Mechanics and Materials Science, Rutgers University,
PO Box 909, Piscataway, New Jersey 08854, USA

The glass transition is of primary relevance to the forming conditions and end-use properties of polymeric materials. Several polymers of industrial importance, most notably polyvinyl chloride (PVC), contain small molecules as processing lubricants (plasticizers) and are, therefore, solutions. Separately, economic and materials advantages have spurred the use of one-phase mixtures (miscible blends) of high polymers. The general theme of the compositional variation of glass-transition temperatures (T_g) includes, in addition, the variation of T_g with degree of polymerization, with cross-link density (network formation) and with copolymer composition. An attempt is made here to find a unified basis for the prediction of these several aspects of an identifiably single topic.

For solutions which are largely random and for phenomena which can be modelled in terms of such solutions, a recent thermodynamic theory for the compositional variation of glass-transition temperatures[1] has provided a method for calculating solution glass-transition temperatures, T_g, from pure-component glass-transition temperatures, T_{gi}, their corresponding glass-transition increments of heat capacity, ΔC_{pi}, and the mole or mass fractions, X_i, of these components. The equation for the glass-transition temperature of a c-component blend is, in the temperature-independent approximation for the ΔC_{pi},

$$\ln T_g = \frac{\sum_{i=1}^{c} X_i\,\Delta C_{pi} \ln T_{gi}}{\sum_{i=1}^{c} X_i\,\Delta C_{pi}} \tag{1}$$

Systems to which this entropic expression has been applied successfully include miscible blends of polymers[1-3] and plasticized straight-chain[4] and network[5] polymers. Additionally, the effect of degree of polymerization[6] and of cross-link density[7] on T_g have been accounted for by the theory.

For binary solutions, the derivative

$$\frac{d \ln T_g}{dX_2} = \frac{\Delta C_{p1} \Delta C_{p2} \ln T_{g2}/T_{g1}}{(X_1 \Delta C_{p1} + X_2 \Delta C_{p2})^2} \tag{2}$$

does not vanish (except in the trivial case) and, therefore, equation (1) predicts a monotonic dependence of T_g on overall composition. For near-random (and other) copolymers T_g can, however, manifest a compositional absolute extreme value. Thus, any model of copolymers as binary solutions cannot be generally acceptable. Nevertheless, as outlined below, it is possible to include copolymers of arbitrary ordering within the theory by recognizing formally that when differences between primary bonds must be considered in connection with the glass-transition properties of entities comprising a solution, the microscopic rather than overall composition determines the solution behaviour.

Sequence-distribution effects on T_g can be accounted for in the nearest-neighbour approximation by formal treatment of the general copolymer as a random solution of mer pairs, fractions f_{ii}, f_{jj}, f_{ij}. The particular version of equation (1) which then arises is

$$\ln T_g = \frac{f_{ii}\,\Delta C_{pii} \ln T_{gii} + f_{ij}\,\Delta C_{pij} \ln T_{gij} + f_{jj}\,\Delta C_{pjj} \ln T_{gjj}}{f_{ii}\,\Delta C_{pii} + f_{ij}\,\Delta C_{pij} + f_{jj}\,\Delta C_{pjj}} \tag{3}$$

The denominator of this relation is, as for equation (1), the solution transition increment of heat capacity, ΔC_p (ref. 1). For copolymers formed by continuous reaction of i and j monomers

0028-0836/82/330729—02$01.00

at constant feed composition, the dyad fractions of equation (3) can be rewritten as a function of the fraction, f_i, of i monomers in the feed and of the monomer reactivity ratios[8]. r_i, r_j (these are a measure of the relative rates at which a chain end grows by the addition of like and unlike mers). The consequent relation,

$$\ln T_g = \frac{r_i f_i^2 \Delta C_{p_{ii}} \ln T_{g_{ii}} + 2f_i(1-f_i)\,\Delta C_{p_{ij}} \ln T_{g_{ij}} + r_j(1-f_i)^2\,\Delta C_{p_{jj}} \ln T_{g_{jj}}}{r_i f_i^2\,\Delta C_{p_{ii}} + 2f_i(1-f_i)\,\Delta C_{p_{ij}} + r_j(1-f_i)^2\,\Delta C_{p_{jj}}} \qquad (4)$$

provides a formal method for the calculation of glass-transition temperatures of the quasi-binary solution from glass-transition properties of the corresponding homopolymers, the fully alternating copolymer, and the monomer reactivity ratios. For values of these properties which admit a physically acceptable value of f_i as a solution of the quadratic equation obtained from the condition $\mathrm{d}\ln T_g/\mathrm{d}f_i = 0$, the copolymer glass-transition temperature will pass through an absolute extremum. The sign of the second derivative $\mathrm{d}^2 \ln T_g/\mathrm{d}f_i^2$ at this value of f_i determines the nature of the extremum. If the quadratic equation gives no admissible value of f_i, the copolymer glass-transition temperature is a monotonic function of feed composition. The compositional variation of the copolymer glass-transition increment of heat capacity can be analysed in a similar manner. Generally, extreme values of T_g and ΔC_p occur at different compositions.

A considerable simplification of the theory occurs for an ideal azeotropic copolymerization ($r_i = r_j = 1$) of monomers for which $T_{g_{ii}} = T_{g_{jj}}$ and $\Delta C_{p_{ii}} = \Delta C_{p_{jj}}$. In these circumstances, the extreme value of the copolymer glass-transition temperature, T_g^*, occurs at $f_i = \frac{1}{2}$ and is given by

$$\ln T_g^* = \frac{\Delta C_{p_{ii}} \ln T_{g_{ii}} + \Delta C_{p_{ij}} \ln T_{g_{ij}}}{\Delta C_{p_{ii}} + \Delta C_{p_{ij}}} \qquad (5)$$

If, further, the difference between $\Delta C_{p_{ii}}$ and $\Delta C_{p_{ij}}$ can be neglected,

$$T_g^* = (T_{g_{ii}} T_{g_{ij}})^{1/2} \qquad (6)$$

Comparison of theory and experiment for ethylacrylate–vinylidene chloride copolymers affords a critical test of the theory, as a well-defined extreme value of T_g occurs. For this system[9], $r_i \simeq r_j \simeq 1$, $T_{g_{ii}} \simeq T_{g_{jj}} \simeq 250$ K and $T_{g_{ij}} = 408$ K. In the absence of information on the dyad transition increments of heat capacity, the approximation $\Delta C_{p_{ii}} = \Delta C_{p_{jj}} = \Delta C_{p_{ij}}$ allows equation (6) to be used, predicting a maximum value of the copolymer glass-transition temperature of 319 K, at $f_i = \frac{1}{2}$. The observed maximum value of T_g is 308 K and occurs at $f_i \simeq \frac{1}{2}$ (ref. 9).

Previous applications of the theory[16] have placed in a more general context a variety of empirical and semi-empirical expressions for specific aspects of the compositional variation of T_g. Similarly, the formal treatment outlined here gives as first or second-order approximations current relations for the variation of copolymer glass-transition temperatures with composition. Finally, note that equations (1) and (3) are in effect integrated, predictive forms of an entropic formal tautology for composition-dependent transitions of the second-order kind[10,11].

Gold deposition at low temperature on sulphide minerals

G. Michael Bancroft & Gilles Jean

Department of Chemistry, University of Western Ontario, London, Ontario, Canada N6A 5B7

Gold deposits are commonly associated with quartz veins containing variable amounts of pyrite and other sulphides. Gold is thought to be transported as $AuCl_2^-$ or $AuCl_4^-$ in strongly acidic and saline solutions and as AuS^- or $Au(S_2O_3)_2^{3-}$ in weakly acidic and alkaline solutions by hydrothermal solutions coming from great depth and rising in rock formations through faults[1,2]. In some cases gold occurs as finely divided particles, intimately intergrown with pyrite, suggesting that gold, quartz and pyrite were probably precipitated in response to a change in temperature. Fyfe and Henley[3] showed that the solubility of gold increases from 10 p.p.m. at 300 °C to 1,000 p.p.m. at 510 °C. In other cases gold may be aggregated in one spot in abundance while the remainder of the ore is barren, indicating preferential precipitation in one site. Using ESCA (electron spectroscopy for chemical analysis), we have studied the reaction between $KAuCl_4$ in solution and various sulphide minerals. Gold(III) was rapidly reduced to metallic gold on the surface of these minerals, suggesting a new mechanism for the deposition of gold at low solution concentration and temperature.

Various sulphide minerals [pyrite (FeS_2), pyrrhotite (FeS), sphalerite (ZnS), galena (PbS)] were cut into plates of 1 × 1 × 1 cm and were reacted with $KAuCl_4$ solutions of 1, 10 and 100 p.p.m. at different pH for various periods of time. Figure 1*a* shows the ESCA spectrum of the gold 4f lines of the original $KAuCl_4$ solution evaporated on Teflon. The binding energy of the gold $4f_{7/2}$ line at ≃87.4 eV (relative to carbon 1s line at 284.5 eV) is representative of Au(III) compounds[4]. Figure 1*d* is the spectrum of pure metallic gold and shows a binding energy for the gold $4f_{7/2}$ line of ≃83.5 eV which is 3.9 eV lower than Au(III). Figure 1*b* shows the ESCA spectrum of sphalerite (ZnS) reacted with a solution of $KAuCl_4$ (10 p.p.m.) at room temperature. This spectrum clearly shows that both Au(III) and Au(0) are present on the surface. Figure 1*c* shows the ESCA spectrum of pyrite (FeS_2) reacted with

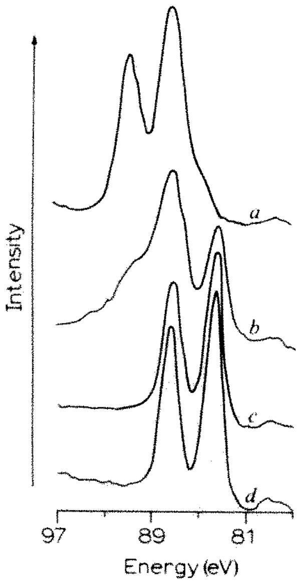

Fig. 1 Gold 4f ESCA spectra for: *a*, $KAuCl_4$ solution (10 p.p.m.) evaporated onto Teflon; *b*, sphalerite (ZnS) plate reacted with this $KAuCl_4$ solution; *c*, pyrite (FeS_2) plate reacted with this $KAuCl_4$ solution; *d*, metallic Au.

0028–0836/82/330730—02$01.00

$KAuCl_4$ in solution. The binding energy of $\approx$83.5 eV indicates that Au(0) only is present on the surface.

The reduction of Au(III) was found to be independent of either the pH or the initial concentration of gold and was found to occur even in saturated KCl solution. Gold was reduced from Au(III) to Au(0) within a minute by every mineral studied except sphalerite. In this latter case, the reduction was slower since both species, Au(III) and Au(0), were observed. This suggests that the nature of metal ion in the sulphide may have an important role in the deposition of gold. Further work is being done to clarify this point.

The mechanism that is thought to occur is: adsorption of Au(III) as the hydrated or the hydrolysed species (chloride is not seen on the surface), followed by reduction of the gold by the sulphide.

$$8\mathrm{Au(III)} + 3S^{2-} + 12H_2O \rightarrow 8\mathrm{Au(0)} + 3SO_4^{2-} + 24H^+$$

The deposition of gold goes on even after the surface is entirely covered, and can actually be seen with the naked eye. After the first layer of Au(0) is deposited, electrons for the reduction are probably coming from the interior of the crystal. This phenomenon is similar to the observed reduction of gold on activated carbon[5]. These results suggest that adsorption of Au(III) by sulphide minerals followed by reduction could have an important role in the deposition of gold in natural systems, especially at low temperature and low solution concentrations of gold.

We thank the NSERC (Canada) for research funds, Professor R. J. Puddephatt for the $KAuCl_4$, and Professor W. S. Fyfe for helpful discussions.

Layered convection and crystal layers in multicomponent systems

R. C. Kerr[*] & J. S. Turner

Research School of Earth Sciences, The Australian National University, Box 4, Canberra 2600, Australia

Laboratory experiments[1–5] in aqueous solutions have been used to model some of the physical and dynamical processes occurring during crystallization in magma chambers. In particular, it has been demonstrated[2,3,5] that crystallization at the side walls can lead to density stratification and layering in an initially homogeneous container, and also to the formation of vertical compositional gradients (that is, to 'differentiation') when more than one solute is present. Density gradients and compositional layers can alternatively be set up by replenishing a container from below with fluid of different temperature and composition[4,6,7]. Underlying all this work has been the concept that some aspects of the regularity and large horizontal extent of layering in well-documented igneous intrusions[8,9] might be explained in terms of 'double-diffusive' effects in the fluid state, with the growth of crystals subsequently being affected by these pre-existing layers. In the latest experiments reported here, we have explicitly addressed the problems of horizontal layering produced in the crystals themselves, when a compositionally-stratified tank of fluid containing several solutes has been cooled from either below or above. The relationship between the scales of the layers in the fluid and in the crystals has also been examined.

Earlier experiments[1,4] in which crystals of a constant composition were grown at the top or bottom of an experimental tank were of two kinds, in both of which layered structures were produced. When an aqueous solution of a single solute (usually Na_2CO_3) was cooled from the top[1], crystals of $Na_2CO_3 \cdot 10H_2O$ formed in horizontal layers, whether the initial fluid was homogeneous, was smoothly stratified, or was set up with several distinct layers of different densities. The dominant effect in all cases was the formation of a cold but less dense fluid layer against the cooled upper boundary as the denser crystals grew (because the density of the saturated solution decreased as the temperature fell). When the top boundary was held below the eutectic temperature, bands were observed in the eutectic layer at levels corresponding to pre-existing fluid interfaces; the advancing front of the crystals growing below this also remained nearly horizontal, and the growth rate was clearly influenced by the positions of the fluid layers. Cooling a compositional gradient from below produced a compact layer of dense crystals of nearly uniform thickness, above which was a fluid layer which increased in depth with time. In this layer convection was driven by the compositional change in the residual fluid generated by the removal of the solid phase at the lower boundary, and the changing depth was a measure of the total volume of less dense fluid produced.

The second type of experiment involving bottom crystallization was conducted[4] to model the evolution of a magma chamber following the sudden influx of a new layer of hot but heavy magma at the base. This lower layer remained chemically isolated from the rest of the chamber, while it cooled rapidly through the interface and crystallization proceeded[6]. In the laboratory model of this process, the lower layer was hot KNO_3 solution and the upper layer was a colder, less dense $NaNO_3$ or K_2CO_3 solution. Crystallization of KNO_3 took place on the bottom, often extending upwards to the interface, which produced a sharp horizontal top to the crystal layer. At the same time the density of the residual liquid in the lower layer decreased due to the compositional change. When this density became equal to that of the upper layer, the interface broke down, so that the two layers mixed thoroughly together leaving a layer of KNO_3 crystals at the base. Related experiments[7] have been conducted with a compositional gradient above the lower layer, and these show that the overturned lower-layer fluid is then confined by the gradient to the lower part of the upper region.

The present experiments represent extensions of each of these cases, with the additional feature that more than one component crystallized out during the course of an experiment, in a sequence and manner which were determined by the evolution of the layered fluid system. Examples have been chosen to illustrate different ways in which crystallization can be controlled by the compositional stratification.

The experimental tank used was a Perspex cube of 20 cm internal dimensions, fitted with a metal base through which coolant could be circulated at a controlled temperature. The procedure was to fill the tank with one or more layers of solution of known composition and temperature (and hence density), to insulate all the side boundaries, and to monitor at intervals the development of the fluid and crystal layers, and in some cases the properties of the residual fluid. Usually the bottom was cooled slowly, by lowering the temperature of the coolant in small steps, but in several experiments the bottom crystallization was produced by cooling from the top, followed by internal heat transfer (through the interfaces between the layers).

Consider first an experiment in which the whole tank was filled with a homogeneously mixed aqueous solution of $CuSO_4$ and Na_2SO_4. The initial compositions were ~19 wt% $CuSO_4$ and 9 wt% Na_2SO_4, well in the range where the copper salt will crystallize first. (The conditions used in this and later experiments are summarized in Fig. 1, where the four cases *a–d* correspond to the photographs in Fig. 3.) When this solution was cooled slowly through the bottom of the tank, a layer of $CuSO_4 \cdot 5H_2O$ crystals did indeed grow, to a thickness of ~1 cm.

---

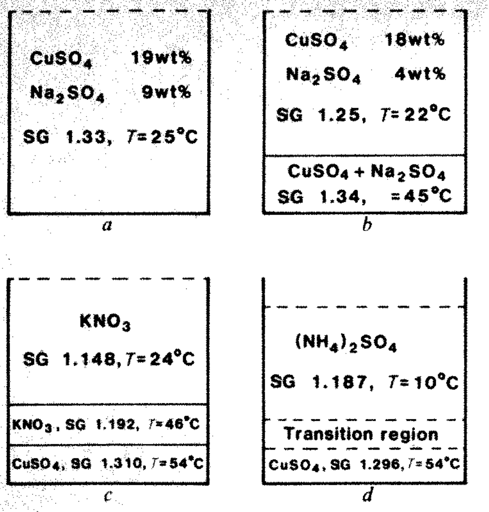

Fig. 1 Summary of the initial conditions in the four experiments for which the final crystal products are shown in Fig. 3*a–d*. The tank was cooled through the base in each case, and insulated at the sides and the top.

At the same time the composition of the residual fluid, well-mixed by 'compositional convection', moved towards the cotectic line as shown on Fig. 2, which is part of a phase diagram prepared for a more detailed study[5] of crystallization of these two components in a different geometry. Before the cotectic line was reached, however, $Na_2SO_4 \cdot 10H_2O$ crystals started growing on top of the previous layer (with just a few crystals of $CuSO_4 \cdot 5H_2O$ visible between them), and built up to a nearly uniform depth of 2 cm, as shown in Fig. 3*a*, while the composition evolved further back into the copper field. This behaviour has been attributed[5] to disequilibrium effects, and the different kinetics of crystallization of the two components, which made it possible for the growth of the copper salt to be suppressed when it was covered by the faster-growing $Na_2SO_4 \cdot 10H_2O$. Similar kinetic effects are also likely in crystallizing magmas, but even if these remained much closer to the equilibrium conditions, the evolution towards, and then along, a cotectic line would nevertheless produce an abrupt change in composition of the crystallizing phases.

The next experiment to be discussed (Fig. 1*b*) started with a 6-cm deep layer of similar composition to that used in the preceding experiment, with specific gravity 1.34 and temperature 45 °C, underlying a layer of depth 14 cm which was relatively rich in $CuSO_4$ and less concentrated in Na_2SO_4 (specific gravity, SG = 1.25 at T = 22 °C). Cooling from below produced the same sequence of crystal layers, first the copper, then the sodium salt, but with the changeover occurring sooner because the composition changes were confined to a shallower fluid layer. During this process, however, the density of the lower layer was decreasing, until eventually it overturned and mixed with the upper layer. This suddenly brought the top of the crystals into contact with a Cu-rich solution, and another layer of $CuSO_4 \cdot 5H_2O$ built up on top of the previous layers, as shown in Fig. 3*b*. Note that though the fluid layers undoubtedly controlled the growth and sequence of the crystal layers, the thicknesses in the two states were not identical, and only indirectly related.

When a layer of mixed solution of copper and sodium sulphates, with a depth of 6 cm and composition similar to that used in the experiments already described, was cooled from above through an interface (using a metal chamber containing coolant in contact with a less dense (SG = 1.055) upper layer of cold Na_2SO_4 solution), the same sequence of crystallization was observed as in the first experiment. A compact layer of $CuSO_4 \cdot 5H_2O$ formed right across the (insulated) bottom and grew to a thickness of 4 mm. On top of this, there was a sudden change to $Na_2SO_4 \cdot 10H_2O$ crystals, which began to grow after about 18 h in a long, spikey form (rather than as a compact mass as they did with bottom cooling) and built up to a nearly uniform thickness of 4.0 cm after about 4 days. There was no overturning in this case, because of the large density difference across the interface between the two layers.

There is no doubt that more complicated crystal sequences can be produced when more fluid layers are present initially, when there are more components which can crystallize over the temperature and composition ranges attainable in an experiment, or when the cooling conditions (for example the temperature of the base of the tank) are changed. The next case to be discussed is a three-layer system in which two solutes were present initially. The top, 12-cm deep, layer was KNO_3 solution at 24 °C, SG = 1.148; the middle layer was also KNO_3 at 46°C, SG = 1.192, 4 cm deep; and the bottom layer (put in last) was $CuSO_4$ solution at 54 °C, SG = 1.310, 4 cm deep (Fig. 1*c*). Cooling from the bottom (with the coolant at 8 °C) produced a 5 mm thick layer of $CuSO_4 \cdot 5H_2O$ crystals in 5.5 h, during which time the three fluid layers remained distinct. Overnight, after a total of 19.5 h, the bottom interface had broken down; some of the $CuSO_4 \cdot 5H_2O$ crystals had redissolved, but a thinner layer survived, above which was an 8-mm layer of paler blue crystals, identified (by X-ray diffraction) as the double sulphate $K_2SO_4 \cdot CuSO_4 \cdot 6H_2O$. The coolant temperature was dropped to 0 °C, and after a further day (a total of 45.5 h) the second interface had broken down, and convection extended over the whole depth of the fluid. On top of the two previously observed crystal layers was a thicker layer of KNO_3 crystals, compact at the bottom but with needles on top (see Fig. 3*c*). Thus each time an interface broke down, the composition of the fluid in contact with the cooled bottom changed abruptly, allowing one or more new solid phases to crystallize.

An example will now be given in which the thickness of the crystal layers was more directly controlled by the depth of the compositional layers in the fluid. A 12-cm deep layer of $(NH_4)_2SO_4$ solution at 10 °C, SG = 1.187, was set up above a 5-cm deep layer of $CuSO_4$ solution at 54 °C, SG = 1.296 (Fig. 1*d*). The interface was initially sharp, but it was stirred gently to produce a transition region 4 cm thick. The coolant circulating through the base was brought down from room temperature to 5 °C; on this occasion the thin insulating layer (usually built into the base of the tank to maintain a uniform temperature over the whole area) was left out, and the coldest temperature were therefore close to the back face. After 1.5 h, a layer of

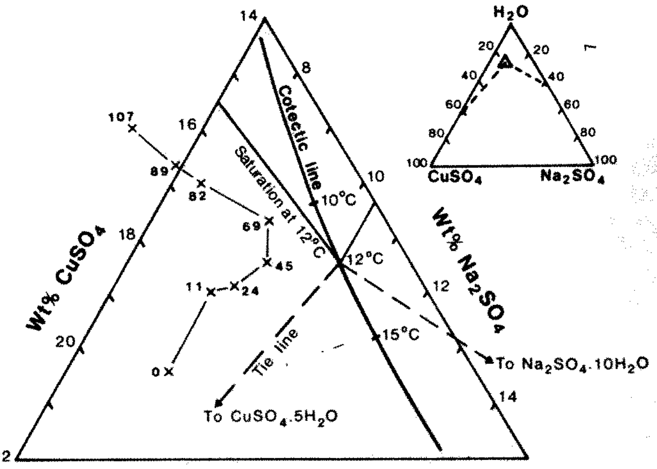

Fig. 2 Part of the phase diagram of the $CuSO_4$–Na_2SO_4–H_2O system, showing the cotectic line (representing solutions in equilibrium with both $CuSO_4 \cdot 5H_2O$ and $Na_2SO_4 \cdot 10H_2O$), and the saturation lines for the two components separately. The region detailed is contained in the small triangle on the full phase diagram sketched at the upper right. The evolution of the bulk composition of the fluid, during the experiment corresponding to Figs 1*a* and 3*a*, is also plotted. Times (in hours since the start of cooling) are marked against the measured points.

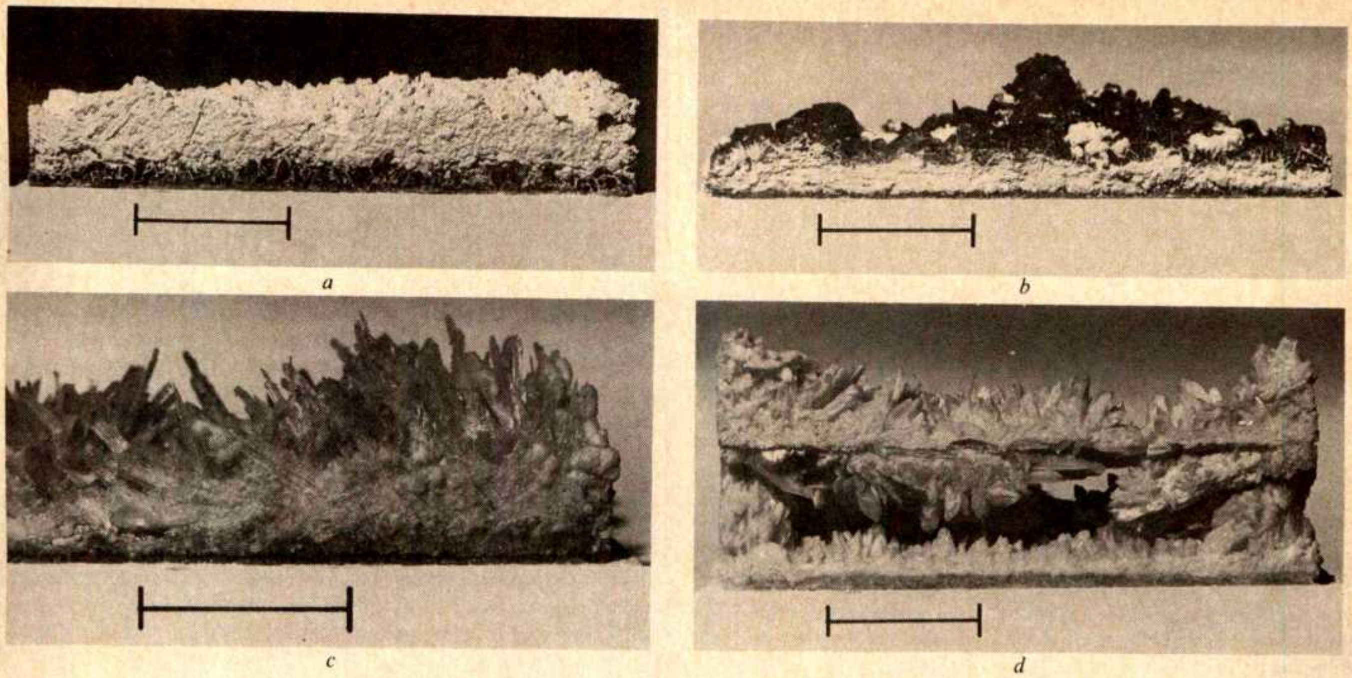

Fig. 3 *a*, Horizontal layers of first $CuSO_4 \cdot 5H_2O$, then $Na_2SO_4 \cdot 10H_2O$ crystals, produced by cooling from below, as the composition of a layer of mixed solution of Cu and Na sulphates evolved with time (see Figs 1*a* and 2). The photograph was taken after the sodium sulphate crystals had dehydrated. (All scale bars, 5 cm.) *b*, The crystal structure produced by cooling a two-layer fluid system from below. The lower layer consisted of a mixture of Cu and Na sulphates similar to that recorded in Fig. 1*a*, and the first two crystal layers grew as described in *a*. The density of the lower layer decreased until overturning occurred, and another layer of $CuSO_4 \cdot 5H_2O$ then grew on top from the Cu-rich solution newly in contact with the crystals. The first indication of a second layer of sodium sulphate is also seen above this. *c*, The crystal structure produced by cooling a three-layer fluid system from below. The upper two layers were KNO_3 (with different concentrations and temperatures, as detailed in Fig. 1*c*), and the lowest was hot $CuSO_4$ solution. The crystal layer which first formed over the bottom was $CuSO_4 \cdot 5H_2O$. As the two interfaces broke down successively, and the composition of the fluid in contact with the top of the crystals changed abruptly, layers of the double sulphate crystals ($K_2SO_4 \cdot CuSO_4 \cdot 6H_2O$) and then KNO_3 crystals formed on top. *d*, Crystal layers which correspond directly to the pre-existing compositional layering in the fluid from which they grew (Fig. 1*d*). A 5-cm deep layer of hot $CuSO_4$ solution was placed below a 12-cm deep layer of less dense cool $(NH_4)_2SO_4$ solution, and the interface thickened by stirring. Cooling from below produced a uniform layer of $CuSO_4 \cdot 5H_2O$ on the bottom and a horizontal band of the double sulphate $(NH_4)_2SO_4 \cdot CuSO_4 \cdot 6H_2O$, with a small fraction of $(NH_4)_2SO_4$, in the interfacial region. When overturning occurred, to produce a single convecting fluid layer, further growth of the double salt took place, extending away from the previous deposit.

$CuSO_4 \cdot 5H_2O$ crystals had begun to grow over the whole floor, and a few paler blue crystals (probably the double sulphate $(NH_4)_2SO_4$. $CuSO_2 \cdot 6H_2O$) were observed on the walls and corners at the centre of the transition layer. No observations were made overnight, but by 19 h the fluid in the tank had overturned, and the structures shown in Fig. 3*d* were observed (looking from the back—above the most strongly cooled region). There is a layer of copper sulphate on the base, with above it a uniform layer of the double sulphate crystals, mixed with a small fraction of $(NH_4)_2SO_4$ crystals. A horizontal layer of the double sulphate plus some ammonium sulphate is also visible at the level of the original interface, and it can be deduced that this is where the composition of the mixed solution initially favoured the formation of these two phases; further crystallization has occurred upwards and downwards from this level following the overturn and complete mixing.

Thus at least three mechanisms have been identified whereby a series of horizontal crystal layers of nearly constant thickness and abruptly changing composition can be produced in a layered multicomponent fluid system cooled from below. First, the composition of a single isolated layer may evolve (more rapidly than would otherwise be the case in a very deep well-mixed container), so that crystallization of a new phase with different kinetics becomes possible above the crystals originally formed on the bottom. Second, the decrease in density of the residual fluid which accompanies crystallization can lead to a sudden overturning and mixing, which rapidly changes the composition of the deeper combined layer in contact with the top of the crystals previously formed. Third, the interfacial region between fluid layers of different composition can provide an environment in which some species will crystallize preferentially, at higher temperatures than any crystals can form in either layer separately. In general the thickness of the various crystal layers is determined only indirectly by the depth of the fluid layers, but in the third case there is a direct relationship between the two scales.

The dynamical principles sketched here should be directly applicable to crystallizing magmas. The justification for transferring results from one fluid system to another, and the associated scaling problems, have been discussed elsewhere[1,5] and the need for this type of study has already been recognized in the recent literature[9,10] on layered intrusions. Further work in progress is aimed at providing a more quantitative understanding of the evolution of crystal layers and the solutions in which they are growing, so that the laboratory results can be generalized and used predictively for more complex magmatic systems.

We thank D. L. Corrigan and R. Wylde-Browne for assistance at all stages of these experiments, and P. W. Berrie for help with the X-ray diffraction analyses.

Lithospheric thinning associated with rifting in East Africa

Richard F. Wendlandt & Paul Morgan

Lunar and Planetary Institute, 3303 NASA Road One, Houston, Texas 77058, USA

A fundamental mechanism of some continental rifting processes appears to be the transmission of thermal energy into the lithosphere by asthenospheric upwelling (the 'active' mechanism of Sengör and Burke[1]), for which the East African rift system is a classic example. The abundance and variety of magma types of predominantly alkaline affinities in the East Rift which derive from the thermal perturbation suggest that studies of igneous petrogenesis may offer a method of investigating the physical as well as the chemical conditions of the upwelling. Systematic variations in the temporal–spatial–compositional relations of igneous rocks associated with rifts are becoming well documented for several different rifts[2–13], and it is generally observed that the degree of silica-saturation of lavas within these rifts increases with time, while incompatible element contents decrease. Furthermore, at any given instant, lavas erupted within the rifts are less silica-undersaturated than lavas erupted outside the rift. These observations are consistent with decreasing depths of origin of magmas with time as would be predicted for magmagenesis associated with an upwelling source region. Here, by deducing the physical conditions of origin of various magmatic products associated with a thermotectonic event in East Africa, the rate of upwelling is calculated and compared with the results of a simple thermal model of lithospheric thinning.

The diversity of eruptive rock types in the Kenya Dome region of the East African rift, corresponding to depths of origin ranging from >170 km to the lower crust (25–30 km), combined with an abundance of dated occurrences permits calculation of the rate of ascent of the thermal perturbation (Fig. 1). As a first approximation it is assumed that the magmas being considered in the analysis were generated and/or segregated from the lithosphere–asthenosphere boundary. The points in Fig. 1 were selected so as to minimize the depth of origin of magmas for a given age. The physical and chemical conditions of origin of the more primitive alkalic varieties of magmas and the flood volcanism in the East Rift are emphasized inasmuch as it is believed that the compositions of these rocks can be related to the depth from which they erupted. The deepest and oldest point in Fig. 1 is defined by the most recent diamond-bearing kimberlite eruption in northern Tanzania, 41 Myr (ref. 14); the depth of origin is based on the intersection of the theoretical and experimentally derived conditions for kimberlite genesis with the diamond–graphite equilibria[15–18], and represents a minimum estimate. The next younger point in Fig. 1, 31 Myr, is based on the oldest known carbonatite associated with rifting, Tororo in eastern Uganda[19]; the range of depths of origin is based on partial melting experiments on carbonated, and carbonated and hydrated peridotite[16,20–27]. The point at ~22 Myr represents the initiation of eruption of ~50,000 km^3 of Miocene flood basalts in northwestern and western Kenya[5]; the depth of origin is estimated from experimental results[28–30]. The two youngest points represent the onset of eruption of flood phonolites and trachytes, respectively, in the East Rift in southwestern Kenya and northern Tanzania[31]; the depths of origin are constrained by experiments in model peridotite systems[16,32] and thermobarometric estimates[33]. Approximately 65,000 km^3 of flood phonolite and trachyte were erupted[5,34]. The depth of origin estimates for the flood trachytes are probably realistic, being situated in the lower crust, although any model assumed in deriving the depth estimate will be, at best, contentious: of greater importance to the analysis is the observation that significant ascent of mantle isotherms must have occurred to enable the accumulation of 10^4–10^5 km^3 of melts of trachytic composition.

The magmatic events forming the basis of the analysis comprise >10^5 km^3 of eruptive rock, an amount approaching estimates of the total volume associated with the Kenya Dome. The data in Fig. 1 are represented by points with respect to time; however, it is important to emphasize, at least with regard to the flood eruptives, that it is the initiation of magmatic events, perhaps comprising many tens of flows and lasting up to several million years, which forms the basis for the analysis. While the general trend of melt composition variation with time is well documented[4–9], the volcanic stratigraphy is complex with intermingling of eruptives of different compositions, and, thus, of different depths of origin, particularly for younger magmas erupted from shallower depths; that is, the progression of deep sourced eruptives to those from shallower depths is not without exceptions, perhaps attesting to complex convective processes in the asthenosphere (textural and structural evidence of episodic deformation and melting that is believed to have originated in an diapirically rising mass has been reported for ultramafic nodules from Lashaine Volcano, Tanzania)[35]. If all the available ages versus depth of origin for volcanics were plotted, however, they would cluster on the concave side of the envelope (Fig. 1), without affecting the exponential trend of the minimum depth of origin for a given age. A systematic decrease in the rate of ascent of asthenosphere is evident (Fig. 1). Complete thinning of the lithospheric upper mantle by asthenospheric upwelling is accomplished over a time interval of ~30–40 Myr.

To understand better the lithospheric attenuation predicted by the analysis of eruptives in East Africa, a simple thermal model of lithospheric thinning has been developed. The lithosphere–asthenosphere boundary (LAB) is assumed to lie at or above the top of the upper thermal boundary layer of mantle convection, with its temperature at the mantle solidus. Heat

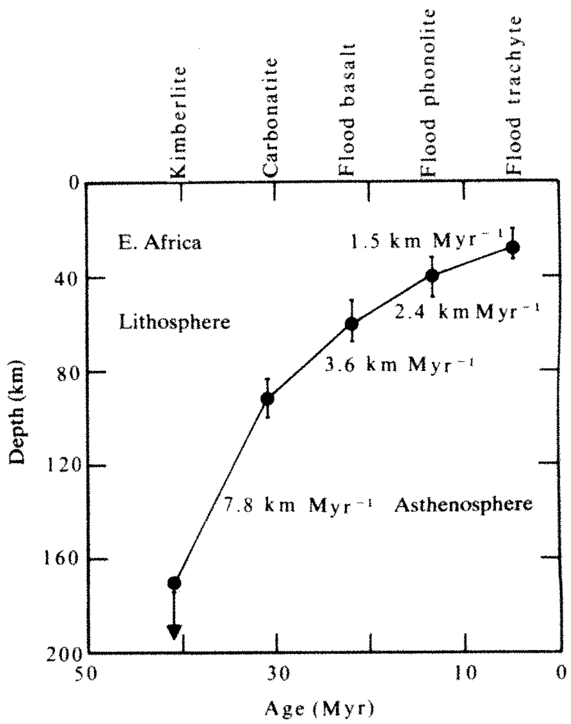

Fig. 1 Asthenosphere ascent rate associated with active type rifting in the Kenya Dome portion of the East African rift system as estimated by changes in the depth of origin of magmatic products with time. Data points are discussed in the text. The ranges of experimentally determined depths of origin are shown by brackets; the selected points are considered to be the best estimates except for the depth of origin of kimberlite which is a minimum estimate.

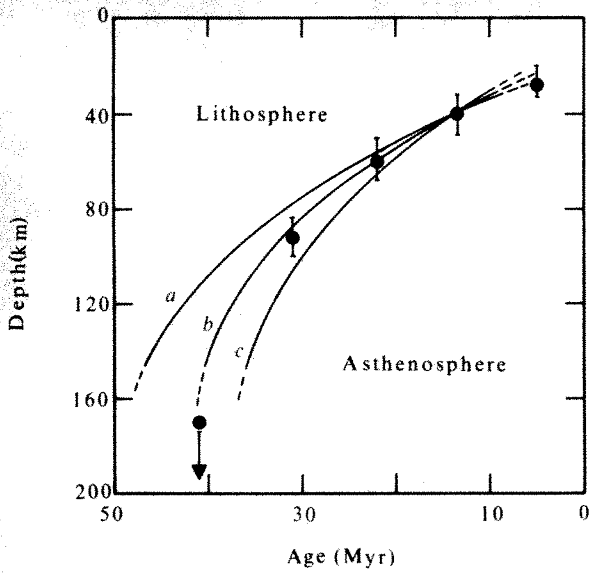

Fig. 2 Asthenosphere ascent, constrained to pass through the phonolite (40 km, 13.5 Myr) data point, calculated from thermal thinning model for 50 km radius lithosphere–asthenosphere boundary perturbation and different temperature gradient increases across the lithosphere–asthenosphere boundary: *a*, 70 °C km^{-1}; *b*, 60 °C km^{-1}; *c*, 50 °C km^{-1}. Curves for 100 km radius perturbation are similar for 65, 55 and 45 °C km^{-1} gradient increases respectively. Data points from Fig. 1 are shown for comparison.

transfer in the lithosphere is assumed to be by conduction only. In stable conditions, heat is conducted through the lithosphere at the same rate that it is input through the boundary layer. If locally the heat supply is increased (mantle 'hotspot'), however, temperatures will increase in the lithosphere, and a perturbation in the LAB will ascend to maintain its position on the mantle solidus. It is this ascent rate, as a function of the undisturbed lithosphere geotherm, the mantle solidus, and the increased heat supply, that we seek to determine.

By simplifying the geometry of the LAB perturbation to be spherical over the heat source, the following equation has been derived for the relationship between the increased heat supply (increased gradient dT'/dr), the temperature increase (T') at the LAB, and the ascent rate (W) of the LAB perturbation, from the solution for the temperature from a stationary constant-strength point-source in a medium moving at constant velocity[36]:

$$\frac{dT'/dr}{T'} = \left[\frac{(1+Wr/k)\exp(-Wr/k)}{r^2} + \frac{(1+W(r+2z)/k)\exp(-W(r+2z)/k)}{(r+2z)^2}\right] \Bigg/ \left[\frac{\exp(-Wr/k)}{r} - \frac{\exp(-W(r+2z)/k)}{r+2z}\right] \tag{1}$$

where r is the radius of the LAB perturbation, z is the depth of its shallowest point and k is the thermal diffusivity of the lithosphere. Although this equation is derived for a constant velocity ascent, a parameter study has shown that it can be used to determine instantaneous velocities at various depths, even if the ascent rate is variable, for radii $\geq$40 km and ascent velocities $\geq$1 km Myr^{-1} (3.17×10^{-11} m s^{-1}), for a typical mantle diffusivity of 1 mm^2 s^{-1}. This approximation is satisfactory because at velocities >1 km Myr^{-1} the ascent rate is effectively faster than the thermal conduction rate above the LAB.

The temperature increase in equation (1) is the temperature required to raise the lithosphere geotherm to the solidus. This has been calculated from a shield geotherm, considered to be appropriate for East Africa before rifting, given by model C1 of Sclater *et al.*[37], and a mantle solidus derived from published experimental data[16]. This mantle solidus was selected because it is internally consistent over a large pressure range, and is a model for the genesis of alkalic magmas, carbonatites and kimberlites, assuming the presence of small amounts of H_2O and CO_2 in the mantle. A thermal diffusivity of 1 mm^2 s^{-1} was assumed, and equation (1) was solved iteratively for ascent velocity at 10-km depth intervals from 150 to 30 km, assuming different radii for the LAB perturbation and different temperature gradient increases across the LAB.

Excellent fits to the experimentally derived LAB ascent rates were obtained for radii of 50 and 100 km and constant gradient increases within the range 55–60 °C km^{-1} over the LAB ascent depth range, as shown in Fig. 2. These radii can reconcile the lateral extent of the eruptives in East Africa[38], as the ascent rate is not sensitive to the radius if the latter is >100 km. The range of gradient increase is more difficult to evaluate, but is not unrealistic, being of the same order in a fixed heat source–lithosphere reference frame as that required in a moving reference frame to reheat the Pacific plate to a bathymetric age of 25 Myr over hotspots, as reported by Detrick and Crough[39]. The ascent rate is sensitive to changes in dT'/dr; a 1 °C km^{-1} change in gradient approximately results in a 0.55 Myr change (~1.5%) in the total ascent time from 150 to 30 km. The apparent 'exponential' decrease in ascent rate with time is predicted even with a constant heat supply (constant dT'/dr). This decrease is due to the increasing differential (T') between the geotherm and the solidus as the depth decreases, and the increasing rate of heat loss to the surface as the thermal wave in front of the LAB perturbation impinges on the surface.

Two direct predictions result from the thermal model. The rapid ascent rate of the thermal perturbation indicates little thermal disturbance above the LAB. The experimental data indicate that the perturbation reached a depth of 30 km 4.8 Myr ago, hence only a small surface heat flow anomaly is predicted outside the areas of Quaternary volcanism and plutonism. This prediction is consistent with surface heat flow data across the Kenya rift[40]. The thermal perturbation should cause thermal expansion in the lithosphere–asthenosphere column as it rises, however, resulting in uplift contemporaneous with lithospheric thinning. Using a volume thermal expansion coefficient of 3×10^{-5} °C^{-1} the model predicts a mean decrease in density of 0.035 g cm^{-3} from 160 to 20 km depth during thinning, which, assuming the lithosphere to be supported buoyantly by the asthenosphere[41], results in an uplift of a little over 1.5 km. This uplift is in good agreement with the uplift determined from geological criteria in Kenya[5].

The temporal–spatial–compositional relations of eruptives in the Kenya Dome region of the East African rift system suggest a shallowing of magma source regions with time, an observation implying encroachment of a thermal anomaly as might be expected from asthenospheric upwelling. Thermal modelling indicates that the rate of this upwelling, and the experimentally determined decrease in this rate at shallower depths can be explained by a constant supply of heat from the asthenosphere, with a magnitude similar to that deduced for other inferred mantle hotspots. The experimentally determined and theoretically modelled lithospheric thinning gives results consistent with observed surface heat flow and uplift across the Kenya rift, and supports the concept of a convective upwelling of the asthenosphere driving rifting in East Africa.

Oligo-Miocene rift of Sardinia and the early history of the Western Mediterranean Basin

A. Cherchi

Università di Cagliari, via Trentino 51, 09100 Cagliari, Italy

L. Montadert

Istituto di Geologia, Paleontologia e Geografia Fisica,
Università di Cagliari, via Trentino 51, 09100 Cagliari, Italy

The geodynamic evolution of the Western Mediterranean Basin, in spite of many studies, is still uncertain. There is some consensus for interpreting this basin as a kind of small oceanic marginal basin. Its opening has generally been related to a subduction process which was active during the Oligocene–Miocene somewhere east of Sardinia–Corsica[1–7]. As the margins of the basin are deeply buried below Miocene-to-present sediments, direct lithological and stratigraphical data which could explain the events responsible for its formation are rare[8–10] or missing altogether. To obtain such data, detailed field studies have been undertaken in Sardinia (Fig. 1), and the first results are presented here. This approach is justified by the fact that in that island, Oligocene and Miocene sediments were deposited in a rift (*fossa tettonica sarda* of Verdabasso[11]), which is the easternmost arm of the complex rift system that affected the European plate during Oligocene and Miocene times. One of these arms evolved towards a small oceanic basin—the Western Mediterranean or Algero–Provençal Basin—while others such as the Gulf of Valencia and the Sardinia rift aborted and remained at the rift stage. Its exceptional exposures make it possible to examine the Sardinia rift to clarify the sequence of events which created it, and to establish a sedimentological model which we believe is directly applicable to the Western Mediterranean Basin.

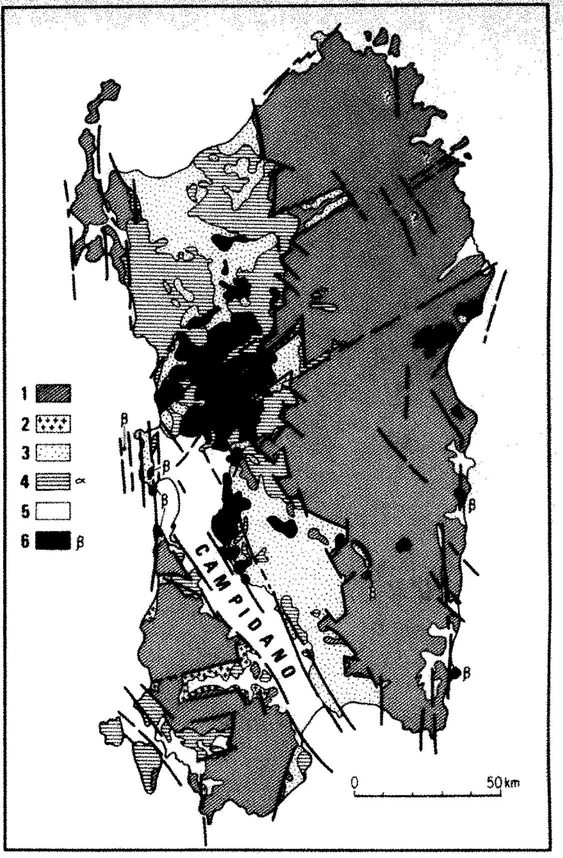

Fig. 1 Geological map of Sardinia. 1, Basement with its Mesozoic and Eocene cover; 2, Cixerri Formation; 3, Oligocene–Miocene rifted basin; 4, Oligocene–Miocene calc-alkaline volcanics; 5, continental Pliocene–Quaternary basin; 6, alkaline Pliocene–Quaternary volcanics.

The Sardinian Oligocene–Miocene rift, which crosses all of Sardinia's 220 km on a N–S trend, must be distinguished from the Pliocene–Quaternary graben of Campidano; the two are often confused. Figures 1, 2*a* and 3 show that the Campidano graben is superimposed on the southwestern part of the Oligocene–Miocene graben, but in an oblique NW–SE direction. It corresponds to an entirely different event, which affected the Central and Western Mediterranean[12]. Detailed structural and sedimentological observations, supported by a good biostratigraphy, can therefore be made of the eastern part of the Oligocene–Miocene rift which appears as a typical rift edge. The Palaeozoic basement of Sardinia, sometimes including its Mesozoic and Eocene cover, is downfaulted by a succession of tilted blocks. The vertical lowering of the pre-rift basement is estimated at at least 1,200 m, and probably much more. The complicated fault pattern can be explained by the complex structure and lithology of the basement. While the general trend of the rift is N–S, local faults vary from N–S to NNW–SSE, and are interrupted by transverse accidents. Among the succession of faults which downfaulted the basement, a master fault is generally observed whose throw can be as wide as 500 m (Fig. 2*b*). It is clearly evident in the morphology of the Sardinian rift, and explains the wall aspect on the eastern edge. Tilted blocks with shorter throw are observed westward and eastward of this master fault. The tectonic style is identical to those described in various intracontinental rifts and on some rifted passive continental margins[13]. This complex pattern controlled the palaeogeography of the basin and the nature and deposition of the sediments along the rift. The width between the two master faults delineating the main trough is 40–50 km.

The Sardinian rift has been infilled by Oligocene–Miocene continental-to-marine sediments ~1 km thick. Volcanics occurring from the late Oligocene, 29.9 ± 1.5 Myr to the middle

Cx, Cixerri Formation; Mu, Oligocene–Miocene synrift Ussana Formation; M, late Oligocene–Miocene marls; PQ, Pliocene–Quaternary; V, volcanics.

Miocene, 13–14 Myr (refs 6–14) can be up to 1 km thick. They are believed to be the products of the volcanic arc linked with the subduction process which was active east of Sardinia. The sediments can be studied in their structural context to determine the timing of the formation, the evolution of the Sardinian rift and the age and nature of the prerift, synrift and postrift deposits.

Before the formation of the Western Mediterranean Basin, the Corsica Sardinia block joined the European plate. Lithological and biostratigraphical data demonstrate this proximity until the early to middle Oligocene. Indeed the continental Cixerri Formation (~300 m thick) outcrops in southwestern Sardinia where it is unconformable to various strata: Palaeozoic, Mesozoic and mainly Lower-base–Middle Eocene. This unconformity corresponds to the Eocene Pyrenean compressional phase recognized and recorded in Sardinia[15,16] with a NW–SE shortening direction[17]. The microfaunal composition and the direction of currents measured on these clastics[18], demonstrate a provenance from northeastern Iberia[19–21] for the material constituting the Cixerri Formation. These observations, and the absence of pebbles of local origin, suggest that the clastics were deposited after the Pyrenean phase and before the initiation of the rift system of the Western Mediterranean. The Cixerri Formation is dated Lutetian at its base by Charophyta and pollen assemblage[22]. It is cut by andesites, the older ones being dated 29.9 ± 1.5 Myr. It can be compared with conglomerates in Provence and in Menorca[19].

The fundamental structural change corresponding to the formation of the rift is recorded by the onset of deposition of the thick clastic Ussana Formation[23]. Its age is post 29.9 ± 1.5 Myr, early Middle Oligocene, in accordance with a Stampian age

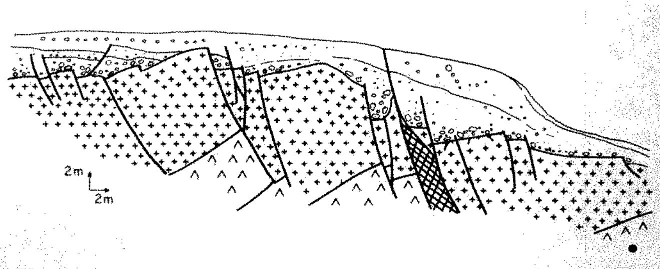

Fig. 4 Detail of the rift tectonics with faulting synchronous of continental conglomerates deposition (north of Cagliari).

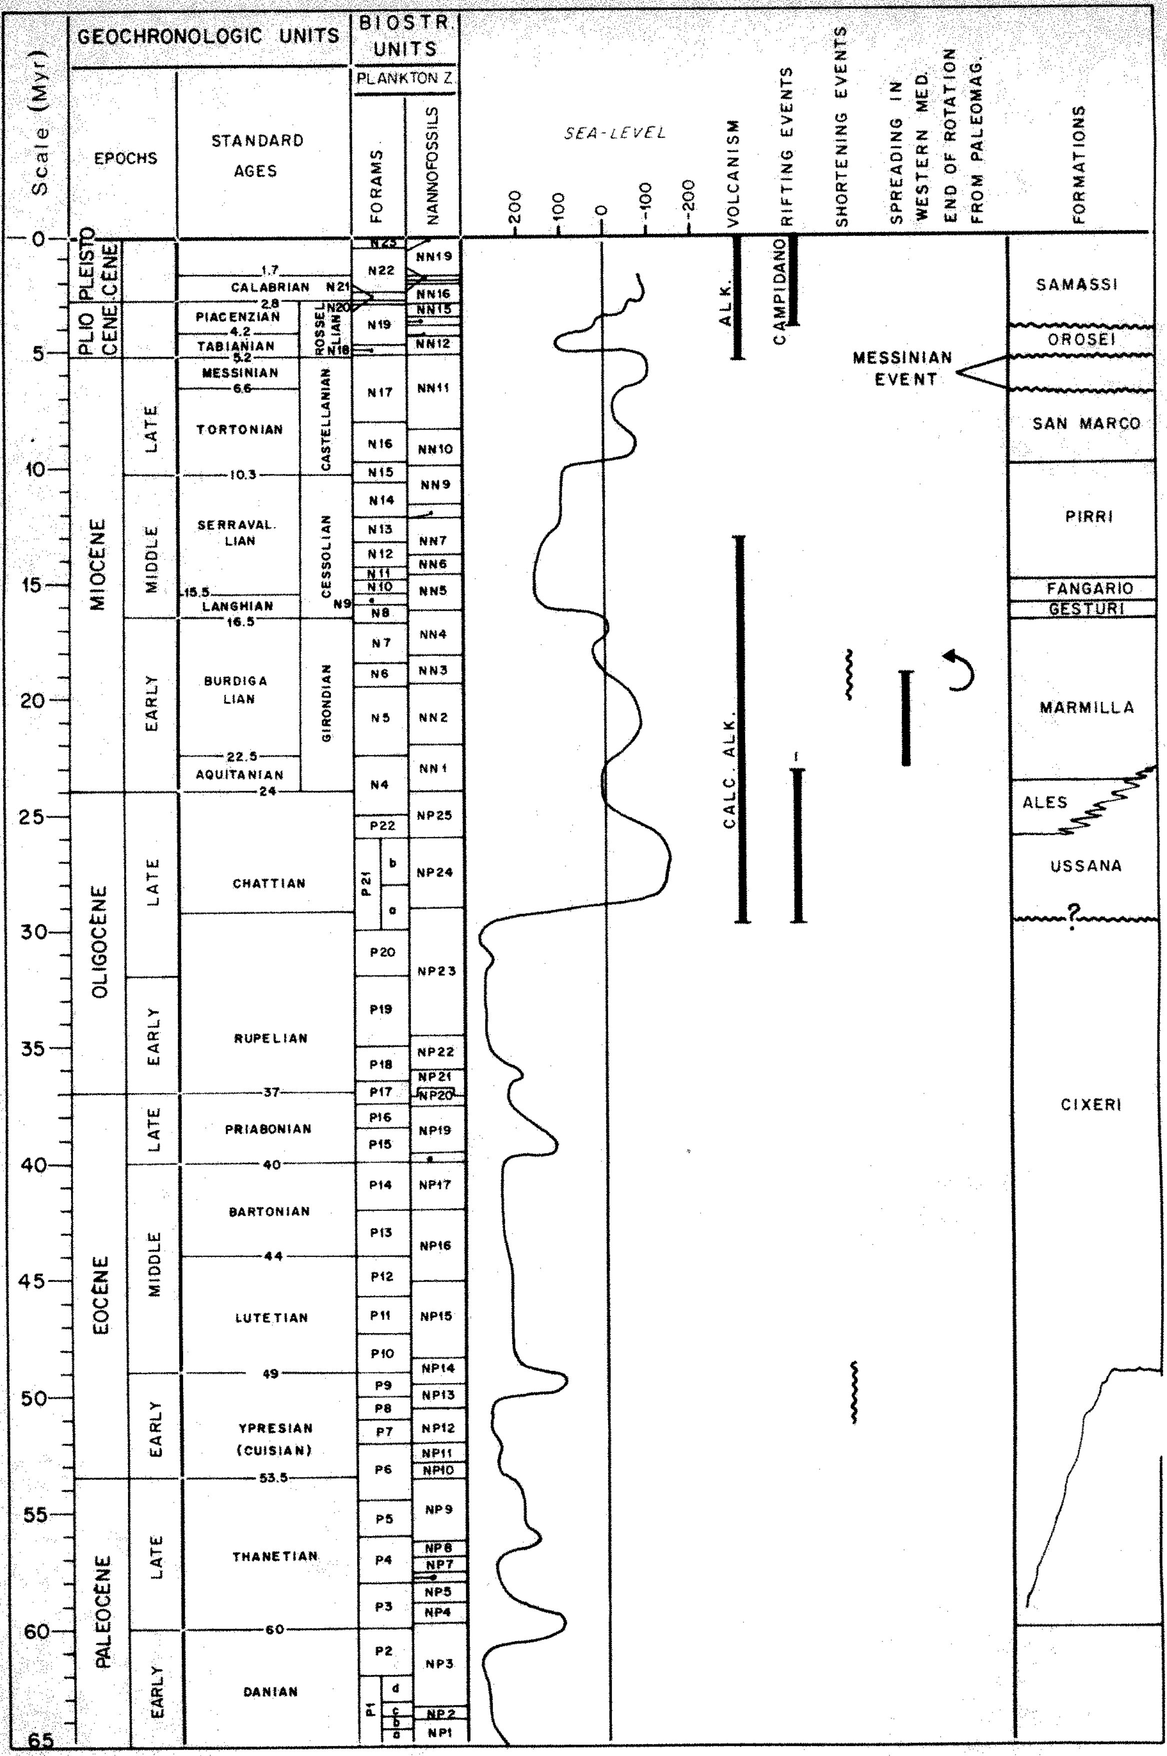

Fig. 5 Main geological events in Sardinia. Time scale and eustatic changes of sea level from ref. 38.

established for grabens in Languedoc (Southern France)[24]. The creation of new reliefs and fault escarpments caused intensive erosion.

First, continental breccias and heterometric conglomerates (from a few centimetres to several metres) embedded in a red-violine sandy-clayey matrix were deposited on and along these escarpments. Their structure is typical of slope deposits, alluvial fans or torrential deposits and they are clearly contemporaneous with faulting (Fig. 4). These observations demonstrate that in its early phase, rifting occurred in a continental environment. Then, fluviatile conglomerates with sandy matrices sometimes including breccias and intercalations of marine limestones with corals, oysters, bryozoans, red algae and pectinids, indicate progressive invasion of the rift by the sea. Thick sandstones are also present. This Ussana Formation, as much as 500 m thick, developed along the edge of the rift, its complex distribution of deposits controlled by the nature and topography of the basement. Locally, along the crest of some tilted blocks, shallow water carbonates made of red algae and >200 m thick were deposited (Fig. 2*b*). As it approaches the axis of the rift the upper Ussana Formation rapidly changes to open marine marls rich in pelagic microfossils (Ales and Marmilla Formations)[25], while on the flank, shallow-water limestones are present. The change from the continental, fluviatile or shallow marine environment to the deeper basin is indicated by intercalations of sands, conglomerates and breccias, with blocks up to several metres, deposited as turbidites and debris flows.

Rifting originated in a continental environment during the early Middle Oligocene. But these data, the pelagic microfossils present in the oldest open marine marls (which are Chattian—P22–NP25—in age), and the shallow-water limestones on the flanks (dated with *Lepidocyclina* and *Miogypsina* gr. *bantamensis*) indicate that the sea invaded the rapidly subsiding axis of the rift during the late Oligocene. The deposition of the Ussana Formation continued until the Aquitanian (N4). Quantitative study[26] of benthic and planktonic foraminifera has resulted in some estimates of the bathymetry at that time. For the Aquitanian deposited at the foot of the master fault, palaeodepths of ~1–1.3 km have been determined, while palaeodepths of 200–300 m were found in Aquitanian deposited higher up. Thus the sea bottom at that time was characterized by high relief.

Deposits equivalent to the Ussana, Ales and Marmilla Formations have been found around the Western Mediterranean. For example, conglomerates and late marine Oligocene have been found in exploration wells in the Camargue trough[27] and in the Gulf of Lions[10] and by submarine sampling on the continental slope of Provence[28–30]. In the Balearic Islands synrift deposits of early Miocene age have also been described[31,32]. Since the Aquitanian, Miocene deposits are essentially marine marls throughout the basin, with the exception of a sandy and carbonate episode in the Upper Serravallian–Lower Tortonian. Calc-alkaline volcanics[33–35] are interbedded throughout the Oligocene–Miocene deposits, and are dated from 29.9± 1.5 Myr to 13–14 Myr (refs 6, 14). They were emplaced either in the air (ignimbrites) or under the sea (pillow-lavas). Associated with them, thick and frequent series of tuffites were deposited. Major events are shown in Fig. 5. Late Miocene-to-present deposits are not considered here.

Thus there is a good set of evidence to support the thesis that rifting in Sardinia, and elsewhere in the European plate, began in the middle Oligocene around 30 Myr ago in a continental environment. At the end of the Oligocene, the trough was deep enough to allow invasion by the sea. The precise estimate of the end of rifting in the Aquitanian 23–24 Myr ago, is based on the following evidence: (1) the typical arrangement of Aquitanian sediments in half grabens, demonstrating that they are synrift deposits; (2) the vertical offset of several hundred metres of shallow marine lower Aquitanian limestones along the master fault; (3) the sealing of faulted blocks by Aquitanian sediments. Further extension with accretion of new oceanic crust was confined to the Western Mediterranean basin. There is no sedimentological evidence in the Miocene marine marls of Sardinia to indicate the end of oceanic accretion in the Western Mediterranean marginal basin, that is the end of rotation of the Corsica–Sardinia microplate. But an intra-Burdigalian compressional phase was recently determined in Sardinia. The shortening direction trends NE–SW[17], as in adjacent areas of Italy and Tunisia. We interpret this as a change in the stress field in the area at that time. The tensional regime in the Western Mediterranean ceased with the end of spreading and rotation of Corsica–Sardinia, because collision occurred east of Sardinia. This timing is in good accordance: (1) with the reinterpretation of the K/Ar ages and palaeomagnetic data of the volcanics of Sardinia[36], as a 19-Myr age (intra-Burdigalian) is proposed for the end of rotation; and (2) with the 19-Myr age of the Tristanite dredged from the axis of the Ligurian sea[37].

We thank Drs De Graciansky, Chenet, Lemoine, Heydman and Grosjean for useful discussions.

High rock stresses as a consequence of glaciation

Anders Carlsson

Swedish State Power Board, S-162 87 Vällingby, Sweden

Tommy Olsson

K-Konsult, S-117 80 Stockholm, Sweden

Knowledge of the stress field in the Earth's crust is crucial for the understanding of processes such as faulting and fracturing. It is also of fundamental importance for the design and construction of underground structures. The two most common methods used for *in situ* stress determinations for engineering geology purposes are (1) the stress relief method, in which the differences in strain resulting from induced stress relaxation are studied, and (2) the hydraulic fracturing method, in which one of the presumed principal stresses is replaced by a hydraulic pressure. Of these, the stress relief method is more applicable to design and construction problems as it enables the three-dimensional stress tensor to be measured. The *in situ* rock stress measurements reported here were carried out in a 500-m deep borehole in Precambrian bedrocks in Sweden and show high stress levels throughout the rock mass. A comparison between the actual recorded stresses and the theoretical stress field from a 2,000 m-thick land ice may provide a possible explanation for the measured stress situation.

0028-0836/82/330739—04$01.00

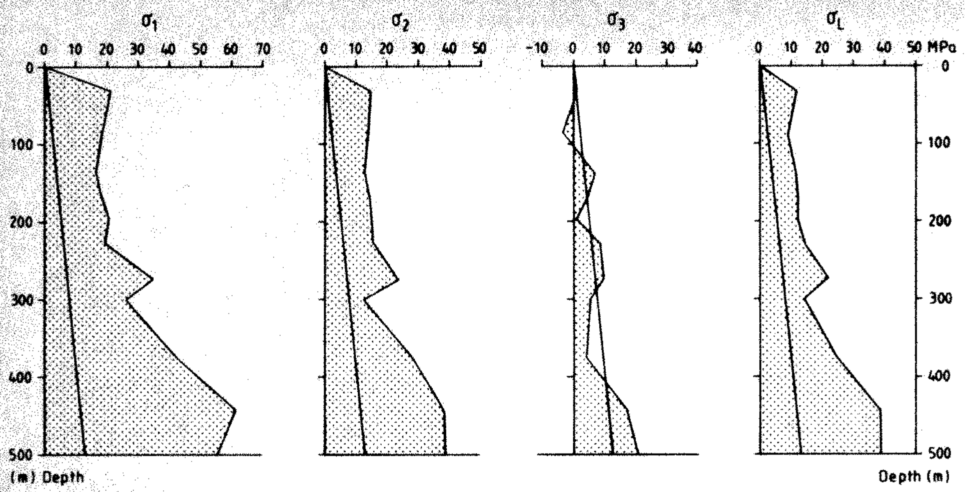

Fig. 1 Principal stresses (σ_1, σ_2 and σ_3) versus depth obtained in borehole DBT1. σ_1 and σ_2 are both nearly horizontal and σ_3 is nearly vertical. The stress level (σ_L), defined as the mean value of the principal stresses, is also shown. The straight lines represent the lithostatic stresses given by the weight of the overburden.

The only one stress relief device that we know of that is suitable for measurements in deep, water-filled boreholes has been developed at the Swedish State Power Board[1]. It is based on Leeman's three-dimensional theories and has been used in Sweden during the past 5 years where recordings have been taken at different locations in virgin parts of the Swedish bedrock.

Measurements have been made in several boreholes drilled from the ground surface, with readings taken at certain intervals down the hole. In the Forsmark area in southern, central Sweden, 30 successful measurements, concentrated to 11 levels, were taken during drilling of a 503 m-deep borehole (borehole DBT1). Another five boreholes have been studied in this area, but with fewer measurements and at shallower depths.

The magnitudes of the principal stresses at each of the 11 levels are shown in Fig. 1 as well as the stress level, defined as the mean value of the principal stresses. Figure 2 indicates the distribution of the orientation of the principal stresses. As may be seen, the stresses are generally high, compared with the weight of the overburden given by the straight line in Fig. 1. The maximum principal stress is ~70 MPa and acts in a plane near the horizontal. The dominating direction of the maximum principal stress (σ_1) is roughly WNW–ESE in the uppermost 300 m, below which level it shifts to a more NW–SE direction. This is indicated by the clockwise arrow in Fig. 2. The dip is approximately horizontal. The smallest of the principal stresses (σ_3) is approximately vertical, acting in a direction that dips steeply to the south. Note that there is a marked increase in the magnitude of stresses below 300 m, which coincides with the observed shift in direction.

The geology of Sweden is characterized by a basement of crystalline rocks of Svecocarelian age (1,500 Myr), which is covered by a thin layer of Quaternary deposits, mainly till. Sweden is located on the western edge of the Eurasian Precambrian shield, bounded to the west by the Caledonian Mountain Range, which forms the border between Norway and Sweden. In large areas, such as Forsmark, the crystalline basement has been eroded down to a peneplain of Precambrian age.

The bedrock at Forsmark is composed chiefly of gneiss granites, mica gneiss and mica schists. The rock stress measurements were performed in the gneiss granitic part of the area.

As shown in Fig. 1, the principal stresses found are of a higher magnitude than would be expected if the stress field were governed by the weight of the overburden alone. This is

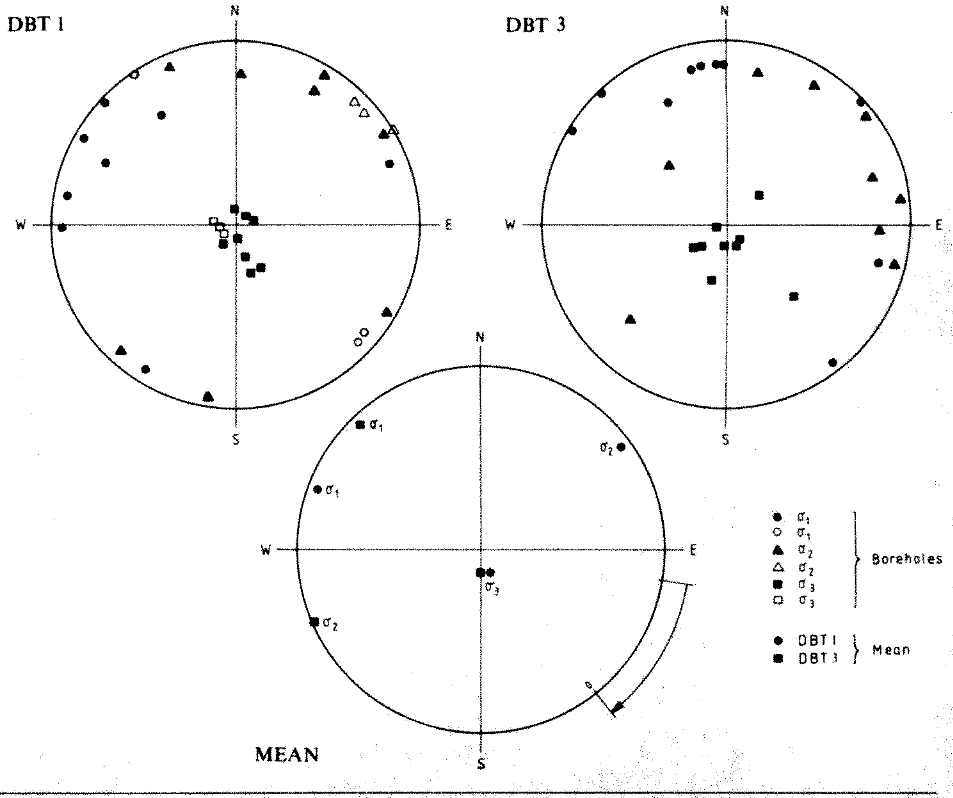

Fig. 2 Orientation of the individual principal stresses and mean values for the boreholes DBT1 and DBT3. The orientations are given as equal-area plots of the intersection of the principal axes with the lower hemisphere. The clockwise shift indicated by the arrow in the lower figure denotes a shift in direction at the passage of the fracture zone at 320 m. Filled and open symbols in DBT1 represent recordings taken above and below the 320-m depth, respectively.

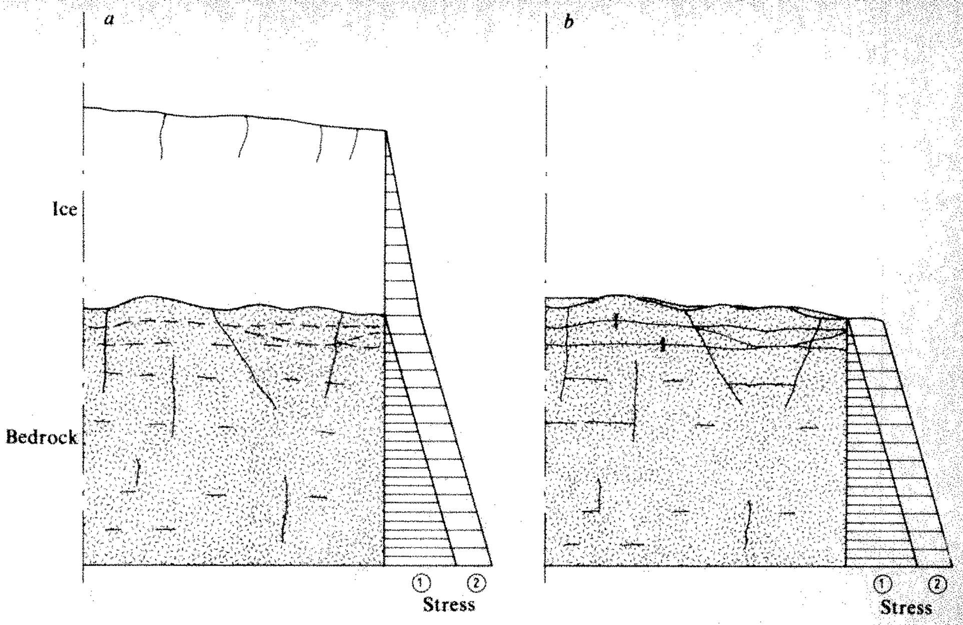

Fig. 3 Hypothetical influence of glaciation. The stress level: *a*, during glaciation; *b*, after deglaciation. Stresses 1 and 2 denote the gravitional stresses due to bedrock and ice respectively.

the case for all principal stresses including the nearly vertical one (σ_3). For the vertical component, the correspondence between the measured stress and the lithostatic is fairly good in the uppermost 300 m, but below this depth, the vertical component is much higher than the theoretically expected value. It is therefore not possible to explain the high stresses which actually exist as gravitional stresses; they must be of some other origin.

A high stress level in the bedrock may be due to many factors. An explanation frequently proposed is that denudation of the rock surface has occurred and this has decreased the weight of the overburden significantly. The lateral stress field created by the earlier formation should then remain, as long as the strength of the rock is not exceeded (allowing for an elastic adjustment of lateral stresses due to vertical stress decrease).

Voight[2] and others have chosen this theory to explain anomalous stress situations. This theory may be applicable to many areas, but not to Forsmark. Here the major denudation occurred in the Precambrian and it is not reasonable to believe that the present stress situation should have its origin back in this age.

Jamison and Cook[3] have analysed many rock stress measurements, and concluded that stresses may be influenced by the frictional resistance to sliding between individual blocks. This explanation is suitable for the stress situation obtained, but it does not provide any information on the origin of the stresses in the Forsmark area, sited as it is on the Precambrian peneplain, on a stable shield of old, crystalline rocks. Other explanations must be sought for the measured magnitude of the stress field at Forsmark. Comparing the results observed with theoretical stresses that could be expected to prevail during a glaciation, it is possible to give a theory for the state of stress in the Forsmark area. Deglaciation is a very rapid process (in the geological time scale) which may be compared with a very rapid denudation, and thus accords with the Voight hypothesis.

At the glaciation maximum the surface of the underlying bedrock is exposed to a vertical stress determined by the weight of the ice cap. By adopting Voight's theories, it is seen that the ice also creates lateral horizontal stresses initially of the magnitude of one-quarter of the vertical stress. This is based on a Poisson's ratio of 0.2 for the rock mass at Forsmark (33 determinations in the range 0.17–0.23). The lateral stress will increase in time due to creep to a value higher than a quarter of, but lower than, the vertical stress. During deglaciation, the vertical stress falls elastically down to zero, while the horizontal stress only falls by one-quarter. Thus it is possible to assume

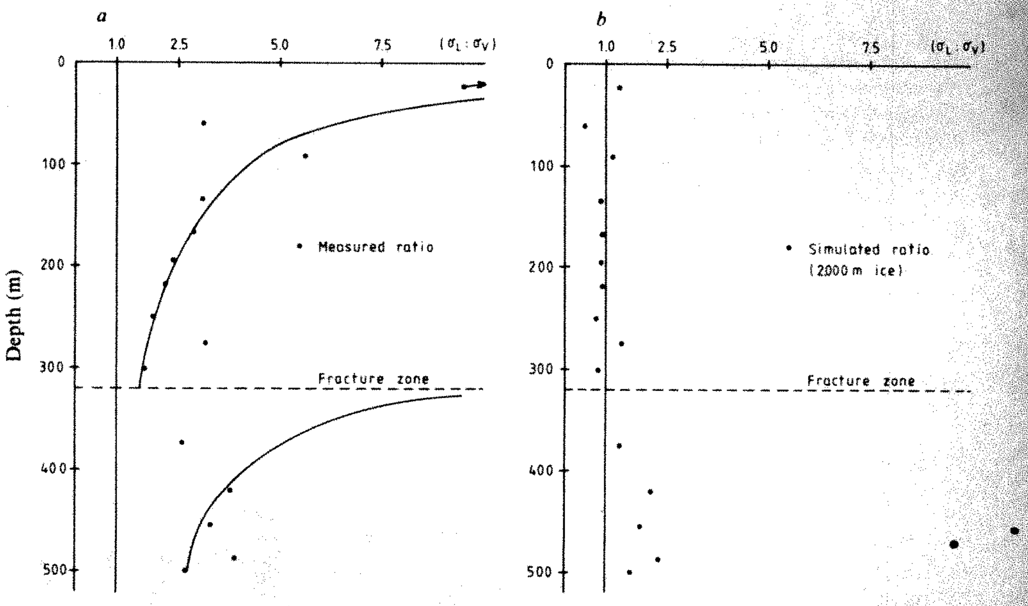

Fig. 4 The ratio between measured (σ_L) and theoretical (σ_V) stress level plotted against depth. *a*, The ratio between the recorded values and the theoretical as it is today. *b*, The ratio between the recorded values and a theoretical value given by the weight of a 2,000 m-thick ice and the weight of the rock mass.

that the glaciation could have created a stress situation as shown in Fig. 3.

To test this theory, the present results of stress measurements have been compared with theoretical effects of an assumed ice cap, 2,000 m thick. The result of the comparison is shown in Fig. 4, where Fig. 4*a* plots the ratio between the actual measured stress level (mean stress) and the theoretical lithostatic stress field (σ_L:σ_V ratio) against depth. This curve indicates that the discrepancy between the measured stress level and the theoretical level decreases with increasing depth. Simulating the pressure from a 2,000 m-thick ice cap gives a stress level of 20 MPa at the bedrock surface, in lithostatical conditions.

Using the sum of this ice-induced stress and a lithostatic stress level in the rock due to the weight of the overlying rock mass to give a new value for σ_V, it is possible to recalculate the σ_L: σ_V ratio, which includes the effects of a glaciation. Figure 4*b* shows that the theoretical, lithostatic stress level equals the measured one. Hence the present stress level, as measured at Forsmark, may be an effect of Quaternary glaciations, where the deglaciation resembles a rapid denudation.

However, the glaciation cannot be the sole cause of the high stresses recorded below a fracture zone at 320 m indicated in Fig. 4. Below this level readings of about 70 MPa for the maximum principal stress were taken. These high stresses could be explained as being stresses of palaeotectonic origin.

The effect of a glaciation on the stress field is discussed more completely in ref. 4.

Evidence for ^{13}C/^{12}C fractionation between tree leaves and wood

Steven W. Leavitt & Austin Long

Laboratory of Isotope Geochemistry, Department of Geosciences, University of Arizona, Tucson, Arizona 85721, USA

An isotopic fractionation step between carbon fixed in the leaves and that assimilated into wood cellulose has not previously been included in atmosphere–plant fractionation models. Data presented here, however, show that the magnitude of such a fractionation step may be significant. In an experiment which involved 10 juniper trees from around Arizona, cellulose of leaves was found to be isotopically lighter than that of the corresponding tree rings in all trees by an average of 2‰. In a second experiment, the δ^{13}C of leaf material from a juniper tree sampled at monthly intervals was compared with the δ^{13}C of the corresponding ring. For cellulose, δ^{13}C of the wood varied with changes in δ^{13}C of the leaves and was persistently isotopically heavier by 3–4‰. Furthermore, the observed change in δ^{13}C through the growing season suggests a temperature coefficient of about −0.27‰ °C^{-1}. The direction of this leaf–wood fractionation precludes diffusion processes as the primary cause.

For the most part, the carbon assimilated into woody tissue of trees is initially fixed from atmospheric carbon dioxide by chlorenchyma of the leaves. This process serves as the basis for using tree rings to decipher past changes in atmospheric radiocarbon production or dilution[1], and more recently to determine the role of the biosphere as a CO_2 source or sink from tree-ring δ^{13}C measurements[2]. The δ^{13}C fractionation between atmospheric CO_2 and C_3 plants, including most trees, is typically about −18‰, the greatest portion of which takes place at the enzyme fixation step. However, models which attempt to account for the atmosphere–plant fractionation either do not consider isotopic fractionation after glucose formation[3,4], or consider any fractionation during the formation of other compounds (including cellulose in tree rings) from photosynthesized sugars to be relatively slight or negligible[5,6,20].

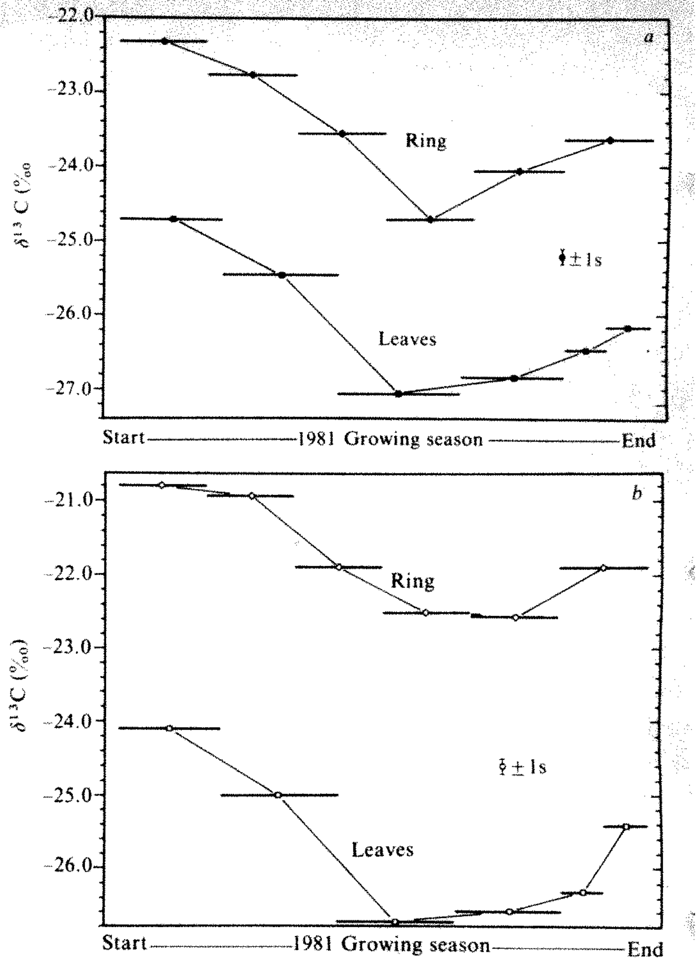

Fig. 1 *a*, Whole-tissue δ^{13}C analyses; *b*, cellulose δ^{13}C analyses of *J. monosperma* ring subdivisions and leaves from the 1981 growing season. Positions of leaf analyses in time have been scaled to their proportion of the total seasonal growth (Table 1).

Evidence, however, suggests isotopic selection during formation of individual organic compounds within plants. For example, a range of several per mil δ^{13}C among different organic constituents is well documented[7,8]. Analysis of whole tissue indicates that leaves are lighter than wood by 1–2‰[6,9,11], which implies isotopic differences between tissues also. Unfortunately, this evidence of leaf–wood δ^{13}C fractionation is inconclusive because of the possibility that such whole-tissue differences may simply reflect varied proportions of organic compounds, each of which has a different isotopic composition. Therefore, analyses of individual compounds such as cellulose are necessary to test more conclusively for this fractionation. So far, such information is scarce. One study (A. L. and J. C. Lerman, unpublished data) examined δ^{13}C of cellulose from leaves and wood of several bristlecone pine individuals and found in most cases that the leaf cellulose was isotopically lighter. Unfortunately, although the leaves were compared with wood of the same sites and of the same age, the leaves and wood were not from the same individual trees.

We conducted two experiments which provide insight into the nature of fractionation between leaves and wood. At the end of the 1979 growing season we sampled juniper trees in Arizona growing at elevations ranging from 1,200 to 2,300 m. Leaf samples were pooled from the four cardinal directions and

4 October 1981	35	2.0	1.2

a section of wood was taken from the base of the tree. Because junipers retain ~10 yr of leaves at any time[12], the rings representing 1970–79, taken about their full circumference, were collected for comparison. Cellulose from the leaf and wood samples was isolated using an acidified sodium chlorite solution in a procedure modified after Green[13]. After combustion of the samples to CO_2, carbon isotopic analyses were performed with a Micromass 602C mass spectrometer. The results reported in Table 1 are expressed in the standard δ notation with respect to the PDB standard[14], with the reproducibility of combustion and analysis estimated to be ±0.1‰. The $\delta^{13}C$ of cellulose in leaves in all cases was lower than the corresponding wood by an average of 2.0±0.7‰.

In the second experiment, we harvested leaf material at approximately monthly intervals over the 1981 growing season from a juniper tree (*Juniperus monosperma*) in the grounds of the University of Arizona. Marking of leaf tips along one major branch at the beginning of the intervals ensured that only the growth for that particular interval would be harvested. Furthermore, marking a large number of tips allowed some to be harvested while others could be remarked for harvesting later. Additional leaf tips, not previously marked, were also marked at the beginning of new intervals. These precautions minimized the effects that the cutting may have had on growth and provided a large pool of leaf tips for cutting at the end of each interval.

Table 2 summarizes the harvesting schedule and average amount of growth for only those tips which were harvested. The average growth values for the 6 August–7 September and the 7 September–4 October periods are higher than the actual growth of all tips during those two intervals because ~20% and 50%, respectively, of the tips marked at the beginning of each of these intervals did not grow at all and were not included in the averages. Finally, on 4 October, several tree-ring cores were taken from the trunk and branch. The 1981 ring from one core was divided into six approximately equal sections and cellulose was isolated from splits of these ring subdivisions and from the leaf samples.

Results of carbon isotopic analysis of the whole-tissue and the cellulose component of these samples are shown in Fig. 1. Strictly speaking, direct comparison of the wood and leaves is difficult because the time period represented by each of the wood subdivisions is unknown. However, as a first approximation we have plotted the wood analysis as equal lengths in time and then scaled the position of each leaf analysis to its proportion of the overall seasonal leaf growth. The major result is that leaves are persistently lighter than wood for both whole-tissue and cellulose by ~2.5 and 3.5‰, respectively, although leaf whole-tissue and cellulose values are quite similar. A pattern of decreasing $\delta^{13}C$ is evident in the spring and early summer followed by increasing values for the remainder of the sampling periods. The magnitude of the $\delta^{13}C$ decrease cannot be explained by the seasonal variation of $\delta^{13}C$ of atmospheric CO_2 which only changes ~0.4‰ in this region[15]. Moisture may be considered non-limiting because this tree is well irrigated, however, allowing us to calculate a significant temperature response of −0.27‰ $\delta^{13}C$ °C^{-1} ($r^2 = 0.86$). This coefficient results from regression of the April to September mean monthly temperatures for 1981 (9.7, 13.6, 18.9, 22.7, 20.2 and 20.4 °C, respectively) with their associated leaf cellulose $\delta^{13}C$ results (−24.1, −25.0, −26.7, −26.6, −26.2 and −25.4‰, respectively). This coefficient is opposite in sign to that calculated in an intra-annual study of *Pinus radiata* tree rings from New Zealand[16]. However, it is similar in sign and magnitude to temperature coefficients from several *in vitro* studies with the carbon-fixing enzyme RuBP-C[17,18].

If we infer similar leaf–wood isotopic differences for other species and locations, these results indicate that detailed models for atmosphere-to-plant carbon isotopic fractionation will need to include an additional fractionation step of +2‰ or more between the leaves and wood. This fractionation probably cannot be explained by diffusive processes because of the large molecular weight of glucose and because diffusion away from the leaves would tend to enrich them in ^{13}C, just the opposite of these results. If some type of ^{12}C preference operates during assimilation, similar to the preference for ^{12}C in carbon fixation, then this may be manifested in a $\delta^{13}C$ change in cellulose away from the photosynthate source. We had hoped to test this explanation of an isotopic gradient from leaves to wood with the other cores, but unfortunately they did not display a clear ring pattern with which to distinguish the 1981 growth-ring boundaries. One previous study[19] of longitudinal variation of $\delta^{13}C$ in *Quercus rubra* found a fairly constant $\delta^{13}C$ in a ring when measured over the relatively short distance of 40 cm.

Oxic diagenetic products as indicators of past oceanic algal populations and diversity

F. T. Gillan* & R. B. Johns

Department of Organic Chemistry, University of Melbourne,
Parkville, Victoria 3052, Australia

Marine sediments contain a great diversity of organic molecules which have originated *in situ* and from planktonic organisms. The establishment of a direct relationship between possible 'chemical markers' and source organisms would enable studies of biomass-turnover time to be undertaken, using dated sediment cores as temporal records. Studies of the influence of long-term environmental variations on the abundance of planktonic flora and fauna are potentially amenable to this approach. Chemical compounds biosynthesized by organisms in the water column are, however, subjected to microbial attack, oxidation and other degradative processes before, and indeed after, sedimentary incorporation[1]. We show here that changes in the sedimentary abundances and distribution of selected chemical moieties produced by oxidative degradation of fatty acids of planktonic origin, can provide evidence for a change in algal abundance and distribution in the overlying oceanic waters.

As part of a continuing study[2] of the geochemistry of Patton escarpment sediments (32°34′.4 N, 120°28′.0 W; depth: 3,800 m), a sediment core has been analysed in detail. Four samples (1), 0–5 cm; (2), 12.5–17.5 cm; (3), 27.5–32.5 cm; (4), 42.5–47.5 cm) from the core were solvent-extracted and the residues from the extraction were saponified. Selected lipid classes from the bound acidic fraction were examined (after derivatization as the methyl esters, trimethylsilyl ethers) by capillary GC on a SCOT SE30 column, and by GC/MS (HP 5995A GC/MS with fused silica SE30 WCOT capillary column). α,ω-Dicarboxylic acids ('diacids') were readily identifiable by their characteristic mass spectra[3]. A group of compounds with a strong m/z 175 in their mass spectra, which did not co-elute with β-hydroxy acids was also observed. These compounds were not observed unless the methyl esters were trimethylsilylated. The mass spectrum of the major component was m/z (I):73(100); 75(62); 89(77); 133(54); 159(31); 175(45); 261(96) and 292(58). The ions: m/z 73, 75, 89, 133, 159 and 175 are indicative of a β-trimethylsilyl ether-methyl ester, while the intense M-31 fragmentation suggests an α,ω-dimethoxyl function in the molecule. The m/z 75 : m/z 73 ratio is higher than we have observed with typical β-hydroxy acid derivatives and probably indicates some contribution to m/z 75 from the characteristic m/z 75 fragmentation of a dimethyl acetal[4]. The most probable structure for this compound is the dimethyl acetal, trimethylsilyl ether, methyl ester derivative of β-hydroxy-ω-oxo-heptanoic acid: such compounds have not previously been reported in sediments. No authentic sample of a compound of this type was available for mass spectral comparison.

Table 1 lists the abundances of bound diacids in the four sediment samples examined. Note that the bound diacid abundance is much greater than that of any other lipid fraction we have determined (for example, solvent-extractable monocarboxylic acids: 6.5 p.p.m., hydrocarbons (aliphatic): 1.3 p.p.m.)[2]. The main component in each sample is the C_9 diacid (9:0), which constitutes ~70% of the total observed diacids; 7:0, 8:0, 10:0 and 11:0 diacids are also major components. The longer chain-length ($>C_{11}$) diacids constitute only a small percentage of the total diacid abundance (~3%). In contrast, in an anaerobic deep-sea sediment from the Santa Catalina Basin, bound 9:0 diacid is a minor constituent (<2% of the diacids) (our unpublished results). This indicates that the short-chain diacids probably originate by oxidation of lipids input to the oxic sediment. The high abundance of the C_9 diacid precludes a major contribution from, for example, higher plant sources. The production of similar diacid distributions to those observed here, in oxidations of algal kerogens[5], supports the probable origin of the short-chain diacids by oxidative degradation of suitable organic substrates present in the lipid mixture deposited in these sediments. $\Delta 9$ monoenoic, monocarboxylic acids are major components of the lipids of marine sediments, 16:1$\Delta 9$ being the most abundant monoenoic acid in many sediments we have studied[6]. Oxidation of this acid could lead to a variety of products (see Table 2). Direct cleavage at the double bond would produce only the C_9 diacid, while hydration followed by oxidative cleavage either side of the hydroxyl would lead to a mixture of C_8, C_9 and C_{10} diacids. ω-Oxidation (to Di-16:1$\Delta 7$)

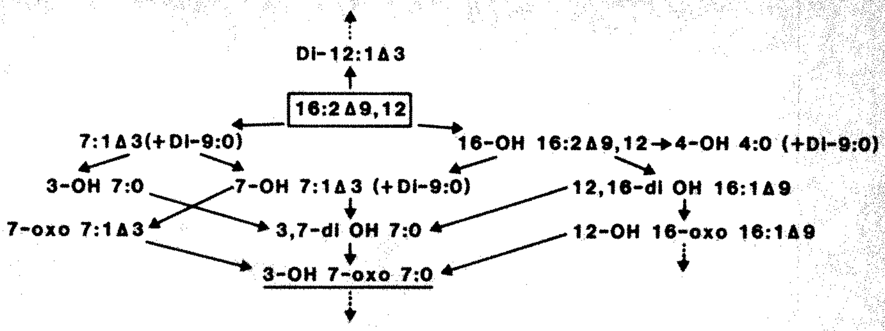

Fig. 1 Oxic diagenesis of a common, diatom-derived dienoic acid.

before oxidative cleavage is also possible. The observed diacid distribution indicates that direct cleavage is the predominant process, and the much higher abundance of C_8 diacid relative to the C_{10} diacid supports some contribution from the ω-oxidation, hydroxylation and then cleavage pathway (the alternate pathway:hydration then cleavage would result in a ~1:1 C_8:C_{10} ratio). The other major diacid, Di-11:0, will probably result from oxidation of $\Delta11$ monoenoic acids. These acids are the second most abundant group of monoenoic acids in marine sediments[6]. Oxidation of the $\Delta11$ acids would result in the production of a small quantity of Di-12:0. This proposed interrelationship of C_{11} and C_{12} diacids is supported by the high correlation of these data ($R^2 = 0.9996$). Whilst ω-oxidation is a known microbial process, microbial degradation of fatty acids generally proceeds through a series of both β-oxidations and ω-oxidations[7]. Reactions such as this would not lead to the observed diacid distribution. No evidence for a microbially-mediated direct cleavage or hydration/cleavage process has been reported: the major degradative pathway is probably abiological. The observed diacid distribution is thus consistent with an input to the sediment of $\Delta9$ (probably $16:1\Delta9$ and $18:1\Delta9$) and $\Delta11$ (probably $18:1\Delta11$) monocarboxylic acids, and subsequent oxidation.

As indicated above, the monoenoic acid distributions of intertidal marine sediments are dominated by $16:1\Delta9$, $18:1\Delta9$ and $18:1\Delta11$ (ref. 6). These acids are believed to originate from *in situ* algae. In the Patton escarpment sediment there is no chemical evidence for the presence of *in situ* algae (algal carotenoids are not detectable[2]), however, particulates derived from planktonic algae are expected to contribute to the lipids of the sediments. The presence of typical algal sterols in these sediments[2], in particular, supports the proposed contribution to the sedimenta y organic matter from algal debris.

The long-chain diacids detected in these sediments exhibit fairly smooth distribution envelopes with Carbon Preference Indices (CPI) near unity. If these acids were derived from a higher plant input the CPI would be expected to be large (>3) (ref. 8). Rather, these acids are probably diagenetic products possibly produced by microbial di-terminal oxidation of alkanes or ω-oxidation of long-chain fatty acids, and subsequent α- and β-oxidations. The traces of monounsaturated diacids detected could originate by ω-oxidation of the corresponding monocarboxylic acid, or may indicate a contribution to the sedimentary lipids from higher plant suberins[8].

The abundances of the β-hydroxy ω-oxo acids are listed in Table 3. By analogy with the mode of formation of the major diacids (Table 2), one can envisage a series of double bond cleavages, terminal oxidations and hydrations that would lead to such acids from a dienoic acid starting material (see Fig. 1). Note that these polyfunctional acids would be intermediates in the overall degradative pathway: it is expected that they would not be very abundant, as observed. The major acid of this class, C_7, could originate from $16:2$ $\Delta9$, 12 monocarboxylic acid, whilst the second most abundant component, C_9, would be derived from dienoic acids such as $18:2$ $\Delta9,12$ or $16:2$ $\Delta7$, 10. The major monoenoic and dienoic acids present in planktonic algae are algal class dependent. A change in the abundances of the different algal classes contributing to a sediment would result in a concomitant change in the input of unsaturated fatty acids, and thus in the abundances in the sediments of their diagenetic products.

Diatoms biosynthesize large amounts of $16:1$ $\Delta9$ and $16:2$ $\Delta9$, 12 compared with most other algae[9], and would thus be expected to be major contributors to the abundances of the C_9

Table 3 β-Hydroxy ω-oxo acids in the Patton escarpment sediments

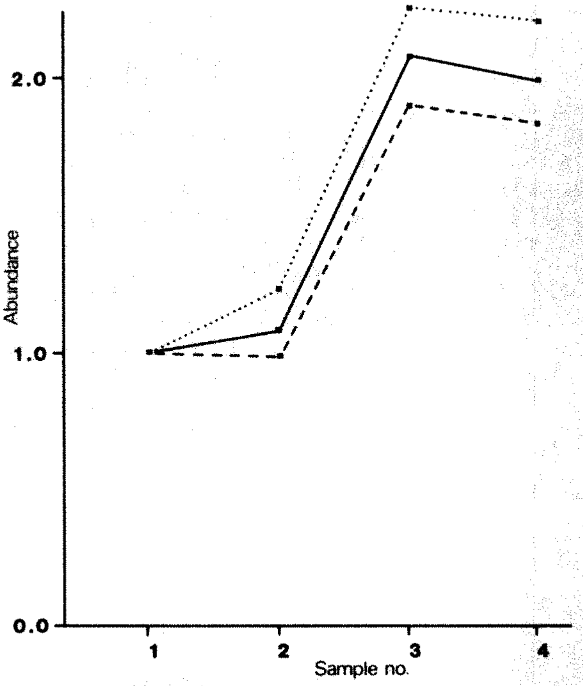

Fig. 2 Diacid ratios (C_{11}/C_9) and abundances of C_7 β-hydroxy-ω-oxo acid and 24-methylcholesta-5,22-dien-3β-ol (all data normalized to 1.00 for sample (1)). · · ·, Diacid; – – –, hydroxy acid; ——, sterol.

diacid and the C_7 β-hydroxy ω-oxo acid found in these sediments. In contrast, coccolithophores produce virtually no dienoic acids that would lead to the formation of the C_7 polyfunctional compound[10]: only C_9 precursors are present in these algae. The $\Delta 11:\Delta 9$ monoenoic acid ratios for the few algae of this class that have been analysed in detail also differ from those of diatoms. Similarly, certain green algae have been observed[11] to biosynthesize some $18:1\ \Delta 11$. Changes in the chain-length distributions of the diagenetically-derived acids could thus be indicative of changes in the algal populations contributing to the sedimentary lipids. 24-Methylcholesta-5,22-dien-3β-ol is a common major sterol in coccolithoptores[10] although it also is found in diatoms[13]. A change in the diatom and/or coccolithophore abundance or distribution should result in a change in the abundance of this sterol.

The dicarboxylic acids (Table 1) exhibit a marked change in the $C_{11}:C_9$ ratio between samples (2) and (3) (ratios: (1):(2):(3):(4):0.039:0.048:0.088:0.086) due mainly to a large increase in the C_{11} diacid abundance. The abundance of β-hydroxy ω-oxo 7:0 similarly changes abruptly between samples (2) and (3). Figure 2 shows a plot of these data together with the abundance of 'bound' 24-methylcholesta-5,22-dien-3β-ol. The high correlation of the data (diacid:hydroxy-oxo-acid $R^2=0.973$; diacid:sterol $R^2=0.996$; hydroxy-oxo-acid:sterol $R^2=0.991$) supports the proposed algal origin for the acids and indicates a probable change in the algal abundance and/or distribution between deposition of samples (3) and (2). The sedimentation rate for these sediments has not been determined, though a rate in the range 0.5–2.0 cm kyr^{-1} could be expected for this near-shore environment[12]. It is tempting to speculate that it may be of the order of 1.5 cm kyr^{-1}: samples (3) and (4) would then have been deposited during the last ice age, at a time when the algal abundance and distribution would surely have differed from that at present.

We thank Dr A. Yayanos for the sediment core and Dr R. Esdaile and CSIRO Division of Materials Science for access to the HP 5995A GC/MS. F.T.G. acknowledges financial assistance from a CPG Research Award. We thank the secretarial staff at the Australian Institute of Marine Science for their assistance.

Age of the Lufeng, China, hominoid locality

Lawrence J. Flynn

Department of Geosciences, University of Arizona, Tucson,
Arizona 85721, USA

Qi Guo-qin

Institute of Vertebrate Paleontology and Paleoanthropology,
Academia Sinica, PO Box 643, Beijing (27),
People's Republic of China

Recently discovered hominoids from a locality near Lufeng, China, are crucial to the understanding of the biogeographical distribution and the pattern of evolution of all later Miocene hominoids. However, the significance of these finds is difficult to assess fully without knowing their age accurately. The Lufeng fauna is diverse and includes several species of the rodent family Rhizomyidae. Rhizomyid evolution is well documented in the Siwalik deposits of Pakistan and provides the most precise method available at present for dating the Lufeng fauna. Based on co-occurrence of *Brachyrhizomys nagrii*, *Brachyrhizomys tetracharax* and cf. *Brachyrhizomys pilgrimi*, we conclude that hominoids inhabited southern China and Pakistan at about the same time, 8 Myr ago.

The success of expeditions in Pakistan[1] and Europe[2] in recovering late Miocene hominoids has stimulated fossil hunting in terrestrial deposits throughout southern Asia. Chinese scientists have recovered remarkably complete fossils from a site near Lufeng, Yunnan. Diverse rodents are frequently associated with hominoid remains and contribute to chronological correlation because evolution in some lineages was relatively rapid and is well documented. Fossil rhizomyids (bamboo rats of Asia and mole rats of Africa) are especially well represented in Pakistan[3] and occur at Lufeng.

The Lufeng fossil locality is near Shihuiba, a small village ~9 km north of Lufeng city (102°4′ E, 25°3′ N). Within a Cenozoic sequence of fluvial-lacustrine deposits, fossils are concentrated in ~3 m of lignite in a small area[4]. This fauna is diverse and includes abundant hominoid primates, numerous ungulates, and several carnivores and large rodents[4]. Unlike Siwalik faunas which span >10 Myr (Miocene–Pleistocene), the Lufeng fauna probably accumulated over a geologically short period of time. The Lufeng fauna resembles late Miocene faunal assemblages almost 3,300 km to the west in Pakistan, but differs from more northerly Chinese faunas[5]. Lufeng and the Pakistan sites apparently occupied the same general biogeographical province distinct from that of northern China in the late Miocene.

The Siwalik deposits of Pakistan are thousands of metres thick and vertebrates are widely distributed throughout the sequence. Palaeontological expeditions have recovered large collections of vertebrates, with documented stratigraphical provenance. Temporal calibration of Siwalik fossil horizons is based on palaeomagnetic reversal sequences and on several radiometric dates. Strata in the temporal interval from ~9 to 6.5 Myr are particularly well documented because the magnetic sequence includes many distinctive reversals, sedimentation was relatively continuous at this time, and magnetic properties of the sediment preserved the polarity sequence without ambiguity. Many palaeomagnetic sections through the 8-Myr

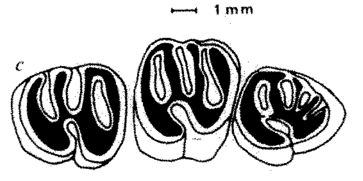

Fig. 1 Rhizomyid dentitions from Lufeng. *a*, *Brachyrhizomys nagrii*; *b* and *c*, *B. tetracharax*.

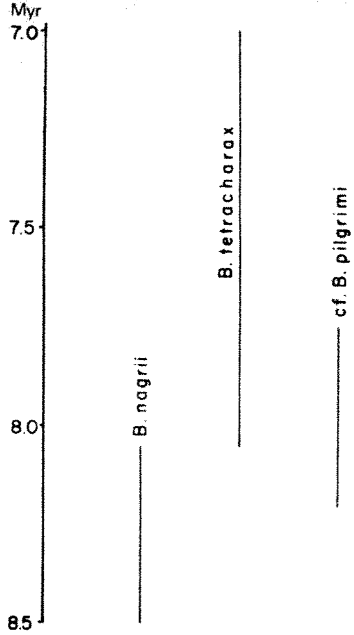

Fig. 2 Temporal ranges in Pakistan of three species of *Brachyrhizomys*.

hominoid level[6] offer exceptionally precise temporal control on Siwalik fossils in this interval.

Temporal ranges of rhizomyid species of the Siwaliks are well documented and evolutionary patterns of the family are clear[3]. The primitive genus *Kanisamys* appeared by 13 Myr and represents a long lineage of small rhizomyids that is not presently known from Lufeng. By 9.5 Myr *Brachyrhizomys* evolved, radiating after 8.5 Myr with as many as four large, burrowing contemporaneous species. After 7 Myr both genera became extinct locally, while three new genera appeared. By the Pleistocene, Rhizomyidae disappeared from Pakistan, but they persist in south-east Asia and in Africa. Today Asian rhizomyids occur throughout southern China, south to Sumatra. Most species have wide geographical ranges, for example *Rhizomys pruinosus* (south-east China, west to Assam), which certainly spans >3,000 km of territory.

The presence of at least three advanced species of *Brachyrhizomys* in the Lufeng fauna demonstrates that Lufeng vertebrates cannot be older than 8.5 Myr on the basis of Siwalik rhizomyid phylogeny. Lufeng *Brachyrhizomys* represent species that occur in the Siwaliks and are described below from casts of four specimens, each with three molars. The original material, collected by one of us (Q.G.) is in Beijing.

The smallest specimen (Fig. 1*a*) is a dentary referable to *B. nagrii*. Size (M_{1-3} length = 11.75 mm) agrees well with Siwalik specimens and M_3 is short (width = 90% of length), a derived character known only in *B. nagrii*. Furthermore, M_2 bears an elongated mesolophid, a primitive trait retained in this species.

Lower and upper dentitions (Fig. 1*b*, *c*) are referable to *B. tetracharax*. Although M_2 is moderately worn, the hypoconid has a weak anterior arm. Suppression of this connection is a derived trait of *B. tetracharax* and later rhizomyids. In addition, M_3 is elongated (width = 70% of length) and M_2 bears a rather long mesolophid, which are primitive characters retained in this species. Tooth row length is comparable to Siwalik *B. tetracharax* for both lower ($M_{1-3} = 14.88$) and upper ($M^{1-3} = 12.56$) dentitions. The upper row in Rhizomyidae is usually shorter than the lower. Aside from this, identification of this upper dentition is preliminary.

A fourth specimen is bigger than the others ($M_{1-3} = 15.6$) but smaller than the holotype of *B. pilgrimi*, the largest known species of *Brachyrhizomys*. Although the cast does not reveal diagnostic details of occlusal surfaces, this individual is closest to a population from Pakistan that has been provisionally named[3] *Brachyrhizomys* cf. *B. pilgrimi*.

Brachyrhizomys nagrii, *B. tetracharax*, and cf. *B. pilgrimi* have well known temporal ranges in Pakistan and coexisted for a short time at ~8 Myr (Fig. 2). Assuming that rhizomyid species ranged geographically about as far as they do now and had similar temporal ranges in southern China and Pakistan, this places the Lufeng hominoid fauna at ~8 Myr also. Further collecting at Lufeng will improve samples of fossil species and screenwashing will probably add smaller taxa to the faunal list that will help to refine this correlation.

It is probable that hominoids in Pakistan and southern China coexisted in the same broad biogeographical province at 8 Myr. Knowledge of temporal relations of samples of fossil hominoids is essential to reconstructing their pattern of evolution and palaeobiogeography and analysis of other faunal elements can elucidate the palaeoecological setting in which hominoids evolved. Continued synthesis of all available data will offer the fullest understanding attainable of human evolution in southern Asia.

We thank Drs E. H. Lindsay, D. R. Pilbeam and L. L. Jacobs for reviewing the manuscript, and Dr Li Chuan-Kuei for many valuable discussions. We are grateful for the cooperation of S. M. Ibrahim Shah (Geological Survey of Pakistan) and the Institute of Vertebrate Paleontology and Paleoanthropology. Natural selection on body size and proportions in house sparrows

Robert C. Fleischer & Richard F. Johnston

Museum of Natural History and Department of Systematics and Ecology, University of Kansas, Lawrence, Kansas 66045, USA

Variation in morphology across a species range is largely a function of climatic conditions. Evidence for this comes primarily from correlations of latitudinal trends of climate with those of body size or shape (the classic ecogeographic rules of Bergmann and Allen[1]). Few studies have documented a temporal sequence of natural selection on size variables within a single population[2–7], and no study precisely documents selection on shape variables. For birds in temperate regions, winter climate can be a major source of mortality[8], and is likely to be an important agent of selection on overall size[2–6]. We reported previously[6] that severe winter weather produced significant changes in the distribution of size classes of a population of house sparrows (*Passer domesticus*). In that study, post-winter males were on average significantly larger than pre-winter males and post-winter females averaged significantly smaller than pre-winter females. We report here further analyses indicating that sparrows also undergo selection for refinement of bodily proportions, consistent with predictions from Allen's ecogeographic rule. Such selection for increased core-to-limb proportions probably results in greater thermoregulatory efficiency. The changes in proportions accompany the changes in overall size[6] and there are major inter-sexual differences in how such proportions are achieved.

The study is based on 14 skeletal measurements[9] from 240 autumn (November 1978) and 196 Spring (March 1979) specimens of house sparrows from Lawrence, Kansas. The 1978–79 winter in Lawrence was one of the most severe on record[11]. Monthly mean temperatures for December–February averaged 4.8 °C below normal, and snow cover lasted for 55 days of the

Values given are mean selection intensities for element groups (number of elements per group in parentheses), selection intensities for PC scores, and a summary of the significant overwinter differences (by t-test) among elements within their respective groupings. + Indicates an increase in the value(s) of the element or PC overwriter, − means a decrease, and ± indicates ambiguity in the direction of selection.

* Significance levels for those elements were significantly different by t-test between autumn and spring samples. No variances differed between autumn and spring samples. Univariate analysis presented elsewhere[6,14]. NS, not significant.

3-month period, compared with about 15 days in an average year.

Within each sex, different comparisons of autumn and spring groups were possible, but only autumn specimens could be satisfactorily identified as first-year birds by the incomplete ossification of their skulls[12]. However, a large number of banded specimens was included in the sample, from a previous study at the site[13]. From these birds of known age, samples of first-year spring specimens were identified and compared with first-year autumn birds. These provide the most useful comparison, in terms of measuring levels of wintertime selection, but a comparison is also made of first-year autumn versus all spring specimens. This mixes a number of separate age classes in the spring specimens, but all members of the group are similar in having had at least one wintertime selective experience. First-year autumn birds had completed skeletal growth[6].

Univariate analyses of the 14 variables over these specimen sets are provided elsewhere[6,14]. Spring means differed significantly by t-test from autumn means for several variables. Variances did not differ among the samples by Levene tests. To analyse the major trends of variation in the skeletal variables, the variance–covariance matrix of the entire log-transformed data set was subjected to principal component analysis[15] (PCA) and PC scores were computed for each specimen. Three principal axes contained significant proportions of variance and were easily interpretable. PC1 contained 42% of the variance and, because of its large, positive loadings for all variables, represents overall size. PC2 (13%) seems to represent a skull to body proportion, and is not included in the present analysis. PC3 contained 10% of the variance, had positive loadings on core variables, negative loadings on limb variables and insignificant loadings on skull variables. Thus, PC3 represents a core-to-limb ratio. Scores on PC1 and PC3 were averaged over each group as defined above.

- Here we compare morphology of autumn and spring groups using calculations of selection intensity[16] (measured as the proportional change in mean fitness, $\Delta\bar{w}/\bar{w}$). Selection intensities estimate the relative amount of morphological change from a pre-selection (autumn) to a post-selection (spring) sample. They are advantageous in that they are standardized and comparable over characters. Because selection acted primarily on the character means in the comparisons, we assume a linear fitness function[7,16–18].

Selection intensities were calculated for each of the 14 skeletal elements, grouped according to their respective bodily component (skull, core or limb) and averaged. These mean values, and the selection intensities for the PC scores, are presented in Table 1, which also includes a summary of significant differences. Selection intensities were large for certain characters. For example, $\Delta\bar{w}/\bar{w}$ was 0.237 for decrease in humerus length in females. By comparison, $\Delta\bar{w}/\bar{w}$ for change in humerus length from O'Donald's[17] re-analysis of Bumpus' data on storm-generated selection in *P. domesticus* was only 0.103. Drought-mediated selection on *Geospiza fortis*[7] produced the largest intensities ever noted: for example, $\Delta\bar{w}/\bar{w}$ on wing chord over a 2-yr period was 0.39.

The pattern of selection intensities differs to some extent between the sexes. On PC1, males show strong selection for increased body size, but females show strong selection for decreased body size. Selection intensities on PC3 are weak to moderate; mean changes are not significant, but all indicate an increased core-to-limb ratio. Selection intensities averaged over body components indicate more clearly a reproportioning of body parts. In males, selection intensities over skull and limb elements are weak, although generally showing a trend towards increased size. In comparison, average selection intensities for core elements are considerably larger for both the first-year autumn versus all spring comparison and for the first-year autumn versus first-year spring comparison. Male core elements, therefore, show a disproportionate increase relative to their limb or skull elements.

For females, the basic pattern of selection is opposite to that of males. Females exhibit low selection intensities in variable directions for skull and core characters, but extremely strong selection for decreased limb size. Females limb elements thus show a disproportionately greater decrease relative to their core or skull elements. In summary, Table 1 reveals that while spring males are larger overall and spring females are smaller overall, each sex has also experienced a differing mode of selection on body components that results for both sexes, in an increased core-to-limb ratio.

Individuals with a high core-to-limb ratio clearly have a selective advantage in severe winter weather. A decreased surface-to-mass ratio results from such a core-to-limb trend, which in turn may result in lower rates of metabolism and heat loss[19,20]. Such trends in the proportioning of body parts are evident in geographical comparisons within a number of species[1], and within house sparrows such a cline also exists[9]. However, we believe this report to be the first to indicate selection for proportioning of body parts on a temporal basis. As there are constraints on body size in each sex, for males to be larger and females smaller post-selection, there must also be constraints on the way each sex accommodates selection for optimal proportioning of body parts. Spring males must have greatly increased cores in relation to their also larger limb elements, and spring females must have considerably smaller limbs in relation to their also smaller core elements.

In house sparrows, therefore, males and females are selectively distinct morphometric entities: sexual selection results in larger-sized males[21]; and females perhaps undergo selection for small size because of reproductive constraints[22]. As shown here, given intense selection pressures, overwinter mortality can support or augment these trends[6]. Even so, males and females, although probably allowed to differ in size because of sex-limited loci, cannot be totally distinct in an evolutionary sense because of the effects of syngamy and recombination. Sexual reproduction annually generates cohorts of offspring of interparental size or shape that cannot wholly anticipate wintertime climate. Selection sometimes then acts on this new cohort to generate post-winter phenotypic distributions better approximating optimal distributions.

Genetic differences in individual behaviour associated with shell polymorphism in the snail *Cepaea nemoralis*

J. S. Jones

Department of Genetics and Biometry, University College London, Wolfson House, 4 Stephenson Way, London NW1 2HE, UK

It is often supposed that genetic polymorphism in a population will be favoured if individuals of different genotype occupy an ecological niche in which they are relatively fit[1]. There are great practical difficulties in establishing whether such genetic differences in behaviour influence the niches chosen by polymorphic animals in nature. I report here a new technique for investigating habitat selection in the land snail *Cepaea nemoralis*. This species is polymorphic for shell colour and banding and hence for shell reflectivity. Differences in the efficiency of absorption of solar energy by the various phenotypes lead to geographical changes in allele frequency[2]. In this study snails of different phenotype in the same population were marked with a paint which fades at a measurable rate when exposed to daylight. This detects individual differences in daytime activity too slight to be identified by direct observation and shows that within a population there are differences in the behaviour of individuals of contrasting shell phenotype when exposed to sunlight. Habitat selection may therefore be partially responsible for the extensive genetic polymorphism of *C. nemoralis*.

There are great differences in gene frequency among geographically separated populations of *C. nemoralis*. Some of these differences result from climatic selection; dark-coloured snails absorb more solar energy than do light-coloured, and hence may be at an advantage in cold and shady microclimates but liable to death through overheating in warm sunny places[2–4]. Much less is known of the forces which maintain genetic variation within a population than of those which lead to genetic change among populations. Individual differences in thermal relations in sunshine might influence the habitat chosen by snails of different genotype, so that the shell polymorphism may be associated with behavioural differences which help to maintain the various alleles in the population.

Observation of differences in behaviour in natural populations is difficult as the snails are often buried or hidden by vegetation. What is needed is to measure the activity of single snails over a period long enough to detect slight individual differences. Most techniques of measuring exposure to daylight are unsuitable as they involve complex instruments or undue physical interference[5]. There are, however, several chemical or electronic methods of integrating solar energy falling on a surface. Chemicals which degrade at a known rate when exposed to the Sun[6–8] are not usually practical for field use as they involve the spectrophotometry of degradation products. I have modified a technique used to measure the stability of textile dyes to give a convenient method of assessing the behaviour of individual animals in daylight.

The Blue Scale is a series of pigments of differing resistance to fading which are dyed onto cloth[9]. The technique can be improved for field use by dissolving the pigments in a stable yellow paint to give a green paint which fades to yellow. The extent of fading is assessed by comparison with a scale produced by mixing this paint with increasing proportions of the yellow base. The paint is primarily sensitive to UV light (which represents only a small part of the Sun's thermal energy[10]) so that paint fading integrates exposure to daylight over time rather than directly assessing thermal stress. Paint fading gives an indication of the activity of individuals over an extended period.

A saturated solution of benzyl blue in monoethyleneglycolmonoethylether was added to yellow polyurethane paint (International Paint Co., Series 101) to produce a dark green compound. Experimental snails were collected in the valley of the Garonne in the Spanish Pyrenees, where *C. nemoralis* is highly polymorphic[11]. Behavioural responses were tested in seminatural conditions in cages in the field at Nettlecombe Court Field Centre, Somerset, UK. These cages have been used by Bantock[12] to study mortality in *C. nemoralis*. His results seem to reflect the fitness differences between shell morphs which exist in natural populations. The cages have the great practical advantage that all surviving marked snails can be recaptured.

Twenty adult yellow unbanded and the same number of yellow five-banded snails were collected from each of 10 natural populations of *C. nemoralis* during the period 19–23 June 1981. In every case snails were collected from an area smaller than that of a panmictic population[13]. Each snail was marked with a small spot of paint placed 5 mm behind the lip at the equator of the shell, and the populations were placed in 10 field cages planted with nettles and grass on 3 July 1981. The extent of paint fading was measured 60 days later (Table 1).

There are significant differences between banded and unbanded snails in mean exposure to daylight. In every cage,

Paint fading on green to yellow scale of marked *C. nemoralis* in field population cages. U, unbanded snails; B, banded.

0028–0836/82/330749–02$01.00

unbanded shells show a lower mean paint fading than do banded. This is in itself significant (sign test: $P = 0.002$), and in five cages the effect is shown by a Mann–Whitney U-test to be individually significant at the 5% level. The overall difference between the mean fading of unbanded (3.85 points) and banded (4.55 points) is highly significant ($t = 7.54$; $P < 0.001$). In addition, in 9 of the 10 cages there is a greater variance of fading among unbanded shells (sign test: $P = 0.022$). There are therefore considerable behavioural differences associated with the shell polymorphism of *C. nemoralis*.

Partitioning of the environment by snails of different genotype may result either from temporal or from spatial differences in activity. There is a general tendency for related coexisting species of small poikilotherm to differ in their times of activity[14]. *C. nemoralis* and *Cepaea hortensis* differ in their period of maximum activity in a way which is related to their preferred microclimate[15]. Australian *Theba pisana* show differences in the seasonal activity of dark and light-coloured snails which depend on their thermal relations in sunshine[16]. This effect might also be important in *C. nemoralis*, so that the dark-coloured banded shells are active for a higher proportion of the day in the cool English climate.

Banded and unbanded snails might also choose to live at a different height above the surface. Behaviour in sunlight is the prime mode of thermoregulation in invertebrates[17]. Temperature stresses are often greater near the ground because of the development of a layer of heated air on sunny days[10] and many organisms exposed to solar stress choose to live at some distance above the surface. Mediterranean *Helicella virgata*, for example, reach a lethal temperature much more often when resting at 3 cm above the ground than when at 70 cm (ref. 18). In *C. nemoralis*, also, snails climb most actively in hot dry weather[19]. Behavioural thermoregulation of this kind is likely to be particularly important in banded *C. nemoralis*, which are more liable than are unbandeds to die of heat shock when exposed on the ground surface on sunny days[20]. Banded snails will therefore climb higher than do unbanded, so that their paint spots will fade to a greater extent. The greater variance of fading scores among unbanded snails suggests that they have a wider range of behaviours and hence a broader niche with respect to general activity, perhaps because they can penetrate both into the layer of heated air near the ground and the direct rays of the Sun at the top of the vegetation. Experiments with *Drosophila* show that temporal fluctuations in habitat are as effective in maintaining polymorphism as are spatial changes[21], so that differences in either time or location of activity by snails of different shell phenotype might favour the evolution of shell polymorphism.

In laboratory populations of various organisms, genetic differences in habitat selection increase the fitness of particular alleles[22–24], and allow a *Drosophila* mutant to be maintained in a heterogeneous environment although it is otherwise harmful to its carriers[25]. Very few examples of genetic polymorphism for habitat selection have been established in natural or semi-natural conditions[16,26]. The experiments described here show that different shell genotypes of *C. nemoralis* have differences in patterns of activity which may influence their fitness and hence promote shell polymorphism. This technique of integrating activity over time may be generally useful in exploring the behavioural ecology of the individual differences thought to exist in various animals as they search for food, for mates or for territory.

This work was supported by the NERC and the Royal Society. I thank the Field Studies Council and Dr S. M. Tilling for help at Nettlecombe Court; Dr C. R. Bantock for the use of his field cages; Professor C. A. B. Smith for statistical advice; Messrs S. Borfield, P. Slepokura and D. Young for help in the field; and Dr M. Tordoff of the Society of Dyers and Colourists, Dr A. Davis of the Propellants, Explosives and Rocket Motors Establishment and Dr K. L. Rabone of Unilever Research for advice on measuring solar radiation.

Pluripotent embryonic stem cell lines can be derived from t^{w5}/t^{w5} blastocysts

Terry Magnuson*, Charles J. Epstein*†,
Lee M. Silver‡ & Gail R. Martin§

New York 11724, USA

Mouse embryos homozygous for t^{w5}, a recessive lethal mutation in the t complex located on chromosome 17, develop normally until the elongated egg cylinder stage, approximately 6.5 days after fertilization. At this time, the endoderm is morphologically abnormal and the embryonic ectoderm begins to show signs of pyknosis. Death of the embryo usually occurs within the next 2 days (ref. 1). A serious difficulty in the study of lethal t-mutant gene expression during embryogenesis has been to obtain appropriate experimental material, particularly during the period immediately following implantation. Recently, a method involving the use of teratocarcinoma-conditioned medium was devised for establishing pluripotent stem cell cultures directly from the inner cell mass (ICM) of a normal mouse blastocyst[2]. Using this method, we have established three embryonic stem cell lines derived from embryos carrying t^{w5}. We report here that one of the cell lines is homozygous for the mutation (t^{w5}/t^{w5}), whereas the other two are heterozygous ($+/t^{w5}$). When injected into athymic mice, each cell line is capable of forming tumours that contain differentiated derivatives of all three primary germ layers.

The three embryonic stem cell lines were obtained from cultures of 10 ICMs isolated from t^{w5}-bearing blastocysts. Mass cultures of the cell lines are indistinguishable from other established embryonic stem cell and teratocarcinoma stem cell lines in both morphological and growth characteristics. When tested for expression of the SSEA-1 cell-surface antigen[3], which is common to teratocarcinoma stem cells and early embryos but not to most differentiated cell types, all three cell lines derived from t^{w5}-bearing embryos were found to be positive by indirect immunofluorescence.

It would be desirable, of course, to identify the genotypes of these embryonic stem cell lines by determining whether they produce the wild-type or mutant t^{w5} gene products. However, as these products are unknown, we have used other genetic markers which identify three different regions of the t^{w5}-bearing chromosome. The validity of the markers depends on the fact that the t^{w5} lethal mutation is carried in the context of a

0028–0836/82/330750—04$01.00

complete t^{w5} haplotype. This t^{w5} haplotype, like all other complete *t* haplotypes, represents a variant form of a large region of chromosome 17 extending from the *T* locus near the centromere to beyond the *H-2* complex (reviewed in ref. 4). In addition to the mutation affecting embryonic development, which for t^{w5} has been mapped near the centre of the complete t^{w5} haplotype[5], all *t* haplotypes carry variant alleles of several other genes, including factors that affect sperm differentiation and function. The integrity of a *t* haplotype is maintained by an extreme suppression of meiotic recombination between *t*-haplotype and wild-type chromatin (for reviews see refs 4,6–8).

The first marker we used identifies the presence or absence of a t^{w5}-bearing chromosome. The embryos from which the stem cell lines were derived were obtained by crossing t^{w5}/Rb(16.17)7Bnr mice. In these embryos, the t^{w5} mutation is carried on an acrocentric chromosome 17, whereas the wild-type allele is carried on the Rb(16.17)7Bnr translocation chromosome (comprising chromosomes 16 and 17 fused at the centromere) which thus serves as a marker for its presence. Consequently, in the absence of recombination, chromosome spreads from embryonic stem cells homozygous for t^{w5} will not have a translocation chromosome, heterozygous cells will have one and wild-type cells will have two. When the karyotype of embryonic stem cell line 1 was examined, none of the spreads contained a translocation chromosome (Fig. 1*a*). In contrast, embryonic stem cell lines 2 and 3 both had a translocation chromosome (Fig. 1*c*).

Because there is a 4–6% chance of meiotic recombination occurring between the centromere and the start of the *t*-

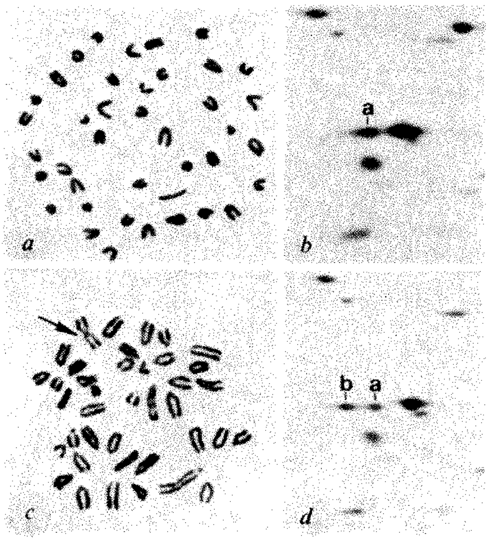

Fig. 1 Identification of embryonic stem cell genotype. Ten ICMs were isolated from blastocysts obtained by mating t^{w5}/Rb(16.17)7Bnr mice. (As the transmission ratio of the t^{w5} haplotype on our background is 87%, we would expect four to five of the ICMs to be t^{w5} homozygotes.) They were seeded on confluent monolayers of mitomycin C-treated fibroblasts in Dulbecco's modified Eagle's medium supplemented with 10% calf serum, 10^{-4} M 2-mercaptoethanol and concentrated conditioned medium[2]. Within 1 week, three of the ICMs had proliferated to form undifferentiated stem cell colonies. These colonies were disaggregated by treatment with trypsin and, with the use of a micropipette, were subcultured to new feeder layers. The cell populations were then expanded according to the procedures outlined by Martin[2], except that the addition of concentrated conditioned medium was discontinued after three passages. When the karyotype of embryonic stem cell line 1 was examined (*a*), 38% of the cells had 40 chromosomes, 30% had 41 and 10% had 42. A translocation chromosome was not observed in any spread. In addition, only the p63a protein was found marked a in (*b*). These data identify line 1 as homozygous for t^{w5}. 39% of the cells of embryo-derived cell line 2 were found to have 42 chromosomes and 22% had 41. 84% of the cells of line 3 had 40 chromosomes. The presence of a translocation chromosome (arrowed in (*c*) and p63a and p63b (a and b respectively in *d*) identifies lines 2 and 3 as heterozygous for t^{w5}. For karyotyping, 10^7 stem cells were seeded in 60 mm^2 tissue culture dishes and cultured overnight. They were then incubated for 30 min in medium containing 10 μg ml^{-1} colcemid (Gibco), washed with phosphate-buffered saline (PBS) and collected after exposure to trypsin. The cells were centrifuged, and the pellet resuspended in 10 ml of 0.56% KCl. After 25 min, the cells were again centrifuged and the resulting pellet resuspended in 10 ml of 3:1 methanol/acetic acid fixative. The fixative solution was changed three times and then refrigerated overnight. The following day, the pellet was resuspended in 1 ml of a freshly made fixative solution, and chromosome spreads were prepared by placing a drop of the cell suspension on cleaned, wetted microscope slides. The chromosomes were stained with 3% Giemsa (GURR) for 5 min. For two-dimensional gel electrophoresis, embryonic stem cells were separated from feeder layer cells by a double preplating technique[2]. The stem cells were then seeded in 16 mm^2 multi-well tissue culture plates (Flow Labs) at a density of 10^6 and cultured overnight. After washing with PBS, the stem cells were incubated in methionine-free medium for 30 min and then for 5 h in methionine-free medium containing 250 μCi ml^{-1} of ^{35}S-methionine (specific activity of 900–1,100 Ci mmol^{-1}; Amersham). The labelled cells were washed with PBS and lysed with 100 μl of isoelectric focusing sample buffer[18]). Two-dimensional gel electrophoresis was performed as outlined by O'Farrell[18] with a 4.5% stacking gel and a 10% separating gel being used in the second dimension. Kodak NS-2T film was used for autoradiography of the dried gels. Only the area of the gel pattern containing p63 is shown.

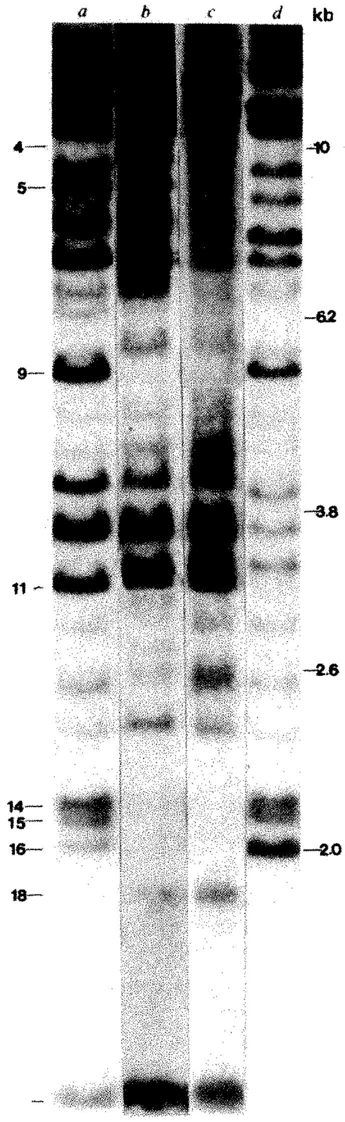

Fig. 2 Blot hybridization analysis of *H-2*-like genes from embryonic stem cell line 1. *Eco*RI restriction patterns of *a*, 129(t^{0}/t^{w5}); *b*, 129(+/t^{w5}); *c*, embryonic stem cell line 1; and *d*, Rb(16.17)7Bnr/Rb(16.17)7Bnr. High molecular weight DNA was prepared from adult livers or embryonic stem cells as described previously[13]. DNA was digested to completion with *Eco*RI and 5-μg aliquots of each sample were electrophoresed through a 1% agarose gel at 0.7 V cm^{-1} for 36 h. Southern blot hybridization was performed with clone pHIIa DNA[19] nick-translated to a specific activity of 2×10^8 c.p.m. μg^{-1}, and used at 8.2×10^4 c.p.m. cm^{-2} of filter. Hybridization and washing conditions were as described previously. Particular *t*-specific *Eco*RI fragments are numbered at the left according to Silver[13]. The numbers at the right denote the size and positions of the DNA length standards, in kilobases (kb). Lanes *b* and *c* are composites of different exposures of the same gel.

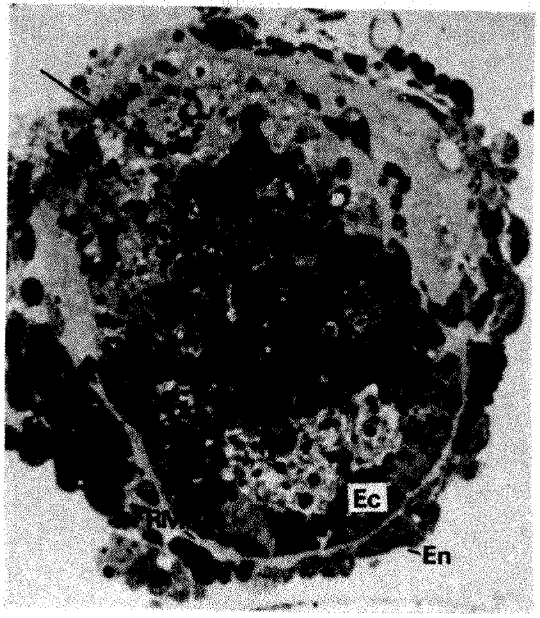

Fig. 3 Section of an embryoid body formed by t^{w5}/t^{w5} embryonic stem cells. Aggregates of cells were cultured in Petri dishes for 16 days. The embryoid bodies which formed were fixed in 2.5% glutaraldehyde, dehydrated and embedded in Epon, and 1.5-μm sections were prepared. Part of a cavitating embryoid body, consisting of columnar ectoderm (Ec) surrounded by a layer of endoderm-like cells (En) with underlying Reichert's membrane-like material (RM), is shown. There are numerous pyknotic cells (arrow) in this embryoid body. ×240.

haplotype region[9], the second marker we used was the *Tcp-1* gene located in the region of the t^{w5} haplotype proximal to the lethal gene[10]. All complete *t* haplotypes, including t^{w5}, carry a variant *Tcp-1* allele (*Tcp-1*^{a}) which encodes a polypeptide p63/6.9a (abbreviated p63a) that is readily distinguishable from the wild-type gene (*Tcp-1*^{b}) product (p63/6.9b or p63b) by two-dimensional gel electrophoresis[11]. Thus, t^{w5} homozygous cells express only the p63a form of the polypeptide, heterozygous cells express both p63a and p63b in equal amounts and wild-type cells express only the p63b form. When the protein gel pattern of embryonic stem cell line 1 was examined, only the p63a form of the polypeptide was observed (Fig. 1*b*). In contrast, both p63a and p63b were expressed in roughly equal amounts by embryonic cell lines 2 and 3 (Fig. 1*d*).

As meiotic recombination within the *t* complex is highly suppressed (recombination frequency between 0.001 and 0.002)[6], the probability that *Tcp-1* has been separated from the t^{w5} lethal mutation and that cell line 1 is not homozygous for t^{w5} is extremely low (≤0.004). Nevertheless, we used the family of genes comprising the *H-2* complex as a third marker to demonstrate that cell line 1 carries only the t^{w5} haplotype. The *H-2* complex is located in the region of the t^{w5} haplotype distal to the lethal factor[5]. *t*-haplotype-specific restriction fragments carrying DNA sequences homologous to the *H-2* class I genes have recently been described[12,13]. With the use of the restriction enzyme *Eco*RI, multiple *t*-haplotype-specific fragments can be observed in the context of the 129/SvJ background pattern (Fig. 2, lane *a*). Although fragments 5, 11 and 17 are shared by all complete *t* haplotypes, fragments 4 and 18 are unique to the t^{w5} haplotype (Fig. 2, lane *b*) and are not present in genomic DNA from other lethal and semilethal haplotypes such as t^{0}, t^{w2}, t^{w12} or t^{12}. All the other well characterized *t* haplotypes display fragments 9, 14, 15 and 16 whereas t^{w5} does not[13]. The *H-2* haplotype associated with the Rb(16.17)7Bnr chromosome also displays *Eco*RI fragments which migrate in the same regions as *t* fragments 9, 14–16 (Fig. 2, lane *d*).

*Eco*RI-digested DNA from embryonic cell line 1 displays *t*-specific *H-2* fragments 5, 11 and 17, and t^{w5}-specific fragments 4 and 18 (Fig. 2, lane *c*). This pattern of *Eco*RI fragments is characteristic of the t^{w5} haplotype. The absence of fragments 9, 14–16 rules out the unlikely possibility that a lethal or semi-lethal haplotype other than t^{w5} is present in this cell line, and also verifies the absence of the *H-2* genomic region of the Rb(16.17)7Bnr chromosome.

Taken together, the analyses of the three markers demonstrates conclusively that line 1 is homozygous for regions of the t^{w5} haplotype both proximal and distal to the t^{w5} lethal gene. As suppression of recombination along the t^{w5} haplotype reduces the probability of a double recombination event to $\sim 10^{-6}$, we can definitely conclude that this cell line is homozygous for the t^{w5} lethal gene.

To determine whether the embryonic stem cells can mimic early embryogenesis, the homozygous and one of the hetero-

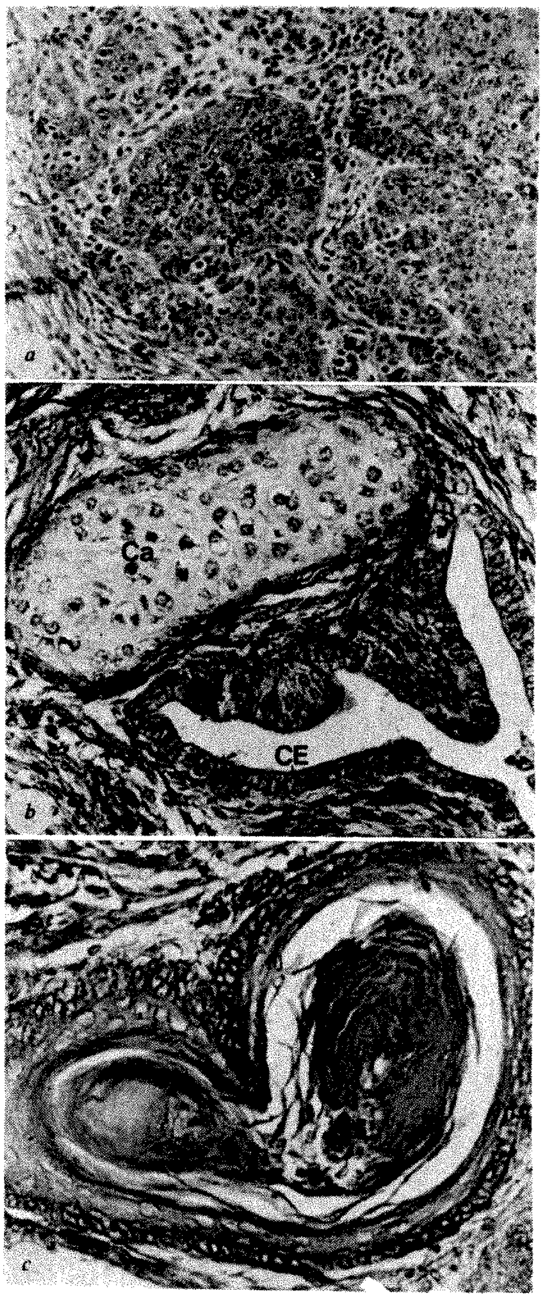

Fig. 4 Sections of tumours formed after subcutaneous injection of 5×10^{6} t^{w5}/t^{w5} embryonic stem cells into an athymic nude mouse. After 2–6 weeks the tumours that had formed were removed, fixed in Bouin's solution, embedded in paraffin and sectioned. The cell types observed in the tumours included *a*, groups of undifferentiated stem cells (SC); *b*, cartilage (Ca) and columnar epithelium (CE); and *c*, keratinizing epithelium. *a*, ×80; *b*, ×104; *c*, ×112.

zygous cell lines were cultured in appropriate conditions[14]. Both cell lines were able to form embryoid bodies. Under the light microscope, the t^{w5}/t^{w5} embryoid bodies were observed to consist of a core of ectoderm-like cells surrounded by a layer of endoderm-like cells. Typical Reichert's membrane-like material, presumably secreted by the endodermal cells, was observed in almost all the t^{w5}-homozygous embryoid bodies, and the beginning of pro-amniotic cavity formation was observed in the core of some (Fig. 3). Extensive death of core cells was observed in some of the t^{w5}/t^{w5} embryoid bodies. However, although ectoderm degeneration is characteristic of t^{w5}/t^{w5} embryos *in utero*, the cell death observed in the t^{w5}/t^{w5} embryoid bodies cannot necessarily be attributed to the effects of the t^{w5} lethal mutation as numerous pyknotic cells have also been observed in the core of embryoid bodies formed by some wild-type teratocarcinoma stem cell lines (G.R.M., unpublished data).

As the variety of cell types formed during the development of embryoid bodies is always limited, each of the t^{w5}-bearing embryonic stem cell lines was injected into several athymic mice (*nu*/*nu*) to determine the extent of their differentiative capacities. Within 2–6 weeks, all the cell lines produced tumours containing undifferentiated stem cells as well as differentiated derivatives of all three primary germ layers. The differentiated cell types included neural, keratinizing, pigmented and columnar epithelium, yolk sac endoderm, cartilage, muscle and connective tissue (Fig. 4*a*–*c*). Similar results were obtained with a subclone of the t^{w5}/t^{w5} embryonic stem cell line. We thus conclude that the t^{w5}-homozygous embryonic stem cell line is pluripotent and capable of differentiating into a large number of differentiated cell types. Many of these cell types are not formed by t^{w5}/t^{w5} embryos *in utero* because the embryo dies before all three primary germ layers are established[1].

The mechanisms of *t*-mutant lethality are not yet understood. One hypothesis is that at least the earlier-acting lethal *t* mutations, such as t^{12}, t^{0} and t^{w5}, are generalized cell lethals that cause embryonic death by perturbing processes such as intermediary metabolism, which are essential for the survival of all cells in the embryo[15]. Wudl and Sherman[16] interpreted their observation that all cells in cultured presumptive t^{w5}/t^{w5} blastocysts die at earlier times than do cells of control embryos as evidence that t^{w5} is a generalized cell lethal. Hogan *et al.*[17] also showed that presumptive t^{w5}/t^{w5} ICMs are smaller, abnormally organized and apparently moribund when compared with ICMs from normal embryos. Our results, however, demonstrate that t^{w5}/t^{w5} ICM cells are sufficiently viable to give rise to an embryonic stem cell line which, in the appropriate environment, can differentiate into a wide variety of cell types. The simplest explanation of these results is that the t^{w5} mutation does not result in generalized cell lethality. Death of t^{w5}/t^{w5} embryos must therefore be due to other causes. The availability of the t^{w5}-homozygous embryonic stem cell line described here should make possible new approaches to the study of how such lethal *t* mutations affect normal development.

Plasminogen activator–plasmin system and neuronal migration

G. Moonen*, M. P. Grau-Wagemans† & I. Selak*

Neuroontogenesis results from a synchronized series of elementary events including cellular proliferation, migration, differentiation, recognition and death. Neuronal migration is a key step in neural morphogenesis since inadequately located neurones may not establish the appropriate connections and this may lead to neuronal death or to functional deficit of synaptic circuits. Impairment of neuronal migration has been implicated in human pathology[1] and well documented in animal pathology, such as the *weaver* mutation in mice[2]. The cerebellum of small rodents is particularly well suited for the study of neuronal migration because a subpial neuronogenesis occurs postnatally. The subsequent inward migration of postmitotic neurones (mostly granule cells) has been studied using classical neuroanatomical methods, such as the Golgi stain[3], and autoradiography after systemic injection of ^{3}H-thymidine[4]. Systematic ultrastructural investigation of neuronal migration at different levels of the central nervous system and in different species led Rakic to propose the radial glia hypothesis—that neurones migrate along radial glia cells which serve as guides during migration[5]. The observation that neurones migrate inside a densely packed neuropile has prompted us to consider the possible role of extracellular neutral proteolysis during neuronal migration. We have focused on the plasminogen activator (PA) serine proteases because these enzymes are known to be involved in several phenomena that involve cell migration or tissue remodelling[6]. The usual substrate for PA is plasminogen, which is converted to plasmin, although other substrates may exist[7]. We report here that both PA and plasmin are released by cultived 7-day-old rat paraflocculus, but not by 1-month-old or adult rat paraflocculus (that is, after granule cell migration), and that inward migration of cerebellar granule neurones, which account for 95% of the cells in adult cerebellum, can be inhibited by inhibitors of the PA–plasmin system.

We have studied PA and plasmin activity with the use of the classical fibrin plate assay[8,9]. When standard plates are used, it is possible to demonstrate both endogenous PA and plasmin activity; with heated plates only endogenous plasmin activity can be detected (see Fig. 1 legend). When a 7-day rat cerebellum paraflocculus (the most lateral part of the cerebellum) was explanted for 24 h at 37 °C on a standard fibrin plate, a fibrinolytic zone formed around it; the fibrinolysis could be inhibited by 6-aminocaproic acid. In the same conditions, but using heated fibrin plates, a smaller but definite fibrinolytic zone could be seen, demonstrating that not only PA but also plasmin are released by the 7-day rat paraflocculus. If these enzymes were to have a role in neuronal migration, we reasoned that 1- or 3-month (adult) rat paraflocculus should not release PA and plasmin. We found that, indeed, provided the meninges were carefully dissected, in neither case could a release of PA or plasmin be demonstrated (see Fig. 1 for example). We also conclude from this experiment that the fibrinolysis observed with the 7-day rat paraflocculus is not due to damage (such as anoxia or nonspecific release of proteolytic enzymes). Extracellular release of PA and plasmin activity is even more obvious

0028-0836/82/330753—03$01.00

if the conditioned medium from 7-day rat paraflocculus suspension culture is assayed using standard or heated fibrin plates. 6-Aminocaproic acid again inhibits the fibrinolytic activity and in these conditions neither PA nor plasmin activity could be demonstrated in medium conditioned by 1-month or adult rat paraflocculus.

We next investigated whether inhibition of PA or plasmin affected cell migration, using organotypic suspension cultures of the 7-day paraflocculus. In these cultures, the external granular layer (EGL) disappears within 2 days. Further experiments, including sequential autoradiography after intraperitoneal injection of ^{3}H-thymidine 60 min before dissecting the paraflocculus, showed that the disappearance of the EGL was due to inward migration of EGL cells such as occurs *in vivo* (in preparation). The persistence of the EGL beyond 2 days could thus be considered as a criterion for migration blockade. The following inhibitors were used: 6-aminocaproic acid, which binds to plasminogen and inhibits the transformation of plasminogen to plasmin; diisopropylfluorophosphate, a general inhibitor of serine proteases; trasylol and soybean trypsin inhibitors which are antiplasmin agents; and D-Phe-Pro-Arg-CH_2Cl and D-Val-Phe-Lys-CH_2Cl which are specific and potent inhibitors of tissue PA and plasmin respectively (ref. 10 and D. Collen, personal communication). All the inhibitors inhibited inward migration of EGL cells (Fig. 2), and, judging from phase-contrast examination of dissociated 7-day rat cerebellum cultures, at the concentration used they had no toxic effect. The data show that (1) not only PA but also plasmin activity are released into the extracellular space of the cerebellum during migration and (2) neuronal migration is inhibited by agents which act on PA and plasmin activity.

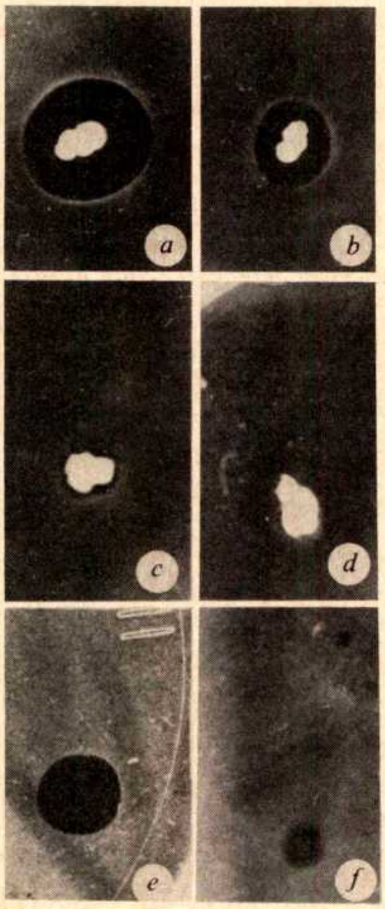

Fig. 1 Demonstration of plasminogen activator and plasmin release by 7-day-old rat paraflocculus. Fibrin plates were prepared as described in ref. 8; 200 mg of crude bovine fibrinogen (containing plasminogen) were dissolved in 100 ml of veronal buffer (*p*H 7.3) with 0.5 ml of 1% merthiolate solution added. To 3 ml of fresh fibrinogen solution (kept at 37 °C), 0.7 ml of thrombin (100 NIH units per ml of Veronal buffer) was added and the mixture layered in the compartments of Petri dishes (Falcon 1004 Y). If the plates are kept at 37 °C, both PA and plasmin activities can be detected. If the plates are heated to 80 °C for 20 minutes, the plasminogen is inactivated and the tissue must generate not only endogenous PA but also endogenous plasmin in order to induce fibrinolysis[9]. The diminished lytic zone, as compared with standard plates, indicates that plasminogen in the tissue sample is the limiting factor. Paraflocculi were dissected from 7-day (*a*–*c*) or 1 month (*d*) rat cerebella. Meninges were carefully removed under the dissecting microscope. The whole (7-day-old) or part (1-month-old) paraflocculus was then explanted in 0.5 ml of N_1MEM medium serum-free culture medium[15] on the fibrin plates which were incubated at 37 °C for 24 h, and then photographed. Serum-free conditioned medium was obtained from suspension cultures of cerebellar paraflocculus in some experiments or of slices of the whole cerebellum in other experiments (see Fig. 2 legend for details on the tissue culture). The medium was collected, centrifuged (100,000*g*, 60 min) and filtered through a 0.22 μm Millipore filter. The conditioned medium was used immediately although activity was not modified by freezing at −20 °C for 1 week. Forty μl of the conditioned medium were then seeded on either 37 °C or 80 °C fibrin plates, which were photographed after 24 h. *a*, 7-day-old rat paraflocculus, 37 °C plate; *b*, 7-day-old rat paraflocculus, 37 °C plate. 5×10^{-4} M 6-aminocaproic acid was added to the medium. At that concentration partial inhibition of the fibrinolysis is observed. Complete inhibition was obtained at 5×10^{-3} M; *c*, 7-day-old rat paraflocculus, 80 °C plate; *d*, 1-month-old rat paraflocculus, 37 °C plate; *e*, conditioned medium from 7-day-old rat paraflocculus suspension culture, 37 °C plate; *f*, conditioned medium from 7-day-old rat paraflocculus suspension culture, 80 °C plate. ×1.7.

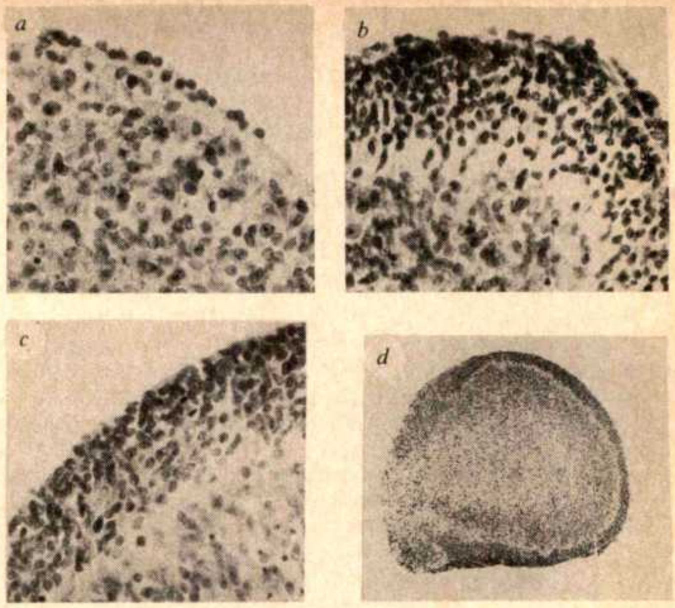

Fig. 2 Effects of inhibitors on neuronal migration. Cerebellar paraflocculi were dissected from 7-day-old rats and cultured in suspension (gyrotory shaker New Brunswick G2, 100 r.p.m.) for 48 h in high-glucose (600 mg%) minimal essential medium supplemented with either 10% heat-inactivated horse serum or with the N_1 component[15] (the same results were obtained with both media). Different inhibitors of the PA–plasminogen–plasmin system were added (see text). *a*, Control culture showing the disappearance of the external granule cell layer after 2 days. *b*–*d* Illustrate the effect of some of the inhibitors used: *b*, 10^{-3} M EACA; *c*, 10^{-4} M D-Val-Phe-Lys-CH_2Cl; *d*, 10^{-4} M D-Phe-Pro-Arg-CH_2Cl. In the presence of inhibitor, the EGL does not disappear, showing that the inward neuronal migration is blocked. At least five samples were examined in each condition. Paraffin sectioning. Gallocyanin stain. *a*–*c*, ×240; *d*, ×42.

The present study is not concerned with cellular location of PA or plasminogen. Recent reports[11–14] suggest, however, that PA is released by neurones and, in the case of the 7–9-day postnatal mouse cerebellum, by granule neurones. The tissue localization of plasminogen is unknown, although there are several possibilities. For example, it could be present on the outer surface of the radial glia or released by the radial glia in the neighbouring extracellular space. Plasmin would be locally generated and the modification of cell surfaces or spaces on or near the glial process would generate an area permissive for inward migration of granule cells. This mechanism is consistent with the radial glia hypothesis. Alternatively, plasminogen could be distributed throughout the extracellular fluid and not restricted to the Golgi epithelial cell. Finally, it should be noted that the molecular nature of the substrate(s) for plasmin in the brain is at present unknown.

Transformation of fast fibres to slow prevented by lack of activity in developing lobster muscle

C. K. Govind* & Karla S. Kent†‡

* Scarborough College, University of Toronto, West Hill, Ontario, Canada M1C 1A4
† Boston University Marine Program, Marine Biological Laboratory, Woods Hole, Massachusetts 02543, USA

Adult mammalian twitch muscle fibres are extremely plastic, being able to transform from one type to another under the direction of their motoneurones[1–3]. The most unequivocal type of fibre transformation is that of fast-twitch to slow-twitch type, either with cross-reinnervation of the fast muscle with a slow nerve[4–6], or with chronic low frequency stimulation of the intact nerve to a fast muscle[7,8]. Moreover, direct electrical stimulation of the muscle itself with a tonic pattern is just as effective in converting fast fibres to slow[9]. All these experiments suggest that activity of the muscle itself, imposed by whatever means, is crucial in the transformation of fast to slow fibres[8,10]. A similar transformation during development may be responsible for producing the adult diversity of fibre types, as fibres begin by synthesizing myosin of an embryonic type which is replaced by a neonatal type and finally the adult type of fast[11] and slow[12], which occurs concurrently with innervation. We report here that during development of the paired claw closer muscle in lobsters, reducing or eliminating activity in one of the muscles by tenotomy or denervation prevents its fast fibres from becoming transformed into slow. Our results therefore suggest a regulatory role for activity in the differentiation of lobster slow fibres.

The adult lobster *Homarus americanus* has dimorphic claws consisting of a slender fast-acting cutter claw and a stout, slow-acting crusher claw[13,14]. The claw closer muscles are similarly differentiated, the cutter having a majority (60–80%) of fast fibres and the crusher having all slow fibres[15,16]. However, in the three larval[17] and first juvenile[18] stage the paired claws and closer muscles are symmetrical. Each muscle has ~30% fast fibres in a central band, with the remaining slow fibres distributed above and below the fast band[19]. During subsequent development, one of the muscles differentiates into a cutter with a majority of fast fibres and the other into a crusher with all slow fibres[18]. Claw and closer muscle type becomes determined some time during the 4th and early 5th stage and remains fixed thereafter[20]. As claw laterality (whether the crusher appears on the right or left side) is not genetically prespecified, extrinsic factors may influence the determination of claw type and muscle fibre type during the critical 4th and early 5th stage. Indeed, rearing juvenile lobsters without a substrate suppresses development of a crusher claw (and slow fibres) and instead produces paired cutter claws[21]. Because juvenile lobsters normally manipulate the substrate with their claws, it was proposed that the lack of exercise in the absence of a substrate suppressed the differentiation of a crusher claw. To test this hypothesis, we have examined the effects on claw dimorphism of rearing lobsters with or without substrates that they could manipulate and while restricting the use of one of the paired claws.

Larval lobsters were obtained from a hatchery and reared communally until the moult to the 4th stage, when they were placed individually in plastic trays[22]. Following experimental manipulation in the 4th and 5th stages, claw laterality was assessed in the 9th stage or beyond. At this stage the cutter claw is distinctly slender, covered with sensory bristles and has a major incisor-like tooth on its pollex. In contrast, the crusher is stout, has few sensory bristles and has a major molar-like tooth. The fibre composition of the claw closer muscles was based on histochemical demonstration of myofibrillar ATPase in frozen serial sections of the entire claw using the method of Padykula and Hermann[23], modified for lobster muscle[24]. As the specific activity of myofibrillar ATPase is two to three times higher in fast crustacean muscle than in slow[25,26], the former fibres stained more intensely than the latter (Fig. 1). Usually,

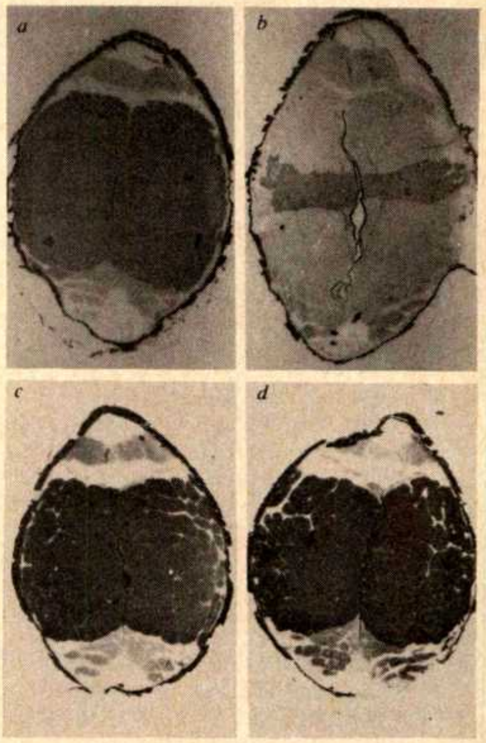

Fig. 1 Representative cross-sections midway through a serial series treated histochemically for myofibrillar ATPase in a pair of dimorphic cutter (*a*) and crusher (*b*) claws and a pair of cutter (*c, d*) claws from 9th stage juvenile lobsters reared with and without oyster chips, respectively. At this stage the closer muscle in the cutter claw (*a*) has almost completely differentiated, consisting mostly of intensely staining fast fibres with a small ventral band of less intensely staining slow fibres. Staining intensity of these ventral fibres is similar to that of the opener muscle which is known to be composed of all slow fibres. The closer muscle in the crusher claw (*b*) has a majority of fibres staining with the same intensity as the opener muscle thus denoting slow fibres except for a narrow central band of intensely staining fast fibres which are transformed into slow fibres in subsequent stages. In a juvenile lobster reared without a substrate, however, the closer muscles in the paired claws (*c, d*) are identical, having the fibre composition of a typical cutter muscle; a crusher muscle is completely suppressed. A detailed description of fibre types based on enzyme histochemistry in the lobster claw closer muscles has been published elsewhere[19]. ×18.

‡ Present address: Department of Biological Sciences, Columbia University, New York, New York 10027, USA.

Table 1 Configurations of paired claws in juvenile lobsters reared with a variety of substrates and without any substrate

	Configurations of paired claws					
	Right cutter and left crusher	Right crusher and left cutter	Double cutter	Total no. reared	No. tested histochemically	*P*
Oyster chips	15	14	3	32	8	
Mud	7	12	3	22	5	NS
Gravel	13	7	2	22	5	NS
Plastic chips	13	9	1	23	8	NS
All substrate	48	42	9	99	26	
No substrate	1	0	33	34	9	<0.001

For each condition the lobsters were reared individually from the 4th stage until the 9th stage or beyond, when the configuration of the paired claws was assessed visually in all lobsters and histochemically in a few lobsters to determine the fibre composition of their closer muscles. The table lists the number of lobsters with each claw configuration, the total number reared and the number examined histochemically. With the oyster chips as the control condition, significance was assessed for each of the other substrate and no substrate conditions using the contingency χ^2 test. A cumulative tally of the different substrate-reared lobsters is given under the 'all substrate' condition. NS, not significant.

for each experimental condition 25% of the animals were tested histochemically (Tables 1, 2) and in each case the external claw type accurately reflected the fibre composition of its closer muscle. In other words, the cutter muscle consisted entirely of fast fibres except for some ventral slow fibres while the crusher possessed all slow fibres except for a central band of fast fibres (Fig. 1*a*, *b*). As the juvenile closer muscles were separated into these two distinct types, the external claw type served as a reliable indicator of the type of closer muscle within it.

We began by repeating the original experiment[21] in which lack of a substrate suppressed development of a crusher claw and hence of slow fibres in 30% of the lobsters. In the original experiment juvenile lobsters were seen pinching the rubber stoppers over the drain hole with their claws. To prevent this, we covered the rubber stopper with a plastic tube and now found that 97% of the lobsters failed to develop a crusher claw (Fig. 1, Table 1). This was significantly different from the control condition of raising lobsters with oyster chips as substrate, which produced 91% with dimorphic claws and only 9% with both cutter claws. The two dimorphic configurations appeared in approximately equal proportions. Clearly, the lack of oyster chips as a substrate prevented transformation of fast fibres to slow and differentiation of a crusher muscle.

To test that it was not any special properties of the oyster chips which was the determining factor but rather their physical presence, we reared lobsters with mud, gravel and even plastic chips as substrate (Table 1). In each case, the majority (78.5%) of lobsters grew dimorphic claws; a minority failed to grow a crusher claw. For each of the different substrate conditions, the claw configurations were not significantly different from the control condition. Consequently, the presence of a substrate, of any kind, as long as it could be manipulated, is necessary for the differentiation of a crusher closer muscle. Furthermore, in the dimorphic condition, the crusher claw appears with almost equal probability on the right or left side, as shown when a tally is made of all substrate conditions (Table 1). This suggests that before the 4th and early 5th stage, each claw of a pair has the potential for developing into a crusher but greater use of one claw in the critical period is the determining factor.

We therefore reared lobsters with oyster chips, but restricted the use of one of the claws to varying degrees. We arbitrarily chose to restrict use of the right claw while leaving the left one intact (Table 2). Keeping the claw immobilized in the closed position with a rubber band or cutting of most of its dactyl did not prevent differentiation of a crusher claw; the right, or restricted claw became a crusher as often as the left, or unrestricted claw. This suggests that use of the claw *per se* was not critical in the differentiation of the crusher claw but that possibly some other minimal condition such as muscle activity was responsible. With neither immobilization nor dactylotomy is activity of the closer muscle prevented.

Consequently, we attempted to reduce muscle activity using more drastic procedures such as deafferentation. This was done by painting either the entire claw or just the pollex and dactyl with a fast-drying lacquer. In the former case the dactyl usually remained in the closed position simply because the entire claw was painted whereas in the latter case it was free to open and close and was seen to do so. Both forms of deafferentation appeared at first glance to suppress differentiation of a crusher claw (Table 2) because the majority of the right claws were cutters. However, when tested statistically the number of right cutter claws in these two experimental groups was not significantly different from those in the control group. These forms of deafferentation with their consequent reduction in motor output were not sufficient to suppress development of a crusher claw and of slow fibres in the closer muscle.

We therefore eliminated activity of the closer muscle by cutting its tendon where it attaches to the movable dactyl, thereby disconnecting the muscle. Tenotomy of the right closer muscle effectively inhibited the treated claw from becoming a crusher compared with its untreated counterpart in the control group (Table 2). As tenotomy has several effects on the closer muscle, it is difficult to determine which particular effect suppressed transformation of fast to slow fibres. For instance,

Table 2 Form of the right claw—whether cutter or crusher, when untreated or treated in various ways

	Right claw				
	Cutter	Crusher	Total no. reared	No. treated histochemically	*P*
Control	18	14	32	8	
Immobilization	9	11	20	5	NS
Dactylotomy	8	7	15	5	NS
Paint claw	15	4	19	5	NS
Paint pollex and dactyl	15	3	18	5	NS
Closer tenotomy	34	3	37	9	<0.001
Opener tenotomy	19	3	22	5	<0.02
Denervation	27	5	32	10	<0.02

* For each experimental group the right claw was manipulated in the 4th and again in the 5th stage and reared to the 9th stage, when its form was assessed visually in all lobsters and histochemically in a few lobsters for determining muscle fibre composition. Significance was determined between the control and each of the experimental conditions using the contingency χ^2 test.

tenotomy not only eliminates activity of the closer muscle but also eliminates its passive stretch and reduces the motor output to the claw muscles by disrupting the proprioceptive feedback.

On the other hand, tenotomy of the opener muscle which is an antagonist to the closer and is a small muscle occupying less than 10% of the claw muscle mass, also inhibited the treated claw from differentiating into a crusher (Table 2). Because this procedure allows the closer muscle to maintain its passive stretch, it rules out the possibility that loss of this stretch when the closer muscle was tenotomized suppressed the transformation of fast to slow fibres. Also, the relatively small size of the opener muscle would not seriously hinder contraction of the massive closer muscle when the opener is tenotomized. It is far more likely that tenotomy of the opener decreased motor output to the claw muscles because of reduction in proprioceptive feedback and sensory input from other sources. For example, some sensory nerve fibres from the dactyl run close to the insertion of the opener tendon and are presumably severed during tenotomy. Therefore, the failure to achieve some critical level of activity in fibres of the closer muscle prevents their transformation from fast to slow type.

As activity of the closer muscle is under the control of its nerve supply, we attempted denervation as a means of eliminating it without interfering with the muscle itself. This was done by destroying the anterior part of one side (right side) of the ganglion in intact animals. The cell bodies of the excitor motoneurones to the claw closer and opener muscles are located in this region of the ganglion in adult lobsters[27]. It was possible to destroy a relatively small anterior region of the ganglion with a finely sharpened pin. The efficacy of this surgery was confirmed by noting the loss of reflex activity in the claws and the destruction of the anterior part of the ganglion in post-mortem dissections of a few test lobsters. This form of denervation had a dramatic effect in that most lobsters failed to develop a crusher on the treated side (Table 2). Eliminating motor activity to the closer muscle prevents its fast fibres from transforming to slow.

Although denervation completely eliminates motor activity to the claw muscles, a reduction in activity such as with tenotomy of the opener muscle is just as effective in inhibiting formation of a crusher claw. Other, less acute treatments such as painting the claw, immobilization or dactylotomy, however, did not suppress development of a crusher claw, suggesting that a minimal level of muscle activity is required for the formation of a crusher claw. Our results therefore show that the reduction or elimination of muscle activity prevents the transformation of fast fibres to slow during development of the claw closer muscles in juvenile lobsters. Furthermore, the denervation experiments demonstrate the regulatory role of motoneurones in the differentiation of fibre types in lobster muscle. Such a crucial role for motoneurones in maintaining and determining fibre properties is well established for adult vertebrate muscle but has not previously been demonstrated in invertebrates and during development.

This work was inspired by the late Fred Lang. We thank H. L. Atwood for criticizing the manuscript, I. M. Campbell for help with statistical analysis, Joanne Pearce and Lena Hill for technical assistance and John Hughes of the Massachusetts State Lobster Hatchery on Martha's Vineyard for supplying us with larval lobsters. The work was supported by grants from the Natural Sciences and Engineering Research Council and the Muscular Dystrophy Association of Canada to C.K.G. and from the NIH (NINCDS) and the Graff Foundation to the late Fred Lang and A. G. Humes, Director, Boston University Marine Program.

Kainic acid stimulates excitatory amino acid neurotransmitter release at presynaptic receptors

Kainic acid (KA), a conformationally restricted analogue of glutamic acid, exhibits potent neuroexcitatory[1] and neurotoxic properties[2]. The mechanism of the neurotoxicity of KA, however, seems to be complex and indirect because in many brain areas neuronal vulnerability requires the integrity of excitatory afferents[3–6]. Nevertheless, neurophysiological studies indicate that the neuroexcitatory effects of KA in the mammalian brain are direct[7]. We have now examined the effects of KA and other excitatory amino acids on the stimulation of cyclic GMP formation in brain slices incubated *in vitro* as a method for monitoring their depolarizing effects[8]. We show in the adult mouse cerebellum that the excitatory amino acid antagonist, D-α-aminoadipate (DAA)[9], blocks the stimulation of cyclic GMP produced by *N*-methyl-D,L-aspartate (NMDLA) but potentiates the effects of KA. Whereas KA causes a significant release of both aspartic (Asp) and glutamic (Glu) acids by a calcium-dependent process, NMDLA is without effect; furthermore, the effects of KA on Glu release are markedly reduced in cerebellum deficient in granule cells. KA also releases Glu and Asp from hippocampal and striatal slices, indicating that this response is not unique to the cerebellum. The results are consistent with evidence that KA has direct excitatory effects on neurones[7] but suggest that its potent neurotoxic action involves the activation of presynaptic receptors on glutamatergic and aspartergic terminals, thereby releasing Asp and Glu.

Male albino mice weighing 25–35 g (Blue Spruce Farms) were used in all experiments. Some mice had been treated with methylazoxymethanol acetate (25 mg per kg) by intraperitoneal injection on the day of birth; this causes a selective deletion of granule cells[10]. Immediately after decapitation the brain was removed, and the cerebellum was rapidly isolated and sliced mechanically at 275 μm at 2 °C before being placed in oxygenated Krebs–bicarbonate buffer. Histological analysis of the slices indicated preservation of the neuronal components in the conditions of slice preparation and incubation used. The cerebellar slices were preincubated for 60 min at 37 °C in Krebs–bicarbonate buffer constantly bubbled with O_2–CO_2 (95:5), with three changes of buffer. Portions of the tissue were

Table 1 Effects of excitatory amino acids on cerebellar cyclic GMP

Condition	Cyclic GMP formed (% of control)
L-glutamate (10 mM)	198 ± 15 (9)*
N-methyl-D, L-aspartate (0.5 mM)	159 ± 10 (9)*
N-methyl-D, L-aspartate (10 mM)	234 ± 22 (4)*
α-Kainic acid (0.1 mM)	156 + 15 (4)*
α-Kainic acid (0.5 mM)	163 ± 9 (11)*
D-α-aminoadipate (0.25 mM)	116 ± 10 (22)
N-methyl-D, L-aspartate (0.5 mM) and D-α-aminoadipate (0.25 mM)	122 ± 14 (9)
α-Kainic acid (0.5 mM) and D-α-aminoadipate (0.25 mM)	251 ± 23 (11)*†

Cerebellar slices prepared from adult mice were incubated in conditions described in the text with the concentrations of amino acids indicated in parentheses and the amount of cyclic GMP formed was measured. The results are expressed in terms of per cent (±s.e.m.) of the cyclic GMP levels in control slices incubated in parallel; basal cyclic GMP levels were 5.4 ± 0.5 pmol per mg protein ($n = 33$). Statistical comparisons were made on the basis of absolute levels of cyclic GMP by ANOVA.

* $P < 0.001$ versus control; † $P < 0.02$ versus kainate alone.

then transferred to vials with 2 ml of fresh buffer containing the compounds of interest, and incubation was continued for an additional 15 min. The reaction was terminated by brief centrifugation, the supernatant was removed, 1 ml of 0.05 M Tris-HCl buffer containing 0.5 mM EGTA was added, and the tissue was immediately boiled for 10 min at 100 °C and then dispersed by sonication. The tissue extract was assayed for cyclic GMP content by the method of Steiner *et al.*[11]. In some experiments, slices were perfused with oxygenated buffer and the fractions were collected as previously described[12]. Amino acids in the medium were measured by HPLC fluorescent detection by the pre-column derivatization method of Hill *et al.*[13].

Incubation of the cerebellar slices with 10 mM Glu or 10 mM NMDLA caused a doubling of cyclic GMP levels (Table 1). Co-incubation of the slices with DAA (0.25 mM) blocked the cyclic GMP formation induced by NMDLA (0.5 mM). Dose–response curves with KA indicated that maximal stimulation of cyclic GMP formation occurred at 0.1 mM, but this concentration caused only a 60% increase in the cyclic GMP levels. However, the addition of DAA, which antagonizes the effects of the granule cell excitatory neurotransmitter[14], markedly potentiated the effects of KA on cyclic GMP formation. This observation raised the question of whether release of endogenous excitatory amino acids in the presence of KA might be attenuating the cyclic GMP response by promoting the neurotoxic effects of KA.

The possible influence of KA on excitatory neurotransmitter release was evaluated by measuring the amount of endogenous amino acids released in the medium during drug exposure (Table 2). With KA (0.5 mM), the concentration of Asp in the medium increased to 233 ± 33% (±s.e.m.; $P < 0.001$; $n = 6$) of control and that of Glu increased to 304 ± 33% ($P < 0.001$) of control whereas the concentrations of glutamine, alanine, tyrosine and taurine did not differ significantly from control. Notably, γ-aminobutyric acid (GABA) was not detected in the medium in the presence or absence of KA. The net release of Glu and Asp stimulated by KA was comparable with that found with a depolarizing concentration of potassium (40 mM). In contrast, neither NMDLA nor dihydro-KA (an analogue with low affinity for KA receptors[1,15]) significantly altered the concentration of the Glu or glutamine in the medium. As dihydro-KA is a more potent inhibitor of the sodium-dependent, high-affinity uptake process for Glu[5,16] than is KA, this result indicates that the KA-induced accumulation of Glu and Asp in the medium did not result simply from inhibition of the uptake process. Tetrodotoxin blocked the depolarization-induced release of Glu and Asp caused by the 40 mM KCl medium whereas tetrodotoxin did not antagonize the effects of KA. Thus, the effect of KA did not depend on the generation of action potentials nor did it result simply from an increased extracellular concentration of potassium, a reported effect of KA[17]. Nevertheless, incubation of the slices in calcium-free medium containing EGTA (1 mM) markedly inhibited the amount of Glu and Asp released by KA although basal release was increased somewhat in this condition; thus, the KA-induced release probably involved stimulus–secretion coupling.

To establish that KA was acting on a neuronal pool of Glu, we examined the effect of KA on Glu release from cerebellar slices deficient in granule cells. Treatment of newborn mice with methylazoxymethanol acetate, a potent alkylating agent, causes a marked and selective depletion of the cerebellar granule cells which are undergoing mitosis at the time[10]. In slices prepared from the granule cell-deficient adult mice, KA (0.5 mM) did not cause a significant release of Glu ($P > 0.10$); rather, the net release of Glu in the presence of KA was only 38 ± 14% of that observed in unlesioned cerebella from littermate controls ($n = 9$). Thus, the granule cells, a reputed glutamatergic system[18,19], seem to be the primary source of Glu released by KA. However, KA did cause a significant release of Asp ($P < 0.01$; $n = 9$) in the granulo-prival slices which was 91% of the amount observed in controls; this is noteworthy because Asp seems to be a neurotransmitter of one of the climbing fibre systems[20], which are spared by the granule cell lesion[21].

The presynaptic effects of KA on excitatory amino acid terminals were not limited to the cerebellum. In perfused slices prepared from cerebellum, hippocampus and striatum, 1 mM KA significantly increased the efflux of Asp and Glu (Table 3). Notably, the ratio of Asp to Glu differed among the three regions, with a greater increase in the Asp than Glu efflux stimulated by KA in the hippocampus. As observed in cerebellum, KA did not cause a release of GABA nor did it affect the efflux of glutamine or alanine. Perfusion with Ca^{2+}-free medium containing EGTA (1 mM) inhibited the KA efflux of Asp and Glu by >80% ($n = 4$; $P < 0.01$) in the hippocampus.

Results of these experiments suggest a resolution to the conundrum that KA has direct excitatory effects[7] although its neurotoxic effects seem to be primarily indirect and require the functional integrity of excitatory inputs[3–6]. The cerebellum offers a particularly favourable region for examining these interactions *in vitro* because the glutamatergic granule cell–parallel fibre system is intrinsic to the region. The present results

Table 2 Release of endogenous glutamate and aspartate from cerebellar slices

Condition	Net release (nmol per mg protein) Glutamate	Aspartate
α-Kainic acid (0.5 mM)	2.04 ± 0.33*	0.61 ± 0.15*
Potassium (40 mM)	2.48 ± 0.02*	0.54 ± 0.14*
N-methyl-D, L-aspartate (0.5 mM)	1.02 ± 0.50	NM
α-Dihydrokainic acid (0.5 mM)	(−)0.03 ± 0.09	0.01 ± 0.14
Tetrodotoxin (5 μM)	0.06 ± 0.12	(−)0.19 ± 0.07
Potassium (40 μM) and tetrodotoxin (5 μM)	0.13 ± 0.14	0.01 ± 0.09
α-Kainic acid (0.5 mM) and tetrodotoxin (5 μM)	2.61 ± 0.70*	1.49 ± 0.28*
α-Kainic acid (0.5 mM) and no Ca^{2+} and EGTA (1 mM)	0.59 ± 0.32	0.36 ± 0.19

Cerebellar slices prepared from adult mice were incubated in the conditions described in the text with the concentrations of drugs indicated in parentheses. The results are expressed in terms of the net amount of amino acids released into the medium in the presence of drug compared with control slices incubated in parallel. Values are the mean ± s.e.m. of five or more preparations. In no condition did the levels of Gln differ significantly from control. NM, not measurable due to interference of *N*-methyl-D, L-aspartate in medium.

* $P < 0.01$ versus control by Student's *t*-test.

Table 3 Effects of kainic acid on the efflux of aspartate and glutamate from perfused slices of mouse brain regions

Region	Aspartate	Glutamate
	(% of baseline)	
Cerebellum	440 ± 79*	963 ± 205*
Hippocampus	1,000 ± 280*	724 ± 57*
Corpus striatum	177 ± 44†	355 ± 66*

Immediately after decapitation, the relevant brain regions of the mice were isolated by dissection at 4 °C and placed in ice-cold oxygenated Krebs–bicarbonate buffer. The tissue blocks were then sectioned at 275 μm. After rinsing in Krebs buffer, the slices were transferred to syringe holders and supported on a bed of Sephadex G-10 (~15 mg wet weight tissue per chamber). The chambers were individually perfused at a rate of 0.5 ml min^{-1} with oxygenated Krebs buffer maintained at 37 °C in a Haake constant temperature circulator. After 60 min of perfusion, spontaneous release of endogenous amino acids stabilized at a constant low rate. Three 3-min samples were collected for baseline values, then buffer containing 1 mM KA was substituted and three 3-min samples were collected for measurement of endogenous amino acid in the buffer by the HPLC method. The results are the mean ± s.e.m. of 4–8 separate preparations.

* $P < 0.01$ versus baseline; † $P < 0.05$ versus baseline.

demonstrate that the activation of guanylate cyclase in cerebellar slices by KA is significantly enhanced by DAA, which antagonizes the effects of NMDLA. The potentiating effect of DAA on KA is compatible with the interpretation that the stimulation of KA receptors combined with the release of endogenous excitatory amino acids has direct neurotoxic effects in the cerebella Purkinje cells, thereby attenuating the cyclic GMP response. This interpretation is consistent with the conclusions of Foster and Roberts[22], who described cooperative interactions between exogenous excitatory amino acids and kainate on cyclic GMP stimulation in cerebellar slices prepared from 8-day-old rats. However, our study demonstrates, for the first time, the existence of presynaptic receptors for KA on the excitatory terminals.

In support of this hypothesis, Nicklas *et al.*[23] have previously demonstrated that KA alone profoundly depresses ATP levels in cerebellar slices, indicative of neurotoxicity[24]. Furthermore, KA stimulates the release of both Glu and Asp in a calcium-dependent, tetrodotoxin-insensitive manner consistent with its action at a presynaptic receptor on parallel fibre and climbing fibre terminals. Ligand binding studies have demonstrated a partial, presynaptic localization of the specific binding sites for ^{3}H-KA on the granule cells as these sites are reduced by 40% in the granule cell-deficient cerebellum[10]. Axonal receptors for KA on dorsal root fibres have also been described by neurophysiological methods[25]. In conclusion, KA seems to act at two sites, one postsynaptic, which accounts for its direct excitatory effects, and the other presynaptic on glutamatergic and aspartergic terminals, which causes release of these excitatory amino acids and may enhance its neurotoxic effects.

Although the benzodiazepines have been extensively investigated since their discovery about 20 years ago[1], only recently have antagonists of the classical actions of benzodiazepines been described[2]. We have now discovered a class of benzodiazepines which have lost all affinity for benzodiazepine binding sites but which have moderate to high affinity for opiate receptors. Depending on the substituents introduced, it is possible to obtain compounds with selective actions on μ, δ and κ subpopulations of opiate receptors. The compounds are effective analgesics in various animal models of pain, exhibit an opioid activity spectrum in various test systems, and show none of the typical effects of minor tranquillizers. Here we report that 1-methyl-2(3-thienylcarbonyl)-aminomethyl-5-(2-fluorophenyl)-*H*-2,3-dihydro-1,4-benzodiazepine (KC5103; tifluadom), acts selectively on opiate κ-receptors.

It has been believed previously that 1,4-benzodiazepines are a unique class of anxiolytic, anticonvulsant and sedative drugs belonging to the group of minor tranquillizers[1] and indeed the recently described antagonist Ro 15-1788 (ref. 2) is specific for these actions on the central nervous system (CNS). It is well established that most of these clinically active substances bind with high affinity to specific benzodiazepine binding sites in the brain and probably exert their specific effects by modulation of neuronal transmission of γ-aminobutyric acid (GABA).

We have studied benzodiazepines having an alkyl group at position 2, in particular the effect that various changes to this alkyl group[3] have on the affinities of these compounds for CNS receptors[4]. We synthesized the 2-methoxymethyl derivative metaclazepam (patent DE-PS 250937; ref. 5), which is a clinically effective anxiolytic[6] although having only low affinity for benzodiazepine receptors. As an extension of this work we developed 2-acylaminomethyl-1,4-benzodiazepines with a variety of substituents on the phenyl rings and in the side chain (patent DE-OS 2952279; ref. 7). Such compounds are effective in the hot-plate test in mice but this analgesia is not typical of the muscle-relaxant pseudoanalgesia shown by diazepam[8], rather the compounds exhibit affinity for opiate receptors and have lost their affinity for benzodiazepine binding sites.

In comparative binding studies on rat brain homogenates, tifluadom (Fig. 1) displaces ^{3}H-naloxone from its binding sites

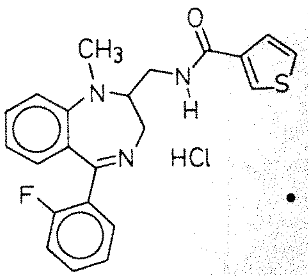

Fig. 1 Structural formula of tifluadom.

Table 1 Displacement of ^{3}H-(−)bremazocine from guinea pig brain homogenates

Substance	IC_{50} (nM)
Tifluadom	14 ± 6 (0.87)
Morphine	350 ± 170 (0.55)
Ketazocine	22 ± 12 (0.85)
Bremazocine	0.75 ± 0.5 (0.95)

Crude guinea pig membrane homogenates (minus cerebellum) were prepared essentially as described elsewhere[16]. ^{3}H-(−)bremazocine (0.5 nM) was incubated with membrane homogenates (17 mg per g wet weight per assay tube) for 40 min at ambient temperature in Tris-HCl buffer (50 mM, pH 7.4), filtered through Whatman GF/B glass fibre filters and washed twice with ice-cold assay buffer. All incubations were done in triplicate, and nonspecific binding was determined in the presence of 0.1 μM bremazocine. IC_{50} values were calculated by appropriately weighted regression analysis (at least four concentrations per decade); Hill coefficients are given in parentheses.

with an IC_{50} (50% inhibitory concentration) of 12 nM and has no effect on ^{3}H-flunitrazepam binding in concentrations up to 1 μM. In contrast, diazepam has no affinity for naloxone sites and displaces ^{3}H-flunitrazepam with an IC_{50} of 15 nM. In the arthritis pain test in the rat[9], a model of chronic pain processes in which classical benzodiazepines are known to give false positive reactions, tifluadom is effective with a 50% effective dose (ED_{50}) of 11 mg per kg orally (p.o.) and this action is partially reversed by pretreatment with 10 mg per kg naloxone subcutaneously (s.c.) but not by doses of up to 32 mg per kg intraperitoneally (i.p.) of the benzodiazepine antagonist Ro 15–1788. In the same test, diazepam is effective at a dose of 6 mg per kg p.o. and its action is readily abolished by Ro 15–1788 at 32 mg per kg i.p. but not by 10 mg per kg s.c. of naloxone. We conclude that tifluadom is an opiate analgesic with none of the actions typical of benzodiazepines.

Receptor binding studies with the universal opiate ligand ^{3}H-(−)bremazocine on guinea pig brain homogenates, a tissue preparation particularly rich in κ- and δ-opiate receptors[10], suggested no particular preference for κ sites compared with μ and δ binding sites. Pharmacological evidence, however, suggested a preference for κ-receptors, therefore we performed comparative studies with the classical μ-agonist morphine, the prototypic κ-agonist ketazocine, tifluadom, and the highly potent κ-agonist bremazocine[11] (see Table 1). Table 2 summarizes the results obtained in electrically-stimulated isolated organs. The rabbit vas deferens (RVD) is unusually specific in its sensitivity to κ-agonists[12,13]. Table 3 shows the effects of the four compounds in the mouse tail flick test[14] and the reversal of these effects by the μ-antagonist naloxone and the putative κ-agonist Mr 2266 (ref. 15).

It is clear from these results that tifluadom is an effective opioid analgesic with a preference for opiate κ-receptors. In keeping with these findings, the compound produces no respiratory depression in rats, is not self-applied by rhesus monkeys, and after programmed administration in the same species does not give rise to opiate withdrawal symptoms on cessation of treatment or after naloxone challenge. The existence of this new class of opioids suggests exciting possibilities for the study of opiate receptor subpopulations.

Table 2 Effects on electrically-stimulated guinea pig myenteric plexus–longitudinal muscle preparation, and mouse and rabbit vasa deferentia

Substance	IC_{50} (nM)			Potency ratio (normorphine = 1)	
	GPI	MVD	RVD	GPI	MVD
Tifluadom	1.7	2.6	4.9	234	43
Morphine	238	159	>10,000	0.9	0.8
Ketazocine	4.7	19.3	54	62	10.1
Bremazocine	0.25	0.5	6.4	1403	453

GPI, guinea pig myenteric plexus–longitudinal muscle preparation; MVD, mouse vasa deferentia[18]; RVD, rabbit vasa deferentia[12]. The IC_{50} is defined as the concentration required to produce 50% inhibition of the supramaximally electrically induced twitch response in each isolated tissue. Results are the means of several experiments: GPI n = 6–12, MVD n = 6–10, RVD n = 5. The absolute potency of normorphine varies strongly from tissue to tissue but is typically 150–400 nM (GPI) and 50–150 nM (MVD).

Table 3 Actions of test substances in the mouse tail flick test and their antagonism by naloxone and Mr 2266

Test substance	ED_{50} (mg per kg s.c., 30 min)	AD_{50} naloxone (mg per kg i.v.)	AD_{50} Mr 2266 (mg per kg i.v.)
Tifluadom	1.1 (0.5–2.4)	0.56 (0.31–1.02)	0.19 (0.08–0.45)
Morphine	3.0 (2.7–4.5)	0.005 (0.002–0.009)	0.08 (0.039–0.16)
Ketazocine	0.3* (0.1–0.5)	0.07 (0.03–0.1)	0.04 (0.02–0.08)
Bremazocine	0.7 (0.3–1.4)	~3.2	0.46 (0.24–0.87)

The ED_{50}(P = 0.05) is defined as the dose that prolonged the reaction time in seconds by >75% in half of the mice. The AD_{50} (P = 0.05) is defined as the dose (intravenous, i.v.) of the antagonist needed to reduce by 50% the analgesic effect of equi-active doses (ED_{90}) of the agonists. The antagonist was injected 15 min after the agonists (ketazocine, 7 min); readings were made 15 min later (ketazocine, 8 min): 5–10 animals were used per dose. Figures in parentheses indicate 95% confidence limits.

The nucleotide sequences of the intercistronic regions from several multicistronic operons have recently been determined. In many cases such intercistronic regions consist of only a few base pairs (bp); in certain extreme cases, where the initiation codon of one gene overlaps the termination codon of the previous gene, intercistronic regions are essentially absent[1,2]. However, in other cases intercistronic regions can be up to several hundred base pairs long; it seems reasonable to suppose that, at least in these cases, such regions have a role in regulating expression of the operon. Indeed, a regulatory function for the large intercistronic region of the *rplJL–rpoBC* operon has been demonstrated[3]. We have now identified a genetic element, common to intercistronic regions from three independent

0028-0836/82/330760—03$01.00

bacterial operons (the histidine transport and the histidine biosynthetic operons of *Salmonella typhimurium* and the *malK–lamB* operon of the malB region of *Escherichia coli*), which we believe to be important in regulating the differential expression of individual genes in these multicistronic operons. A similar element is also found immediately following the *trpR* gene of *E. coli* although in this case it is not known whether or not a distal gene exists. Each of these elements consists of a long dyad symmetry which, once transcribed, could form an exceptionally stable stem–loop structure with a stem of up to 35 bp. In each case smaller palindromic units are also found, some of which overlap the main symmetry. The stem–loop structures show remarkable homology (~90%) and probably have a common evolutionary origin, possibly an insertion element. It seems that the function of these structures is to effect a decrease in expression of distal genes in an operon.

The histidine transport operon of *S. typhimurium* consists of four cistrons, coordinately transcribed from a single promoter (see accompanying letter[4]). Between the first two genes of this operon, *hisJ* (encoding the periplasmic histidine-binding protein) and *hisQ* (encoding a membrane-bound protein), there is an intercistronic region of 183 bp. An exceptionally long dyad symmetry (32 bases in each arm of the repeat) is evident within this region which, once transcribed, could form a very stable stem–loop structure ($\Delta G = -54.4\ \text{kcal mol}^{-1}$)[5] (Fig. 1*a*). The *hisG–hisD* intercistronic region of the histidine biosynthetic operon of *S. typhimurium* also contains a long dyad symmetry (Fig. 1*c*) which shows remarkable sequence homology with the dyad symmetry in the *hisJ–hisQ* intergenic region. A third example of this long intercistronic dyad symmetry is found in the *malK–lamB* operon of *E. coli*[6] (Fig. 1*e*) and again, it is almost identical in sequence to the two examples described above. This third example lies between *lamB* (encoding the λ receptor) and *molA*, a gene whose function is unknown[6]. As no obvious promoter or terminator is found between *lamB* and *molA* it is reasonable to assume that these two genes form part of the same operon. A further example of this long dyad symmetry is found immediately following the *trpR* gene of *E. coli*[7,8]. However, in this case it is not known whether the region is intercistronic (that is, whether a distally located gene exists and is co-transcribed with *trpR*) or whether it marks the end of a transcription unit.

The remarkable homology between these dyad symmetries is shown in Fig. 2. For example, the long dyad symmetries in *hisJ–hisQ* and *hisG–hisD* show 90% homology (42/47 bases); a comparably high level of homology is evident whichever combination of regions is compared. Interestingly, the loops of these potential stem–loop structures show no significant homology.

Detailed analysis of sequences in and around these long dyad symmetries shows the presence of several copies of a smaller palindromic unit (Figs 2, 3). A computer search of sequence data banks did not reveal further copies of this unit at any other locus. These smaller palindromic units are not completely symmetrical (Fig. 3) and consecutive copies are always in opposite orientations. Thus, once transcribed, stem–loop structures could not only be formed within each unit (Fig. 1*b*, *d*, *f*), but could also form between units, giving rise to a variety of larger, secondary structures. Indeed, the intercistronic elements (long dyad symmetries) described above are the result of just such base-pairing between two of these smaller palindromic units. Thus, stem–loop structures, some of which are mutually exclusive with the intercistronic element, can be formed; such structures may or may not be functionally significant. Interestingly, the attenuator of the *rplJL–rpoBC* operon[3] also shows considerable homology with this smaller palindromic unit.

Fig. 1 Intercistronic regulatory elements. Sequences are found in: *a*, the histidine transport operon of *S. typhimurium* (*hisJ–hisQ*); *c*, the histidine biosynthetic operon of *S. typhimurium* (*hisG–hisD*); *e*, the *malK–lamB* operon of *E. coli* (*lamB–molA*). For each region alternative stem–loop structures are shown (*b*, *d* and *f*, respectively). The overlapping nature of these alternative structures is shown by the arrows (labelled 1 and 2) alongside the major structure which indicate the position of the alternative symmetry. Bases identical in all three sets of structures are boxed. Nucleotide sequences and base numberings are from ref. 4 (*hisJ–hisQ*), ref. 6 (*lamB–molA*) or unpublished data of W.B. (*hisG–hisD*).

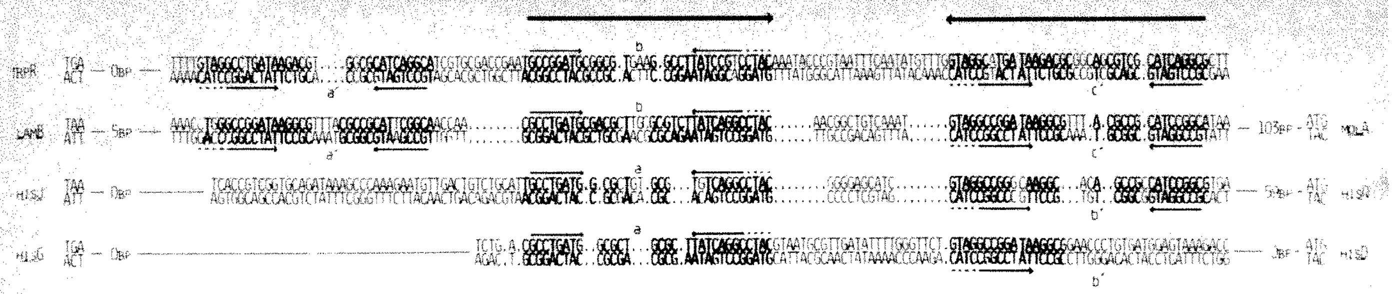

Fig. 2 Alignment of intercistronic regions. The *hisJ–hisQ*, *hisG–hisD* and *lamB–molA* intercistronic regions together with sequences immediately following the *trpR* gene are aligned for homology. Shaded bases indicate significant homologies between the sequences, corresponding to the consensus sequence for the smaller palindromic unit (Fig. 3). A dot in the sequences indicates the absence of a base. Arrows above the sequences indicate the position of the long dyad symmetry (intercistronic element) discussed in the text. The shorter arrows above and below each sequence indicate the position of the smaller palindromic units. The homologous sequence 5′ to each of these smaller palindromic units (see Fig. 3) is indicated by a series of dots following the arrows. Nucleotide sequences were obtained and are numbered as described in Fig. 1 legend or were taken from refs 7 and 8 (*trpR*).

What is the function of the intercistronic elements? Because of their location, we postulate that they are responsible for the lowered expression of distally located genes in a multicistronic operon. In the histidine transport operon, *hisJ* is expressed about 10 times more efficiently than *hisQ*[4]. Similarly, in the histidine biosynthetic operon, the dyad symmetry is found between two genes expressed to different extents: *hisG* is expressed at about three times the level of the distal *hisD* gene[9]. Unfortunately, in the *malK–lamB* operon the relative levels of expression of *lamB* and *molA* are unknown, although the *lamB* protein is known to be expressed at very high levels. It seems unlikely that regulation by these elements operates at a translational level: they are clearly separated from the ribosome-binding sites of the genes immediately downstream and bear no constant spatial relationship to the translation initiation codon. Indeed, evidence that regulation is transcriptional, rather than translational, has been obtained in studies of β-galactosidase production in strains carrying fusions of *lacZ* to *hisJ* and *hisQ* (M. Stern, C. F. H. and G. F.-L. A., in preparation). The elements might either cause premature termination of transcription, or they might serve as a processing site in the message after transcription. It is known that RNase III can cleave certain large stem–loop structures in mRNA[10–12] and it has been postulated that in doing so it regulates gene expression[3]. Perhaps, after RNase III cleavage, the distal portion of the message is rapidly degraded. It is also possible that these elements serve to protect long untranslated intercistronic regions from degradation, thus affecting the expression of distally located genes.

What is the origin of these elements? It seems unlikely that these homologous sequences have arisen independently to allow specific interactions with a common nucleic acid sequence or protein: sufficient specificity could be imparted by very much shorter sequences. More probably, the extensive homology reflects a common evolutionary origin. It is interesting to speculate that these intergenic regulatory elements may have arisen from insertion sequence-like elements, that is, 'regulatory building blocks', becoming fixed at locations in which they provide a selective advantage. The lack of a short direct repeat on either side of the regulatory elements, typical of insertion sequences[13], may be a result of mutational fixation of the element at these specific locations. Note, however, that these intergenic regulatory elements show no homology with known insertion elements of *E. coli*[13].

Fig. 3 Consensus sequence of palindromic units. The several copies of the smaller palindromic units identified in and around the intercistronic elements are aligned for maximum homology. Arrows above the sequence indicate regions of dyad symmetry. The location of these sequences with respect to each other is indicated in Fig. 2. A consensus sequence for these palindromic units is given: Py indicates a pyrimidine base, Pu a purine. Note that the units are not completely symmetrical; a conserved sequence, CTAC, is found 3′ to each of the dyad symmetries, giving directionality to each unit. The potential stem–loop structure which might be formed by these units is shown schematically. Sequences were obtained as described in Figs 1 and 2.

Although we have identified three of these stem–loop structures in operons whose nucleotide sequences have been partially or completely determined, two lines of evidence indicate that very similar, if not identical, structures also occur at several other locations on the chromosome, presumably in other intercistronic regions where a step-down in expression of distal genes occurs. First, chromosomal rearrangements involving the histidine biosynthetic operon frequently have one end point within the *hisG–hisD* intergenic region[14]. It has previously been suggested that such *recA*-dependent rearrangements involve recombination with homologous sequences elsewhere on the chromosome[14]. Second, we have observed[15] that a clone of the histidine transport operon of *S. typhimurium* hybridizes with a number of fragments from a total chromosomal digest, in addition to those fragments which cover the transport operon itself. This may be due to hybridization with homologous sequences dispersed throughout the chromosome. The precise number and location of these additional elements remain to be determined.

We thank Bruce Ames and D. Brutlag for many helpful discussions. This work was supported by NIH grants AM12121 and GM24956 to G.F.-L.A. and W.M.B., respectively, by a NATO/SRC fellowship to C.F.H., and by grants from the DDRST and the Fondation pour la Recherche Medicale to M.H.

The centriolar region is a complex structural entity comprising not only centrioles, but also an abundance of associated electron-dense material identified at present only at the ultrastructural level[1,2]. It is known to contain initiation sites necessary for the assembly of both cytoplasmic and spindle microtubules. Basal bodies, which are structurally related to centrioles, contain the template and serve as initiation sites for the assembly of other microtubule-containing structures, such as the axonemes of cilia and flagella. Immunoglobulins in the sera of some apparently normal rabbits have the ability to bind specifically to centrioles and basal bodies, and have allowed the distribution of these structures to be localized at the light microscope level by immunofluorescence[3–5]. The identity of the molecule(s) detected by these sera in the centriolar region is unknown, although it is not tubulin, the major identified protein of centrioles[4]. We describe here the identification of a protein recognized by the immunoglobulins in some normal rabbit sera, of approximate molecular weight (MW) 50,000 in both basal bodies isolated from *Tetrahymena pyriformis* and in extracts of chicken tracheal epithelial cells.

When a monolayer of mammalian cells is stained with one of these sera the centrioles are strongly labelled and their position in cells can be readily identified[4]. The staining of centrioles is not species-specific and can be seen in basal bodies and centrioles in a wide variety of species including protozoans such as *Tetrahymena* (Fig. 1*a*). When cells are treated with 0.5% Triton X-100 before fixation, the immunofluorescence staining of centrioles and basal bodies by these normal sera is abolished, suggesting that the centriolar antigen(s) is loosely bound to the centriole. Because it would be advantageous to use Triton X-100 to disrupt membranes and thus isolate the basal bodies from the pellicles of *Tetrahymena*, the basal body staining was stabilized by using EDTA (see Fig. 1*b*), a method previously used to stabilize the basal bodies in *Chlamydomonas*[6].

A preparation enriched in basal bodies and retaining the centriolar antigen was made by breaking deciliated cells by vortex agitation in Triton X-100 containing 10 mM EDTA, *p*H 6.8, and separating the basal bodies from the cells and cellular debris by differential centrifugation (Fig. 2). Basal bodies were further purified by centrifugation on a discontinuous sucrose gradient. When basal bodies prepared in this way were stained for immunofluorescence with centriole-specific sera, the presence of the reacting antigen was clear. The protein components of the isolated basal bodies were then examined by SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Numerous bands could be seen, including prominent ones at positions corresponding to molecular weights of 30–35,000, 45–47,000 and 55,000 and numerous less abundant ones at higher molecular weight (Fig. 2*a*). The band at about 55,000 apparently corresponded to tubulin, as it had the same electrophoretic mobility as the phosphocellulose-purified pig brain tubulin that was co-electrophoresed in a companion slot. This identity was confirmed by immunoautoradiography of nitrocellulose[7] sheets with antibody against pig brain tubulin.

To identify conclusively the antigen in the basal bodies which is responsible for the staining of the centrioles, we used the same electrophoretic blotting procedure. The basal body proteins were separated by SDS-PAGE (Fig. 2*a*) and electrophoretically transferred onto a nitrocellulose sheet (Fig. 2*b*). The sheets were then treated with several different centriole-positive normal rabbit sera and autoradiographed. With all the sera, one band could be readily detected in the autoradiographs (Fig. 2*c*) which, by comparison with marker molecules, corresponded to a molecular weight of 50,000 (Fig. 2). The band was not labelled with antisera to tubulin or with normal sera lacking specificity for centrioles (Fig. 2*c*), indicating that these sera did not contain any immunoglobulin against the 50,000-MW basal body protein. Treatment of the nitrocellulose sheets with ^{125}I-labelled protein A alone showed no binding between the

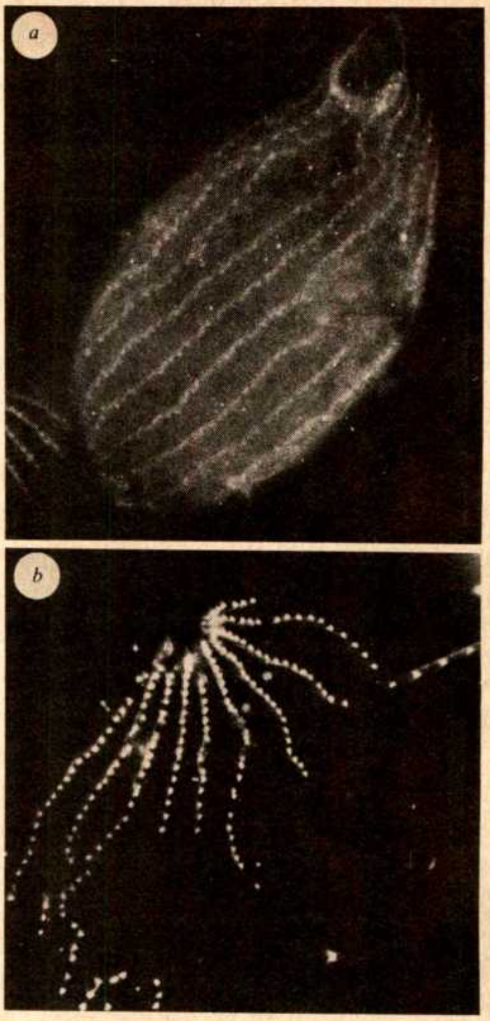

Fig. 1 Immunofluorescence micrograph showing typical basal body staining of isolated *Tetrahymena* pellicles by normal rabbit sera before (*a*) and after treatment with Triton X-100 + EDTA (*b*) stained with the same serum. Mass cultures of *T. pyriformis* strain GL cells were grown at 28 °C for 18–21 h in 6-l Erlenmeyer flasks, each with 1 l of culture medium containing 2% w/v protease peptone (Difco), 0.1% w/v liver extract L (US Biochemical). Cells were collected by centrifugation, and deciliated according to the procedure of Bird and Zimmerman[10]. Pellicles were isolated according to ref. 11. For immunofluorescence, purified pellicles were allowed to settle onto poly-L-lysine (Sigma, 0.1% w/v)-coated coverslips; they were fixed in methanol at −20 °C for 4 min, washed in phosphate-buffered saline (PBS) and then processed for indirect immunofluorescence (see below). For extraction, pellicles on poly-L-lysine-coated coverslips were fixed in freshly prepared 3% paraformaldehyde (Fisher) in PBS. The coverslips were then extracted in 1% Triton X-100 (Sigma)-containing 10 mM EDTA (Fisher) *p*H 6.8, for 5 min at room temperature and washed in PBS. They were then processed for indirect immunofluorescence. Standard indirect immunofluorescence: the coverslips after fixation were washed briefly in PBS, then incubated with normal rabbit serum (1:20 dilution in PBS) for 30 min at room temperature in a humidified chamber. The coverslips were then washed three times with PBS for 10 min and incubated for 30 min with fluorescein-labelled goat IgG against rabbit IgG (FITC-GAR, Hyland, diluted 1:5 in PBS) which was preabsorbed with *T. pyriformis* acetone powder. Finally, coverslips were washed three further times with PBS for 10 min. Coverslips were mounted in 50% glycerol in PBS, *p*H 7.8. The preparations were viewed with a Zeiss Photomicroscope-II equipped with epifluorescent illumination. Pictures were taken using Ilford FP-4 film. *a*, *b*, ×1,080.

^{125}I-protein A and *Tetrahymena* basal body proteins (data not shown). Although the antisera to tubulin did stain the tubulin bands, this staining was clearly not due to the centriole-associated protein, as in companion gel slots the bands recognized by tubulin antisera and centriole sera were different. This was demonstrated further by labelling a nitrocellulose sheet containing basal body proteins simultaneously with both centriole-specific normal serum and tubulin-specific immune serum. This procedure clearly distinguished the tubulin band from the lower molecular weight (50,000) protein recognized by the centriole-specific serum (Fig. 2). Non-centriole-staining normal rabbit sera did not label any bands in these basal body extracts (not shown).

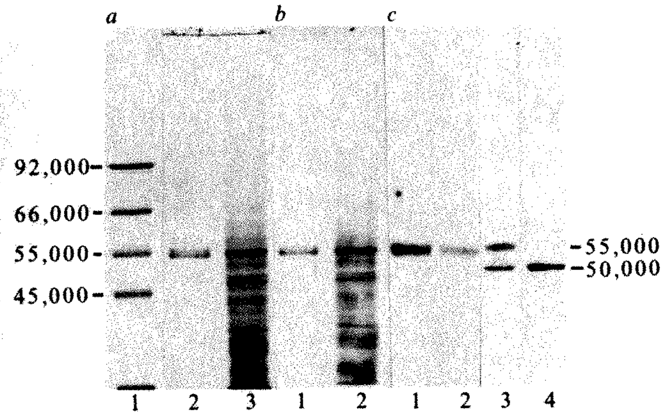

Fig. 2 Immunoelectrophoretic detection of the centriole-associated protein. *a*, SDS-PAGE stained with Coomassie blue. Lane 1, molecular weight standards phosphorylase *b* (92,000), bovine serum albumin (66,000), ovalbumin (45,000; Bio-Rad) and pig brain tubulin (57,000 and 55,000); 2, pig brain tubulin; 3, basal body-enriched fraction from *T. pyriformis*. *b*, Nitrocellulose sheet corresponding to gel in *a* after electrophoretic protein transfer and amido black staining. *c*, Immunoautoradiogram from nitrocellulose sheets labelled with antibodies and ^{125}I-protein A. Lane 1, pig brain tubulin labelled with rabbit antiserum (1:750) to pig brain tubulin; 2, basal body-enriched fraction labelled with rabbit antiserum (1:500) to pig brain tubulin; 3, basal body-enriched fraction labelled simultaneously with rabbit antiserum (1:500) to pig brain tubulin and with centriole-staining rabbit serum CT-2 (1:500); 4, basal body-enriched faction labelled with centriole-staining rabbit serum HMW-3 (1:200). To isolate fractions enriched in basal bodies, deciliated cells were washed twice with fresh medium and broken in 1% Triton X-100 containing 10 mM EDTA, *p*H 6.8, by vortex agitation for 30 s. Unbroken cells and large debris were removed by centrifugation at 4,000*g* (Sorvall HB-4 rotor) at 4 °C, for 10 min. The supernatant was further centrifuged at 8,000*g* for 10 min at 4 °C. Finally, basal bodies were pelleted by centrifugation at 12,000*g* for 30 min at 4 °C. This pellet is called the basal body-enriched fraction. In some experiments, the above pellet was run on a discontinuous sucrose gradient for further purification of basal bodies. For sucrose gradients, the basal body-enriched pellet was suspended in 1 ml of a 5% sucrose solution and was layered on a 0.7:1.2:1.7 M sucrose gradient (10 ml each) and centrifuged at 4,000*g* for 1.5 h using a Sorvall HB-4 swinging bucket rotor at 4 °C. The band containing the basal bodies was at the 1.2:1.7 M interface. This band was removed carefully and diluted with distilled water. The basal bodies were pelleted by centrifugation at 12,000*g* for 30 min at 4 °C. Basal body proteins were separated by SDS-PAGE using the buffer system of Laemmli[12]. The samples were electrophoresed at a constant current of 30 mA, using a Bio-Rad slab gel apparatus model 220. A 3% stacking gel and 8% resolving gel were used. Basal body proteins were transferred to nitrocellulose sheets as described in ref. 7, and antigens were detected using ^{125}I-protein A. Briefly, the nitrocellulose sheets were saturated with 3% bovine serum albumin (BSA, Fraction V, Sigma) in 10 mM Tris-buffered saline (TBS), *p*H 7.4 by incubating for 1 h at 37 °C. Sheets were then washed with TBS at room temperature and incubated for 24 h with rabbit sera in TBS buffer containing 3% BSA. The nirocellulose sheets were washed for 1 h with TBS and incubated for 3 h with ^{125}I-protein A in TBS buffer containing 3% BSA. The nitrocellulose sheets were then washed in TBS containing 0.1% Tween 20 (Sigma) and dried in air. The blots were exposed to Kodak X-Omat XAR-5 film with an intensifying screen (Dupont) at −70 °C. Protein A was iodinated at room temperature for 15 min in a reaction mixture (50 µl) containing 100 µg protein A (Pharmacia), 0.5 mCi carrier-free Na^{125}I (Amersham), 2.5 µg chloramine-T (Kodak), 5 µl dimethyl sulphoxide (Fisher). The reaction was stopped by addition of 5 µg of sodium metabisulphite (Sigma). The labelled protein and unreacted ^{125}I were separated on Sephadex G-25. The radioactively labelled protein A was rechromatographed on Sephadex G-25. Pig brain tubulin was purified as described[13]. The tubulin antiserum used in these studies was prepared against electrophoretically purified tubulin isolated from pig brain as previously described[14].

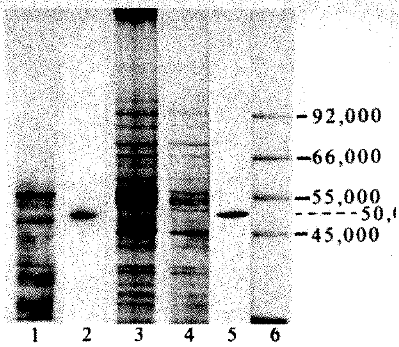

Fig. 3 Immunoelectrophoretic detection of the centriole-associated protein in ciliated chicken trachea cell extracts. Lane 1, nitrocellulose sheet with basal body-enriched fraction as in Fig. 2*b*, lane 2. Lane 2, immunoautoradiogram corresponding to lane 1 but labelled with a centriole-staining serum CT-2 (1:200) and ^{125}I-protein A. Lane 3, SDS-PAGE of Triton X-100 extract of ciliated cells from chicken trachea. Lane 4, nitrocellulose sheet corresponding to gel in lane 3 after electrophoretic protein transfer and amido black staining. Lane 5, immunoautoradiogram corresponding to lane 4 with nitrocellulose sheet labelled with centriole-staining rabbit serum CT-2 (1:200). Lane 6, molecular weight standards (see Fig. 2 legend). Ciliated cells were isolated from adult chicken trachea, obtained from a local abbatoir, as described previously[3]. Briefly, the tracheae were rinsed with PBS and cut open at the midline. The tracheal epithelium was removed by gently scraping with a glass coverslip. Cells were collected by centrifugation at 4,000*g* (Sorvall HB-4 rotor) at 4 °C for 10 min and extracted with Triton X-100 (Sigma) for 10 min. Cellular debris was removed by centrifugation at 12,000*g* for 10 min at 4 °C. The supernatant was used in identification of the centriole-associated protein. The samples were electrophoresed and incubated as for Fig. 2.

Since the centriole-specific sera were known to label cells from diverse species of higher organisms, it was of interest to determine whether or not the same or a similar 50,000-MW protein could be detected in the centriolar structures in any of these organisms. Thus ciliated cells from chicken trachea were treated with Triton X-100, as the centriole staining of these cells was known to be lost by Triton X-100 extraction. When the detergent extracts of the ciliated cells were used for immunoautoradiography, the centriole serum specifically labelled a band corresponding to MW 50,000 which co-migrated with the antigenicity detected in basal body preparations (Fig. 3).

These results show that certain centriole-staining normal rabbit sera have IgG molecules directed against a protein with a mobility on SDS-PAGE corresponding to a MW of ~50,000. Similar IgGs are absent from sera which do not stain centrioles, or stain only the tubulin-containing component of centrioles.

The function—whether enzymatic or structural—of the 50,000-MW protein is unknown. However, it, or a very similar protein, seems to be present in centrioles and basal bodies of diverse cell types and organisms ranging from protozoa to mammals, suggesting that it has been conserved and may be functionally important. Recently, two other polypeptides (of MW 14,000 and 17,000) have been localized at the centriolar region using other preimmune or immune sera[8]. The use of these, and perhaps other, sera, as well as precise biochemical analyses (for example, ref. 9), may help to decipher important constituents of these complex structures which have not previously been defined. Finally, it would also be of interest to determine whether the ability to make these antibodies to centriolar proteins is genetically inherited or whether they are produced by the rabbits as a result of infection by basal body-containing microorganisms, or as a result of an immune response to centrioles, basal bodies or their constituents released by dying cells into the circulation.

We thank Dr A. Zimmerman for providing *T. pyriformis* strain GL. This work was supported by grant MT-3302 from the MRC of Canada to V.I.K.

Mycoplasma pneumoniae adhesin localized to tip structure by monoclonal antibody

J. Feldner, U. Göbel & W. Bredt

Institute for General Hygiene and Bacteriology, Center for Hygiene, University of Freiburg, D-7800 Freiburg, FRG

The human respiratory pathogen *Mycoplasma pneumoniae* has several peculiar properties: despite its diminutive size[1] it possesses a specialized tip structure[2–4]; it is motile and glides with considerable speed along inert surfaces[5,6], and it exhibits strong attachment to animal cells[7] and to inert surfaces[8]. The latter property is a prerequisite for the survival of this obligate parasite in the host organism. Experimental evidence[9–12] suggested that the binding site(s) mediating attachment of the pathogen is a protein, but so far this substance has not been characterized, nor has it been localized in the cell. By using a monoclonal antibody we have been able to localize the adhesin at the surface of the tip structure; it was identified by autoradiography as a protein of molecular weight (M_r) 160,000–190,000. We report that the monoclonal antibody inhibited erythrocyte adherence, attachment to glass and gliding motility of *M. pneumoniae*.

A hybridoma cell line was isolated according to the hybridization protocol described elsewhere[13]. Briefly, 6-week-old BALB/c mice were injected intraperitoneally with 0.5 ml of a *M. pneumoniae* (strain FH) cell suspension (1 mg ml^{-1}) in phosphate-buffered saline (PBS) *p*H 7.2. The injections were repeated four times at 2-week intervals. Mice were killed 3 days after the final injection, and their spleens removed. Lymphocytes were fused with Sp 2/0 myeloma cells[14] and macrophages were used as feeder cells. The hybridoma clones were screened after 10 days for adherence-inhibiting properties by a haemadsorption method[11] and positive wells were cloned by limiting dilution. The supernatants were also tested by indirect immunofluorescence on *M. pneumoniae* cells grown on glass[15]. Of the 120 hybridomas examined, one clone was found to have adherence-inhibiting antibody, designated M43. On immunofluorescence, this antibody stained only one pole of the cell (Fig. 1*a*). The association of antibody with the tip structure of the *M. pneumoniae* cell was confirmed by electron microscopy using ferritin-labelled antibodies to mouse immunoglobulins (Fig. 1*c*). Controls treated with an unrelated mouse monoclonal antibody were negative (Fig. 1*d*). The immunofluorescence was reduced by pretreatment of the *M. pneumoniae* cells with trypsin (10–20 µg ml^{-1}) at 37 °C for 30 min).

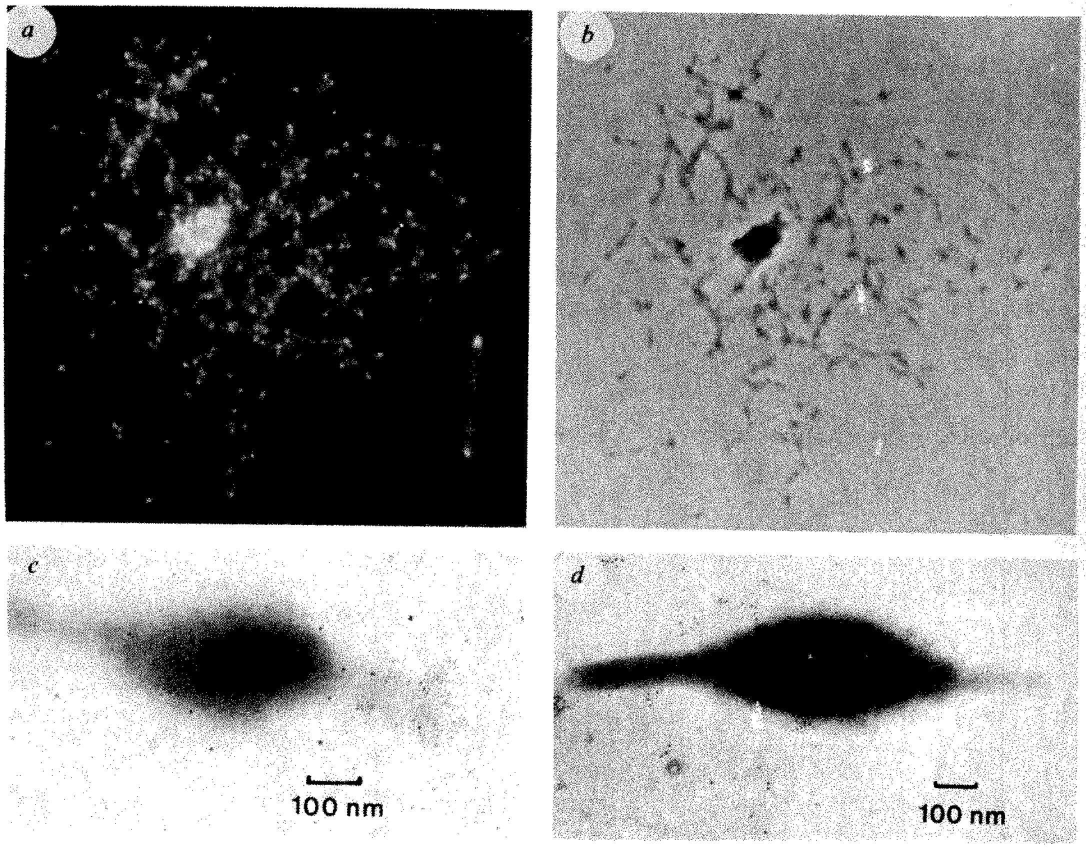

Fig. 1 Immunofluorescent and immunoferritin labelling of *M. pneumoniae* cells by monoclonal antibody M43. *a*, For indirect immunofluorescence the glass-attached mycoplasmas were fixed either in 0.1% glutaraldehyde or in 5% formaldehyde in PBS for 15 min at room temperature and rinsed twice with PBS. The cells were then treated with M43 hybridoma supernatant at 37 °C for 15 min, rinsed with PBS, and fluorescein isothiocyanate-conjugated goat anti-mouse antiserum (1:40) was added as second antibody. Incubation at 37 °C for 15 min was followed by two rinses with PBS. Finally, the cells were covered with a buffered glycerol–phenylenediamine solution to reduce the fading of the fluorescence[21]. The preparations were examined in a Zeiss photomicroscope equipped with epifluorescence illumination. The photographs (3-min exposures) were taken using 400 ASA film (Ilford) and show a microcolony consisting of single cells (×2,200). The insert shows dividing cells (×4,400). *b*, Phase contrast of *a* without the insert. *c*, *M. pneumoniae* cells grown on parlodion–carbon-coated platinum grids were pre-fixed with 0.1% glutaraldehyde in PBS at room temperature for 15 min. After washing they were incubated with anti-adherence antibody (1:100) at room temperature for 15 min, then washed and incubated with ferritin-labelled goat anti-mouse immunoglobulin at room temperature for 15 min. The grids were then rinsed six times with PBS, fixed with 2.5% glutaraldehyde at room temperature for 15 min and examined in a Siemens Elmiskop 102 at 80 kV. Ferritin molecules are seen predominantly at the tip structure. *d*, As a specificity control, *M. pneumoniae* preparations were incubated with mouse monoclonal anti-human immunoglobulin instead of the M43 antibody. Further controls used bovine serum albumin, fetal calf serum or the ferritin-labelled antibody alone (not shown).

0028–0836/82/330765—03$01.00

The antibody was identified as belonging to the IgM class by immunodiffusion and gel filtration on Sephacryl S-300. Pretreatment of *M. pneumoniae* sheets with antibody M43 caused strong inhibition of adherence of sheep erythrocytes (Table 1). Similar results were obtained with human, rabbit and guinea pig erythrocytes. The adherence inhibition titre of hybridoma supernatant was 1:16; this increased to 1:256 when the antibody was precipitated with 40% ammonium sulphate and resuspended in PBS to 30 mg ml^{-1}. Similar titres (1:10 and 1:128, respectively) were found also for the inhibition of attachment to glass surfaces (Table 1).

Table 1 Monoclonal antibody M43 inhibits erythrocyte adherence and attachment to glass

	Adherence of sheep erythrocytes to mycoplasma sheet	Attachment of mycoplasmas to glass
Control	100	100
M43		
1: 32	3	1
1: 64	5	3
1:128	17	23
1:256	21	57
1:512	77	Not tested

Attachment of sheep erythrocytes was assessed by a haemadsorption technique[11] which allows photometric measurement of lysates of sheep erythrocytes attached to sheets of *M. pneumoniae*. Attachment of glucose-energized mycoplasmas to glass was quantitated in an experimental system[12,20] which measures the settling of ^{3}H-palmitic acid-labelled cells on to glass coverslips. After incubation and rinsing of the coverslips, the radioactivity attached to the glass was determined.

The monoclonal antibody caused no growth inhibition and was ineffective in the metabolic inhibition test[16]. Furthermore, no complement-mediated lysis of antibody-coated cells was observed. These negative results suggest a localization of the corresponding antigen at a non-vital site.

To identify the binding substance, the monoclonal antibody was labelled by adding ^{35}S-methionine to the hybridoma culture medium[13]. *M. pneumoniae* cells were solubilized by SDS and the proteins separated on a SDS-polyacrylamide gel[17]. The gel was then treated with the labelled antibody. Autoradiography revealed that the activity bound to a protein at a position corresponding to a molecular weight of 160–190K (Fig. 2*a*). The same protein band was reactive when a similar gel was overlaid with sheep erythrocytes (Fig. 2*b*), suggesting that this polypeptide was not only antigenically but also functionally identical to the binding site material.

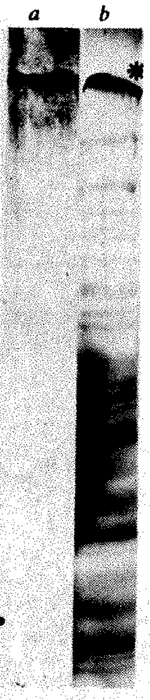

Fig. 2 Localization of the proteins stained by monoclonal antibody or by sheep erythrocytes after polyacrylamide gel electrophoresis[17] of whole *M. pneumoniae* cells. After electrophoresis, the SDS was eluted from the gel by washing with PBS at room temperature for 45 min. *a*, The gel was then covered with ^{35}S-methionine-labelled antibody, incubated at 4 °C for 20 h, then washed with PBS. The fixed gel was impregnated with Enhance (NEN), then dried and exposed at −70 °C for 2 days to Kodak X-Omat X-ray film. *b*, Instead of antibody, sheep erythrocytes were used to overlay the gel (room temperature for 45 min). After several washes with PBS the gel was stained with Coomassie blue. The asterisk indicates the position of the erythrocyte-labelled protein.

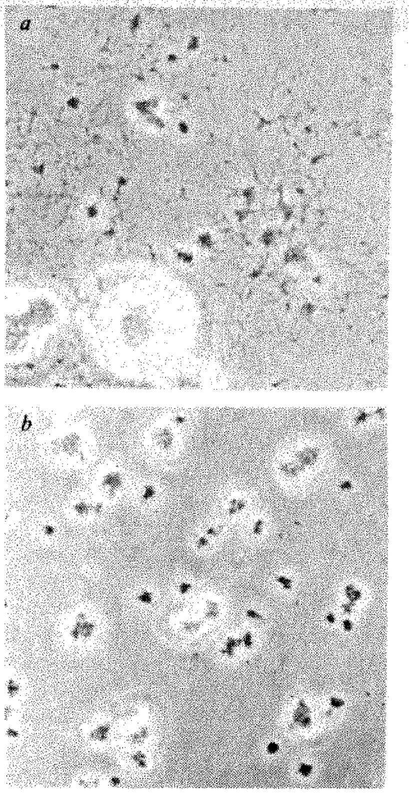

Fig. 3 Effect of antibody M43 on migration of *M. pneumoniae* cells. Mycoplasmas were grown on glass in coverslip chambers[15] in the absence (*a*) or presence (*b*) of antibody M43 (1:3,200). In *b*, normal growth of microcolonies can be seen but no individual cells migrated out of the colonies.

The gliding movements of *M. pneumoniae* were completely abolished when antibody (up to 1:1,000) purified by ammonium sulphate precipitation was added to the medium. This inhibition occurred within 5 min; the shape of the cells was not affected nor did they lose contact with the glass surface. When the antibody was added to growing cultures, the single cells remained aggregated in clusters and did not migrate out of the microcolonies to spread over the coverslip (Fig. 3). The immobilization of the cells suggests that some mobility of the binding site within the membrane that is required for gliding, is inhibited by the bound antibody.

Attempts to isolate the adhesin protein of *M. pneumoniae* have so far had only limited success[18]. Using the specific monoclonal antibody described here it should be possible to purify and characterize the binding site protein, which may further elucidate the mechanisms of motility and adherence. Furthermore it could be used to study parasite–host interactions, and may have potential value in diagnosis and immunoprophylaxis.

After submission of this letter, an article describing a similar antibody[19] was published. We thank A. Vogt for stimulating discussions, and D. Preusse and U. Burger for technical assistance.

A multicopy insertion sequence in the bovine genome with structural homology to the long terminal repeats of retroviruses

R. E. Streeck

Institut Pasteur, 28 rue du Docteur Roux, 75724 Paris Cedex 15, France

Many of the transposable elements characterized so far in eukaryotes are a few thousand base pairs (bp) long and there are usually 20–50 copies per genome[1]. In addition, families of short interspersed repeated sequences have been discovered, some of which may also be transposable[2]. During analysis of the bovine satellite DNAs, I have found two types of sequence which have structural features in common with insertion elements[3]. They are only 0.6 and 1.2 kilobases (kb) long and are present in two different satellites at frequencies of 3.5×10^4 and 5×10^4 per genome, respectively. Sequence analysis of the 1.2-kb insertion and of satellite repeats carrying or lacking this sequence has now shown that a 6-bp duplication is generated at the site of insertion. I report here that the organization of this sequence is very similar to a retrovirus long terminal repeat (LTR). The 1.2-kb insertion and the related 0.6-kb sequence are highly homologous near their ends but unrelated in their internal sequences. These two elements may constitute precursors or descendants of an unknown retrovirus.

The bovine genome contains at least seven satellite DNAs, two of which have a density of 1.711 g cm^{-3} in CsCl (1.711A, 1.711B)[4]. Restriction and hybridization analysis of the 1.711B satellite (7.1% of the genome) has previously shown that it consists of two types of repeat unit: 1.4-kb units homologous to the 1.4-kb repeat units of another bovine satellite (1.715 g cm^{-3})[5,6] and 2.6-kb units which correspond to 1.4-kb units carrying in addition a 1.2-kb insertion[3]. About 50% of the repeat units carry this insert, each at the same position. Thus, digestion of the satellite with *Sst*I, which cleaves once in the 1.4-kb sequence but not in the insert (Fig. 1*a*), yields mainly fragments of 1.4 and 2.6 kb. *Hin*dIII digestion, which cleaves once in the insert but not in the 1.4-kb sequence (Fig. 1*a*), gives mainly 2.6- and 4.0-fragments, while fragments ≥5.4 kb are less frequently found. This indicates that the 1.2-kb insertions occur most often in repeat units that are neighbouring or separated by one additional 1.4-kb unit, and with less probability in more distant ones.

I have determined the nucleotide sequence of the entire 2.6-kb repeat unit and have compared it to the 1.4-kb sequence derived from the 1.715 satellite DNA[7]. Uncloned restriction fragments were used for both sequences. They were therefore 'prototype sequences' corresponding to the most frequent nucleotides at each position of the repeat units. The sequence analysis confirmed that the 2.6-kb repeat unit consists of a 1.4-kb sequence highly homologous to the 1.4-kb repeat units, and an unrelated 1.2-kb sequence interrupting the 1.4-kb sequence. The homology between the 1.4-kb sequences in the repeat units carrying or lacking the 1.2-kb insertion is of the order of 95% (to be published). The nucleotide sequence of the 1.2-kb insertion (which is termed INS-1.711B) has several remarkable features:

(1) It is flanked by a 6-bp direct repeat (CCCTAC) which occurs only once at the corresponding position in the 1.4-kb unit (Fig. 1*b*–*d*). Such a duplication is highly characteristic for the insertion of transposable elements[1].

(2) The insertion is bounded by a 3-bp terminal inverted repeat TGC ... GCA (Fig. 2). If some mismatches are taken into account, the repeat could be extended to 13 bp.

(3) Following the terminal repeat, at the 5′ end there is a repetitious sequence of ~100 bp consisting of several tri- to heptanucleotides repeated two to five times and interspersed with each other and some non-repeated DNA: for example, there are five copies of GCATATT. (These oligonucleotides are underlined in Fig. 2*a*.)

(4) An open reading frame of ~200 bp is found in the 5′ half of the sequence. It is terminated by two successive TAA codons that are boxed in Fig. 2*a*.

(5) Several sequences thought to be important for the regulation of transcription are found in the 3′ half of INS-1.711B (Fig. 2). These are a Goldberg–Hogness box, TATAAAAA, at positions 947–954 and a polyadenylation signal, AATAAA, at 966–971 which is followed 15 bp later by a polyadenylation site, Ca. The sequence GCAAG (900–904) precedes the Goldberg–Hogness box in a position where the related sequence CCAAT is frequently found. Finally, TTGGT (995–999) is found in a region where TTGT or related sequences are thought to have a role in the termination of RNA synthesis[8] (Fig. 2).

The arrangement of these sequences in INS-1.711B is remarkably similar to that in a LTR of retroviruses. A comparison between INS-1.711B and the prototype of a retrovirus LTR is shown in Fig. 2*b*. A LTR contains sequences derived from both the 3′ and 5′ ends of the viral RNA (U3, U5) as well as one copy of the terminal redundancy (R), thus signals for the initiation and termination of transcription and for polyadenylation occur characteristically close to each other at fairly constant positions (Fig. 2*b*). In INS-1.711B the same or closely related sequences (see above) occur in these positions. Furthermore, the TG, CA-termini and the terminal inverted repeat present in all LTRs are also found in INS-1.711B. By analogy to retroviruses, the sequence 1–977 would then be U3-like, 978–987 would be R-like, and 988–1198 U5-like. It is not known, however, whether INS-1.711B is transcribed in bovine cells.

There are two structural features in INS-1.711B which have not been found in any of the sequenced LTRs: one is the repetitious region at the 5′ end (Fig. 2*a*); the other is a 13 bp sequence (position 116–128), at the end of the repetitious

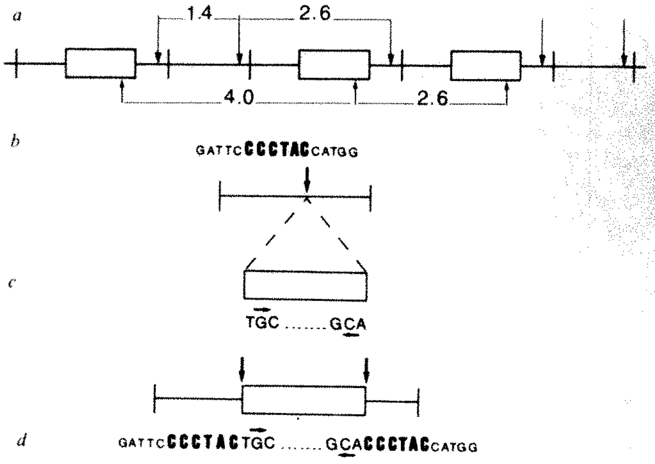

Fig. 1 Organization and partial sequences of repeat units in the 1.711B satellite DNA. *a*, Possible arrangement of 1.4-kb units lacking and 2.6-kb units carrying the 1.2-kb insertion. The sizes of fragments obtained by digestion with *Sst*I(↓) or *Hin*dIII(↑) are given in kb. *b*, 1.4-kb repeat unit. The arrow indicates the site of insertion. The nucleotide sequence at this site is given[7]. *c*, 1.2-kb inserted sequence (INS-1.711B). The 3-bp terminal inverted repeat is indicated. *d*, 2.6-kb repeat unit carrying INS-1.711B. The sequences flanking the insertion and its 3-bp terminal inverted repeats are given, the duplicated hexanucleotide in bold letters.

0028–0836/82/330767—03$01.00

region, that is related to the terminal repeats. In fact, this sequence forms a closer inverted repeat with the 3′-terminal sequence than does the 5′-terminal sequence (Fig. 2*a*).

No major differences were found when DNAs from thymus, liver and brain of different animals were digested by restriction nucleases and compared by Southern blot analysis[9] using cloned INS-1.711B as a probe. Therefore, major rearrangements of INS-1.711B in the satellite DNA during ontogenesis can be excluded. Some background smears observed in the hybridization experiment suggest that INS-1.711B-like sequences are dispersed throughout the genome.

I have shown previously that a 0.6-kb sequence related to INS-1.711B occurs in the repeat unit of the bovine 1.711A satellite (termed INS-1.711A)[3]. It was therefore interesting to compare INS-711B with INS-1.711A, which also exhibits some features of an insertion element[3]. The homologous regions of the two sequences are the first 250 bp of INS-1.711A, which correspond to the sequence 116–358 in INS-1.711B, and the last 140 bp of both elements; their internal sequences are completely unrelated (Fig. 3). The homology is greatest near the ends, for example, two transitions being the only base changes in the last 35 bp at their 3′ ends. The homology then gradually decreases to ~80% before ending abruptly. The 100-bp repetitious sequence found in INS-1.711B is absent from INS-1.711A. The region of homology near the 5′ end which contains the largest open reading frame in INS-1.711B (Fig. 2*a*) is also conserved in INS-1.711A. The region of homology at the 3′ end contains sequences characteristic of a polymerase II promoter in INS-1.711A[3]. In INS-1.711B this region is interrupted by a 19-bp sequence that is non-homologous. In summary, the homology found strongly suggests a common origin of the two sequences.

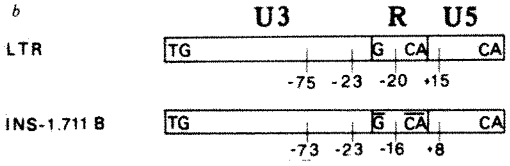

Fig. 2 Nucleotide sequence of INS-1.711B. Bovine 1.711B satellite DNA was purified from calf thymus DNA (Boehringer Mannheim) by isopycnic centrifugation[4] analogous to that described for bovine 1.706 satellite DNA [illegible]. Sequence analysis of restriction fragments from the purified satellite was carried out according to Maxam and Gilbert[13], using the *Alu*I, *Dde*I, *Hin*dIII, *Hin*fI, *Sau*3A and *Sau*96 sites in the insertion sequence for terminal labelling; 96% of the sequence was determined from at least two different overlapping restriction fragments, 40% being determined from both strands. *a*, Location of sequences mentioned in the text: the 3-bp terminal inverted repeats are indicated by arrows; the repeated oligonucleotide sequences near the 5′ end are underlined; and the largest open reading frame is marked by the boxed ATG and the two successive TAA codons. the other boxes indicate regulatory signals and related sequences thought to be important in transcription and polyadenylation. They are, in succession, a CCAAT-like sequence, a Goldberg–Hogness box, a polyadenylation signal and a transcription termination signal. A possible adenylation site, CA, and a presumptive cap site, G, are overlined. *b*, Diagrammatic representation of a LTR[8] and INS-1.711B. U3 and U5 correspond to sequences derived from the 3′ and 5′ ends, respectively, of the viral RNA; R indicates the terminal redundancy. The location of the regulatory signals mentioned above is marked. Their distances from the U3–R boundary (−75, −23) and R–U5 boundary (−20, +15)[8] are given in bp. The locations of the homologous signals in INS-1.711B (boxed in *a*) are analogously indicated assuming that the sequence 978–987 (Fig. 2*a*) corresponds to R. The overlined G and CA in the R-like region correspond to those of *a*.

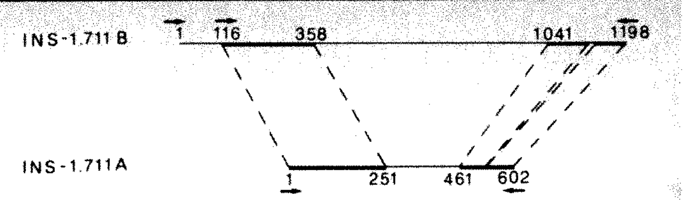

Fig. 3 Homologous regions of INS-1.711A and INS-1.711B. The nucleotide sequence of INS-1.711A is from ref. 3. INS-1.711A has been re-defined as the sequence bracketed by the inverted repeats, that is, the sequence 550–1,151 of the 1,413-bp repeat unit of bovine 1.711A satellite DNA[3]. The homologous sequences are indicated by bold lines, and their limits are represented by the corresponding nucleotide numbers. The arrows indicate the terminal inverted repeats and their internal repetition in INS-1.711B, respectively.

It is not known whether the high copy number of INS-1.711B is due to multiple insertion events or, more likely, to a passive amplification in the satellite DNA. In addition, it is not known whether INS-1.711B itself is transposable. Although the duplicated target sequence flanking the insertion is a strong indication of integration by transposition[1], it is also possible that INS-1.711B was a LTR of a larger movable element, for example, a retrovirus, which was first integrated and then excised by homologous recombination between the two LTRs (before being amplified in the satellite DNA). An analogous situation can be found for the solo δ-sequences of the Ty*1* elements in yeast[10]. Bovine leukaemia virus, the only bovine retrovirus for which partial sequences are known (A. Burny, personal communication), is unrelated to INS-1.711B.

Alternatively, INS-1.711A and INS-1.711B may be different stages in the evolution of a cellular insertion sequence, which were conserved by (or possibly evolved through) their integration into repetitive sequences. According to Temin's hypothesis on the genesis of retroviruses[11], INS-1.711B might then be an immediate precursor of a retroviral LTR.

This work was carried out at the Institut für Physiologische Chemie, Physikalische Biochemie und Zellbiologie der Universität München, D-8000 München 2, FRG, and was supported by Deutsche Forchungsgemeinschaft. I thank A. Burny for the communication of unpublished results, D. Brutlag for help in using the computer facilities at Stanford University, and K. Beer for technical assistance.

DNA synthesis in purified DNA–membrane complexes extracted from a *Bacillus subtilis* pol A mutant

Patricia Benjamin, Paul Strumph, Mark Kenny & William Firshein

Department of Biology, Wesleyan University, Middletown, Connecticut 06457, USA

The cell membrane of prokaryotes has been implicated as the site of DNA replication in the replicon model first proposed by Jacob, Brenner and Cuzin[1]. Ultrastructural, genetic and biochemical data have since been compiled suggesting an association between the cell membrane and replicating DNA (for review, see ref. 2). However, few studies have attempted to test this aspect of the replicon model directly by investigating the ability of DNA–membrane complexes to synthesize DNA *in vitro*. Such studies have been performed mainly with *Pneumococcus* and it has been shown that DNA–membrane complexes extracted by the M-band technique[3] retain their capacity to synthesize DNA even after extensive purification[4]. However, mutants defective in various aspects of DNA replication are unavailable in *Pneumococcus*, and this is an important requirement for elucidating the physiological significance of the complex. Fortunately, they are available in *Escherichia coli* and *Bacillus subtilis*, and of the two organisms, much of the important work with the complex has been accomplished with *B. subtilis*[5-12]. These studies have indicated that the origin and terminus of replication are permanently associated with the cell membrane. Nonetheless, there have been no previous studies of the synthetic capacity of *B. subtilis* DNA–membrane complexes. We now offer evidence that two DNA–membrane subcomplexes extracted and purified from a pol A mutant of *B. subtilis* are capable of synthesizing DNA *in vitro* and that these activities are inhibited by hydroxyphenyl azouracil, a specific inhibitor of DNA polymerase III activity in *B. subtilis*.

Many studies involving the DNA–membrane complex have been performed with only crude material, basically one step removed from whole cells. Because such complexes probably contain a variety of nonspecifically adsorbed components, it was considered essential to 'purify' the complex before analysing DNA synthesis. The purification procedure followed that developed for pneumococci[4] because it fulfilled three important criteria. First, a large amount of excess macromolecules was dissociated during the purification procedure. Second, the complex retained its ability to synthesize DNA *in vitro* without added template or enzymes. Third, the specific activity of DNA polymerase(s) increased throughout the purification procedure (except in one step, see below). Table 1 shows the percentages of macromolecules remaining in the complex after the various purification steps. CsCl centrifugation separated membrane-bound DNA from the crude M-band[3] into two peaks, one (corresponding to 94% of the total DNA in the crude complex) which sedimented at the buoyant density of free *B. subtilis* DNA, the other (corresponding to only 0.9% of the total DNA) floating at the top of the gradient as a pellicle together with 90% of the total lipid and 35% of the total protein.

These results indicate that DNA firmly bound to membrane represents a small fraction of the total DNA in the crude complex. One problem in this procedure is the possible contamination of the complex with 'free' protein which also floats at the top of the CsCl gradient. However, ~22% of the total protein of the crude complex was still associated with the subcomplexes after the final purification step described below. This suggests that at least this portion of the protein was firmly bound. The pellicle was dialysed to remove CsCl and centrifuged in a 5–20% (w/v) neutral sucrose gradient. Two peaks of DNA were observed (Fig. 1), one sedimenting near the bottom of the gradient and the other sedimenting near (but not at) the top. Both peaks contained varying amounts of co-sedimenting lipids (Fig. 1) and proteins (Table 1), suggesting that two DNA–membrane subcomplexes were resolved in the neutral sucrose gradient. Note that 'free' DNA and protein did

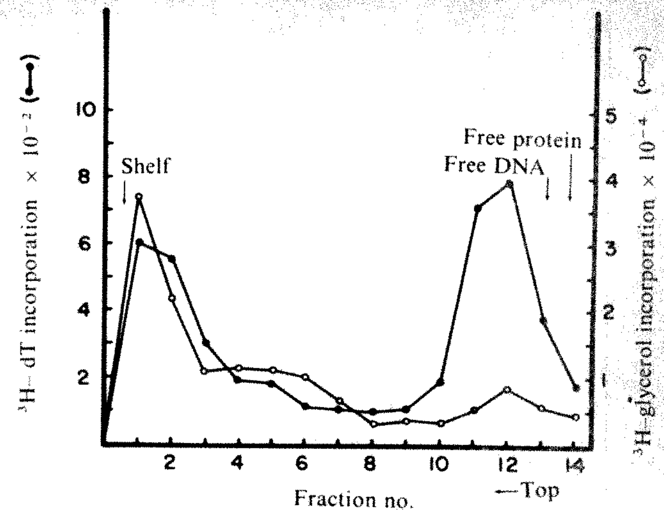

Fig. 1 Distribution of two DNA–phospholipid subcomplexes in a sucrose gradient. Methods are described in Table 1 legend. The experiment was repeated twice, once with a single label for DNA synthesis (^{3}H-thymidine) and once with a single label for phospholipid synthesis (^{3}H-glycerol).

Table 1 Purification of the DNA–membrane complex

Treatment of complex	% DNA	Macromolecule protein	Remaining lipid
1 DNA–membrane dialysis	100	100	100
2 CsCl centrifugation, dialysis	0.86	35.6	90.0
3 Sucrose gradient centrifugation (total)	0.64	22.3	49.0
(*a*) More slowly sedimenting complex	0.28	18.9	9.1
(*b*) Faster-sedimenting complex	0.36	3.4	39.9

Cultures (500 ml) of *B. subtilis* strain 841 (thy, tryp, pol A) were labelled with 100 μCi of ^{3}H-thymidine or 100 μCi of ^{3}H-glycerol and grown to the mid-logarithmic phase in Penassay broth. Cells were washed twice with TMK buffer, *p*H 7.0 (0.01 M Tris, 0.01 magnesium acetate, 0.1 M KCl) and incubated in the same buffer containing 25% sucrose (w/v) and lysozyme (20 μg ml^{-1}) at 4 °C for 10 min. Protoplasts were collected, resuspended in TMK buffer containing 0.3% sarkosyl and 1 mM phenylmethylsulphonyl fluoride (PMSF), and incubated for 10 min at 4 °C. The cell lysate was layered onto a biphasic 25/60% (w/v) sucrose gradient and centrifuged at 18,000 r.p.m. for 20 min at 4 °C in an Sw 41 rotor and Beckman L2 65B ultracentrifuge. The M-band was collected from the 25/60% interphase and dialysed overnight in TK buffer (0.01 M Tris, *p*H 7.0; 0.1 M KCl) containing 1 mM PMSF at 4 °C. Solid CsCl was added to the dialysate to obtain a mean density of 1.7001 at 30,000 r.p.m. for 48 h at 25 °C in an Sw 50.1 rotor. The pellicle was removed from the top of each gradient, pooled and dialysed in TK buffer overnight at 4 °C. The dialysate was layered onto 5–20% (w/v) neutral linear sucrose gradients containing an 80% sucrose shelf and centrifuged at 35,000 r.p.m. for 90 min at 4 °C in an Sw 50.1 rotor. The gradients were fractionated by puncturing the bottom of the tube, each fraction precipitated with trichloroacetic acid (5%, final concentration) and assayed for radioactivity in a Mark III liquid scintillation counter. Samples were also taken from the pellicle fraction and other areas of the CsCl gradient for assay of radioactivity as well as from the M-band fraction. Protein content was determined by the Bio-Rad reagent.

0028-0836/82/330769—03$01.00

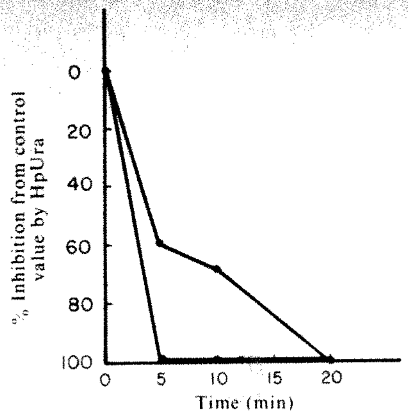

Fig. 2 Inhibitory effects of 6-(p-hydroxyphenyl azouracil) on DNA synthesis by the two subcomplexes. Methods are described in Table 2 legend. The concentration of reduced Hpura (with sodium dithionate) was 400 μM. The greater inhibitory activity (sharper slope) is observed in the fast-sedimenting subcomplex which is totally inhibited after 5 min, whereas the activity of the slowly sedimenting complex is totally inhibited only after 20 min. After 5 min the activity of the latter subcomplex is inhibited 60% from control values.

not sediment in the areas of the two subcomplexes but remained at or near the top of the gradient away from the slowly sedimenting subcomplex.

To determine whether the various complexes could synthesize DNA *in vitro* and whether purification of this activity was achieved, DNA polymerase assays were performed with the crude M-band, the CsCl pellicle fraction and the two subcomplexes detected in the sucrose gradient. Table 2 shows that both the total activity and the specific activity decreased after CsCl centrifugation and dialysis but increased significantly after sucrose gradient centrifugation. The reasons for this inhibition are unknown, but it has been observed consistently in our experiments. One possible explanation is that inhibiting factors are activated after this step but are removed after the subsequent sucrose gradient procedure. The more slowly sedimenting subcomplex showed a slight increase in specific activity while that of the faster-sedimenting complex was markedly enhanced. It is interesting that the more active complex contained a higher concentration of lipids. Firshein and co-workers[13] have shown that membrane glycolipids which are present only in Gram-positive bacteria stimulate DNA polymerase III activity in *Pneumococcus*. A similar phenomenon may be operating in *B. subtilis* if, in fact, the activity observed in both complexes is related to DNA polymerase III. Although it is probable that such is the case because of the pol A mutation (which virtually eliminates pol I activity), it was important to confirm this possibility by other means. Fortunately, 6-(p-hydroxyphenyl azouracil)(HpUra) specifically inhibits the activity of DNA pol III in *B. subtilis*[14]. Tests on the effects of this drug on the activity of the two subcomplexes show (Fig. 2) that with the addition of HpUra DNA synthesis is almost totally inhibited within 5–20 min, depending on the subcomplex, relative to controls.

Considerable evidence regarding the nature of membrane-associated DNA in *B. subtilis* has been provided by Sueoka and co-workers[8,11,12] and Yoshikawa and co-workers[7,9]. Their experiments have revealed several facts, which include (1) that the origin and terminus of replication are attached to the cell membrane throughout the cell cycle and (2) that the DNA–membrane complex can also be separated into two subcomplexes, both of which contain markers close to the origin. Although their subcomplexes were extracted and separated by different methods[9,11,12] from those used in the present experiments, it was of interest to determine whether there was any similarity in the composition of the complexes, at least with respect to some of the genetic markers present. Accordingly, the ability of the DNA in each of the complexes to transform markers near the origin, terminus and middle of the *B. subtilis* genome was compared.

Table 3 shows that both the slow- and fast-sedimenting subcomplexes (as well as CsCl-derived complex) were enriched for a genetic marker (gua Al) which is located less than 1° from the origin of replication on the *B. subtilis* genetic map[16]. The commonly used origin marker (pur A), which has been mapped to ~10° from the replication origin[16] and a genetic marker (met B5) which has been frequently used to detect enrichment for the terminus of replication, were not enriched in any of the DNA–membrane complexes isolated. In addition, no enrichment was detected for a marker (leu 8) located in the middle of the chromosome.

These results suggest that an unusually small area of the origin region may be represented in the subcomplexes. Although no enrichment for the terminus marker (met B5) was detected in the DNA–membrane complexes, it is possible that a smaller portion of the terminus region (including the actual terminus) is present in at least one of the subcomplexes. This suggestion is based on the possibility that the terminus marker (met B5) is positioned ~20° from the actual terminus of replication[16], whereas only 0.64% of the DNA in the M-band complex

Table 2 DNA synthesis *in vitro* in various fractions during purification of the DNA–membrane complex

Fraction	Total activity (counts per min)	Specific activity (counts per min per mg protein)
1 DNA–membrane, dialysis	725,940	2,902
2 CsCl centrifugation, dialysis	52,425	526
3*a* Sucrose gradient centrifugation, more slowly sedimenting complex	119,040	3,737
3*b* Sucrose gradient centrifugation, faster-sedimenting complex	150,240	19,603

Cultures (4 l) of *B. subtilis* strain 841 were grown to the mid-logarithmic phase in Penassay broth in the same conditions as for Table 1 except that radioactively labelled precursors were omitted. The DNA–membrane complex was extracted and purified according to the conditions described in Table 1 legend. The fractions were assayed for DNA polymerase activity in a reaction mixture containing 1.7 mM triethanolamine phosphate buffer, pH 7.5; 0.5 mM EDTA; 0.025% Triton X-100; 2.0 mM β-mercaptoethanol; 0.01 M $MgCl_2$; dATP, dCTP, dGTP (25 μg ml^{-1}); and ^{3}H-dTTP (73 Ci mmol^{-1}), 1 μCi per assay tube. Each assay tube was incubated at 37 °C for 30 min and the reaction terminated with the addition of ice-cold 5% trichloroacetic acid containing 1% (w/v) sodium pyrophosphate. Acid-insoluble radioactivity was determined by liquid scintillation techniques.

Table 3 Transformation for genetic markers in the DNA–membrane complex

Transforming *B. subtilis* DNA	Transformants per ml cells gua Al$^+$/leu 8$^+$	pur A$^+$/leu 8$^+$	met B5$^+$/leu 8$^+$
M-band-derived complex	20,000/445	413,000/104,000	40,000/5,500
CsCl-derived complex	600,000/10	90/40	38,240/610
Slowly sedimenting subcomplex	100,000/25	150/50	500/420
Fast-sedimenting subcomplex	120,000/20	60/30	660/80

Bulk *B. subtilis* DNA was extracted according to the method of Anagnostopoulos and Spizizen[17]. Although not shown, the ratios of the various transformations for bulk DNA were similar to those of the M-band because the M-band contains ~80% of the total cellular DNA. The DNA membrane complexes were prepared as described in the legend (Table 1). These fractions were used at concentrations of 2.5 μg ml^{-1} to transform recipient *B. subtilis* 1A177 (gua Al, ery-1), BUL717 (pur A, leu 8, met C), Mu8u5716 (pur A, met B5, leu 8) and a derivative of Mu8u5716 (gua Al, leu 8, pur A).

remains firmly bound in the subcomplexes (Table 1), a percentage corresponding to less than 2° of the *B. subtilis* chromosome. That this relatively small percentage does not represent a random area of the chromosome is indicated by the enrichment for the gua marker in most of the DNA–membrane complexes, but not for the pur A marker.

Finally, concerning the nature of the DNA synthesized, we can only surmise that since the assay solution does not contain components required for initiation of DNA replication (such as ribonucleoside triphosphates and high concentrations of ATP), an extension of strands from the replication fork is occurring with DNA pol III, rather than initiation of new strands. This possibility as well as attempts to determine whether initiation can be detected *in vitro* will be investigated. Nevertheless, this is the first report of a 'purified' DNA–membrane complex that can synthesize *B. subtilis* DNA *in vitro* using DNA pol III as the native enzyme.

This study was supported in part by NSF grant PCM 8110082 and by biomedical funds from Wesleyan University.

In vivo aminoacylation of brome mosaic and barley stripe mosaic virus RNAs

L. Sue Loesch-Fries* & Timothy C. Hall

Department of Horticulture, University of Wisconsin, Madison,
Wisconsin 53706, USA

The genomic RNAs of several plant viruses are now known to be able to bind a specific amino acid at their 3′ ends in a tRNA-like manner. Where the nucleotide sequence of the 3′-terminal region is known, it can be folded into an extensively base-paired secondary structure having the essential features of tRNAs[1,2]. The high degree of nucleotide sequence conservation of the 3′-terminal regions of the four RNAs of the three known bromoviruses[3], and the loss of infectivity of brome mosaic virus (BMV) RNA after chemical modification of its 3′ end[4], strongly suggest that the tRNA-like structure has a biological function in infection[2]. To elucidate this it has been important to determine whether viral RNAs are aminoacylated within infected host cells. We studied BMV and barley stripe mosaic virus (BSMV), which belong to very different groups but which have genomic RNAs that are capable of both accepting tyrosine and infecting barley protoplasts. We report here that single-stranded RNAs of both viruses are aminoacylated *in vivo*, but that the encapsidated RNAs of BMV are not.

Both BMV and BSMV have segmented genomes. The molecular weights (MWs) of the genomic RNAs of BMV are 1.1×10^6 (RNA1), 0.99×10^6 (RNA2), and 0.75×10^6 (RNA3). RNA 4, a subgenomic RNA coding for coat protein, is encapsidated with RNA3 and has a MW of 0.28×10^6 (ref. 7). The RNA of the Type strain of BSMV (ATTC strain 43) used in this investigation can be resolved by gel electrophoresis into two RNAs of MW 1.4×10^6 (RNA1) and 1.25×10^6 (RNA2)[8,9]. BMV and BSMV differ widely in their physical properties and transmissibility and thus have been assigned to separate virus groups; however, RNAs of both specifically accept tyrosine in an *in vitro* reaction catalysed by aminoacyl tRNA synthetase[5,6] *In vitro* studies have shown that aminoacylation of BMV RNA does not have a direct role in translation events[10,11]; however, it may be necessary for RNA transcription or encapsidation[12,13].

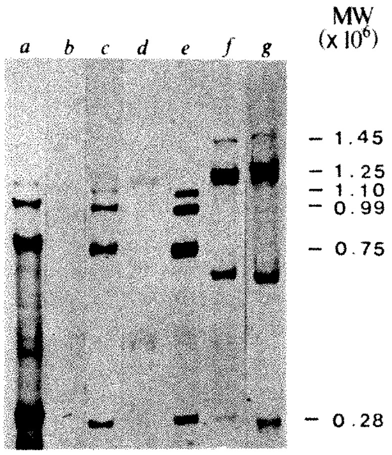

Fig. 1 Electrophoretic analysis of ^{3}H-labelled RNAs from: *a*, BMV Tyr-RNA charged *in vitro*[3]; *b*, mock-inoculated protoplasts cultured in ^{3}H-Tyr; *c*, BMV-infected protoplasts cultured in ^{3}H-Tyr; *d*, mock-inoculated protoplasts cultured in ^{3}H-uridine; *e*, BMV-infected protoplasts cultured in ^{3}H-uridine; *f*, BSMV-infected protoplasts cultured in ^{3}H-uridine; g, BSMV-infected protoplasts cultured in ^{3}H-Tyr. BMV and BSMV were extracted from infected *Hordeum vulgare* L. cv. 'Dickson' or 'black hulless', respectively[8,17]. Viral RNA was isolated by phenol extraction[8,18]. Protoplasts from primary leaves of 'black hulless' barley (20 ml, 1×10^5 ml^{-1}) were mock-inoculated or inoculated with BMV or BSMV RNA at 5 μg ml^{-1} and cultured in the presence of ^{3}H-Tyr (30–60 Ci mmol^{-1}) at 30 μCi ml^{-1} for 18–20 h, or ^{3}H-uridine (40–60 Ci mmol^{-1}) at 40 μCi ml^{-1} and actinomycin D at 10 μg ml^{-1} for 24 h. RNA was phenol-extracted from the protoplasts using buffer containing 100 mM sodium acetate, 10 mM EDTA *p*H 4.5, 1% SDS and 1 mg ml^{-1} bentonite for the samples labelled with ^{3}H-Tyr, or buffer containing 10 mM glycine, 10 mM EDTA, 100 mM NaCl *p*H 9.5, 1% SDS and 1 mg ml^{-1} bentonite for samples labelled with ^{3}H-uridine. After ethanol precipitation, the RNA samples were suspended in water and stored at −80 °C. Samples containing 2,000–3,000 c.p.m. were analysed by electrophoresis in 12.5 cm × 15.5 cm × 1.5 mm slab polyacrylamide gels containing 2.4% acrylamide, 0.1% methylene bisacrylamide and 0.45% agarose, using 90 mM Tris-borate *p*H 8.3, 2.5 mM EDTA (TBE buffer). Electrophoresis was at 25 mA for 2 h at 4 °C. The radioactive bands were detected by fluorography using EN^{3}HANCE (NEN). Exposures of 30–50 days were required to detect radioactive bands. The MWs of the viral RNA bands are indicated.

Primary leaf protoplasts of barley were inoculated with BMV or BSMV RNA[14]; for mock-inoculation RNA was omitted. Protoplasts were cultured either in the presence of ^{3}H-uridine and actinomycin D to label virus RNAs synthesized during infection, or in the presence of ^{3}H-tyrosine (^{3}H-Tyr) to label aminoacylated RNAs. Samples of RNA from inoculated protoplasts labelled with ^{3}H-Tyr had approximately the same number of trichloroacetic acid (TCA)-precipitable counts as did a comparable sample from mock-inoculated protoplasts. However, striking differences in the patterns of aminoacylation became evident when the samples were analysed by gel electrophoresis (Fig. 1). Protoplasts inoculated with either BMV or BSMV RNA and cultured in ^{3}H-Tyr (Fig. 1*c*,*g*) contained radioactive RNA species that co-migrated with the ^{3}H-uridine-labelled viral species from infected protoplasts (Fig. 1*e*,*f*). The four radioactive bands of BMV RNA also co-migrated with BMV Tyr-RNA prepared by aminoacylation *in vitro* (Fig. 1*a*). RNA preparations from mock-inoculated (uninfected) protoplasts did not contain these labelled RNA bands. In addition to the genomic RNAs of BSMV, two smaller RNA bands were present in samples labelled with either ^{3}H-Tyr or ^{3}H-uridine. Low levels of these RNAs (MWs ~0.65×10^6 and 0.30×10^6) are present in virion preparations; considerable amounts of them occur in infected protoplasts and they may represent subgenomic

0028-0836/82/330771—03$01.00

messengers that are infrequently encapsidated[15]. They are also present in polysome preparations from infected barley; however, their translation products have not yet been identified (J. E. McFarland and A. O. Jackson, personal communication).

The ester bond between the amino acid and the viral RNA is readily hydrolysed. Therefore, although the viral RNAs from protoplasts cultured in ^{3}H-Tyr were labelled, it was possible that the radioactivity did not represent an aminoacylated tyrosine. When BMV Tyr-RNA was heated in Tris-borate, *p*H 8.3 at 60 °C for 30 min, only 4% of the original radioactivity remained TCA-precipitable; if ^{3}H-uridine labelled BMV RNA was similarly treated, 96% of the radioactivity remained TCA-precipitable. Electrophoretic analysis of these samples is shown in Fig. 2*a*–*d*. BMV Tyr-RNA (Fig. 2, lane *c*) contained an RNA that migrated as a broad band ahead of RNA4—this probably resulted from slight degradation during *in vitro* aminoacylation. This band is present in Fig. 2*m*, which also contains BMV Tyr-RNA. The RNA samples from BSMV- and BMV-infected protoplasts cultured in ^{3}H-Tyr (Fig. 2*e*,*f*,*i*,*j*) behaved as expected for aminoacylated RNAs in that all radioactive viral bands lost most of their radioactivity during heating. Gels containing RNA samples from protoplasts cultured in ^{3}H-Tyr subjected to electrophoresis for a shorter time (Fig. 2*h*–*j*) contained a rapidly migrating radioactive RNA band that appeared to be tyrosylated tRNA. This was confirmed by comparison of its electrophoretic migration with wheat germ tRNA aminoacylated *in vitro* (Fig. 2*k*,*l*).

RNA isolated from infected protoplasts includes viral molecules involved in translation and transcription as well as those encapsidated into virions. To determine whether encapsidated RNA was tyrosylated, virus was purified from infected protoplasts cultured in ^{3}H-Tyr by a modified extraction procedure using differential centrifugation with unlabelled carrier virus[14]. RNA was isolated from the virus and analysed by polyacrylamide gel electrophoresis; RNA collected 18 h after inoculation contained only trace levels of radioactivity, but RNA from virus collected 24 h after inoculation contained detectable levels of radioactivity. Figure 3 shows that all four encapsidated RNAs were radioactive—this was surprising as comparisons of the acceptor capacity for batches of RNA isolated in acidic or alkaline conditions from virions suggested that encapsidated BMV RNA was not tyrosylated[2]. Therefore, the RNA was tested for the ability to lose radioactivity by deacylation in alkaline conditions. Figure 3*c*,*d* shows that most of the radioactivity remained after heating, suggesting that the radioactivity associated with the encapsidated RNA was not due to an aminoacylated tyrosine. It is likely that turnover of the ^{3}H-Tyr during the 24 h incubation period resulted in the formation of ^{3}H-labelled nucleotides that were subsequently incorporated into viral RNA, and thus the radioactivity was relatively stable to hydrolysis.

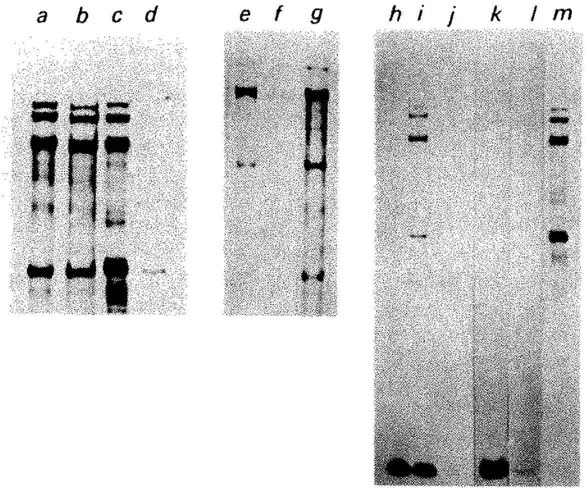

Fig. 2 Electrophoretic analysis of deacylated RNAs. Aliquots of RNA were prepared in either TBE buffer (see Fig. 1 legend) or in water as a control. The RNA samples suspended in TBE buffer were heated to 60 °C for 30 min and cooled on ice; samples suspended in water were brought to 50 °C for 5 min. All samples were made dense with urea. Electrophoresis was as described in Fig. 1 legend, except that RNAs in lanes *h*–*m* were subjected to electrophoresis for only 1.5 h. RNAs added to the gel lanes were: *a* and *b*, ^{3}H-uridine-labelled BMV RNA from infected protoplasts; *c* and *d*, BMV Tyr-RNA aminoacylated *in vitro*; *e* and *f*, RNA from BSMV-infected protoplasts cultured in ^{3}H-Tyr; *g*, RNA from BSMV-infected protoplasts cultured in ^{3}H-uridine; *h*, RNA from mock-inoculated protoplasts cultured in ^{3}H-Tyr; *i* and *j*, RNA from BMV-infected protoplasts cultured in ^{3}H-Tyr; *k* and *l*, wheat germ Tyr-tRNA aminoacylated *in vitro*; *m*, BMV Tyr-RNA aminoacylated *in vitro*. RNAs in lanes *b*, *d*, *f*, *j* and *l* were heated in TBE buffer; the other lanes contain control RNA.

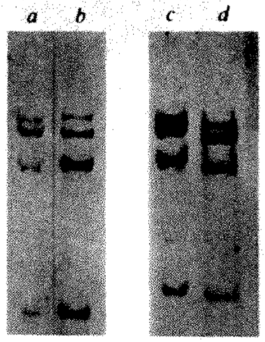

Fig. 3 Analysis of encapsidated RNA. Infected protoplasts (~1×10^6) collected 24 h after inoculation were homogenized in 500 mM sodium acetate, 80 mM magnesium acetate *p*H 4.5, using a ground-glass tissue homogenizer. Unlabelled BMV (200 μg) was added as a carrier and the sample was subjected to differential centrifugation to isolate virions[14]. The virus pellet was resuspended in 400 μl of a 1:10 dilution of the above buffer. RNA extraction and electrophoresis were as described in Fig. 1 legend except that 1M sodium salicylate was used as the autoradiographic enhancer for lanes *c* and *d*. Mock-inoculated protoplasts contained no radioactivity. *a*, *c*, *d*, RNA isolated from virus extracted from BMV-infected protoplasts cultured in ^{3}H-Tyr; *b*, BMV Tyr-RNA charged *in vitro*. RNA contained in lane *a* was from a separate experiment than that contained in *c* and *d*. RNA in *d* was heated in TBE buffer (as in Fig. 2).

These results demonstrate that non-encapsidated viral RNA is aminoacylated within a natural host cell. The tyrosylated viral RNA appeared to be full-length as it co-migrated in polyacrylamide gels with full-length BMV RNA. This differs from the situation described by Joshi *et al.*[16] for aminoacylation of turnip yellow mosaic virus RNA with valine in *Xenopus laevis* oocytes, in which the aminoacylated RNA appeared to have been cleaved into a fragment similar in size to tRNA; no full-length charged viral RNA could be detected. This discrepancy may reflect differences between plant and animal cells or possibly differences in methods of detecting charged RNAs.

Subgenomic RNA4 of BMV and two putative subgenomic messengers of BSMV were found to be aminoacylated. If aminoacylation is involved in RNA replication, such as the mechanism postulated by Hall and Wepprich[12] wherein aminoacylated viral RNA binds elongation factor and subsequently replicase, these results suggest replication of the subgenomic RNAs via their own templates.

We thank Dr A. O. Jackson for 'black hulless' barley seed and BSMV Type culture and for useful discussions. We also thank P. A. Kiberstis for the gift of *in vitro* aminoacylated BMV Tyr-RNA. This work was supported by NIH grant AI 11572 and NSF grant PCM 78-22526.

Helices are expected to scatter circularly polarized light preferentially. According to theory, the scattering depends on the pitch, radius and sense of helix[1–4]; however, experimental data have been lacking. We now report quantitative measurements of the differential scattering of left and right circularly polarized light from the sperm head of the octopus *Eledone cirrhosa*. This sperm head is a left-handed helix with pitch and diameter of about 1 μm. It preferentially scatters left circularly polarized light versus right circularly polarized light in the forward direction, with a maximum differential scattering of 2% at 35° to the incident beam (wavelength = 0.442 μm). The preferential forward scattering of left circularly polarized light is consistent with theory[1–4]. As a differential scattering of 0.1% is easily measured, this can be a useful new method to characterize helical biological objects.

Circular dichroism (CD) studies of complex biological macrostructures sometimes produce anomalies in the measured spectra. CD signals are observed outside the absorption bands of the chromophores, thus making the interpretation of the spectra difficult[5–7]. These artefacts have been shown to arise from a difference in scattered intensities when left and right circularly polarized light is incident on the sample[8–11]. This differential scattering produces a differential extinction, which is recorded by the CD spectrophotometer as if it were differential absorption. Experimental techniques exist to characterize these spurious scattering effects and to eliminate them[9,12]. However, recent theoretical work[1–4] has shown that the differential scattering contains detailed structural information. The theory shows that the angular dependence of the circular intensity differential scattering, CIDS $= (I_L - I_R)/(I_L + I_R)$, reflects the structure of the chiral macromolecule. Here I_L and I_R are the intensities of the scattered light at a given angle when left and right circularly polarized light is incident. Application of the general theory to helices shows that polar plots of CIDS versus scattering angle give lobes whose sign, number and position are characteristic of the sense, pitch and radius of the helix.

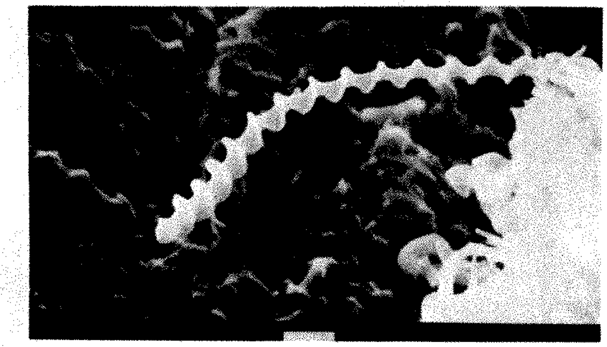

Fig. 1 Scanning electron micrograph of a freeze-dried sperm head from the octopus *Eledone cirrhosa*. The sperm head is a left-handed helix with a pitch of about 0.65 μm. Scale bar, 1 μm.

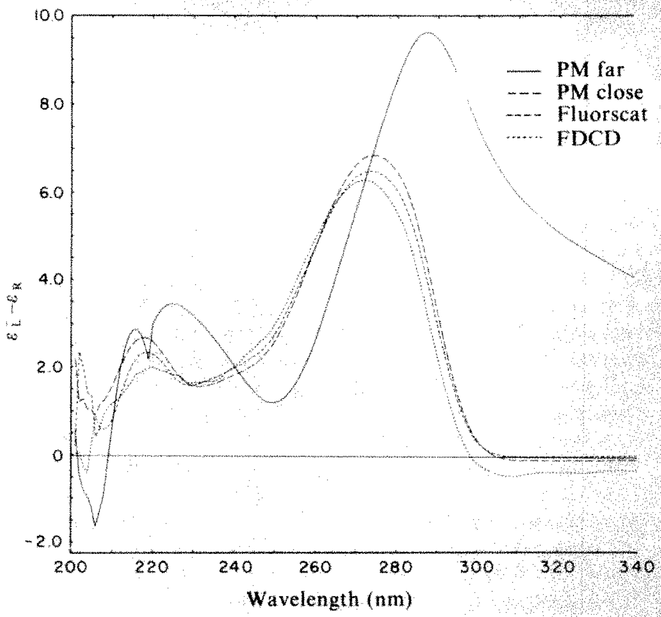

Fig. 2 Circular dichroism spectra in arbitrary units of *E. cirrhosa* sperm heads, measured by techniques having different solid angles of detection of scattered light. ——'PM far' is the conventional configuration; — —, 'PM close' has the photomultiplier detector close to the sample to detect most of the forward scattered light; - - -, fluorscat method; · · · · ·, fluorescence detected circular dichroism, FDCD, method. Sample contained 1 mg lyophilized heads in 10 ml of a 0.1 M NaCl, 10 mM Tris, *p*H 7.5 buffer.

We have built an instrument to measure the angular dependence of differential scattering of circularly polarized light (CIDS), and report some preliminary results that indicate the usefulness of such measurements. The nuclei of sperm cells from the octopus *E. cirrhosa* were chosen for initial study, because their large helical structure ensures large CIDS values, and their chirality and dimensions could be measured independently. Figure 1 illustrates the remarkable size and complexity of the helical head of the mature sperm from *E. cirrhosa*. These rigid nuclei have been measured by light microscopy to be 43 μm long, and to form a left-handed helix with a pitch of 1 μm and radius of 0.5 μm (ref. 13) Our measurements in the scanning electron microscope gave values for the pitch of 0.65 μm, with an outside diameter of 0.60–0.65 μm and an inner diameter of 0.25 μm. The difference in the two sets of values probably reflects the difference in techniques. On suspending purified nuclei in a buffer solution, intense light scattering is observed. Figure 2 shows the CD spectrum of the suspended nuclei. The curve labelled 'PM far' is the usual experimental arrangement, in which the photomultiplier mainly detects the transmitted beam; only light scattered very close to this beam is also detected. Note that the CD signal is very strong at long wavelengths, where the components of the nuclei (DNA and protein) do not absorb light, suggesting a large contribution from differential scattering of circularly polarized light. Of particular interest is the fact that this differential scattering effect is essentially eliminated by bringing the photomultiplier close to the sample and thus increasing the angle of acceptance of the scattered light (Fig. 2, curve labelled 'PM close').

Further small corrections were achieved by use of fluorscat cuvettes[8] and fluorescent detected circular dichroism (FDCD) techniques[9]. Fluorscat is a double-chambered cuvette with the outer chamber filled with a fluorescent solution that captures all light not absorbed by the sample, except for a small sector

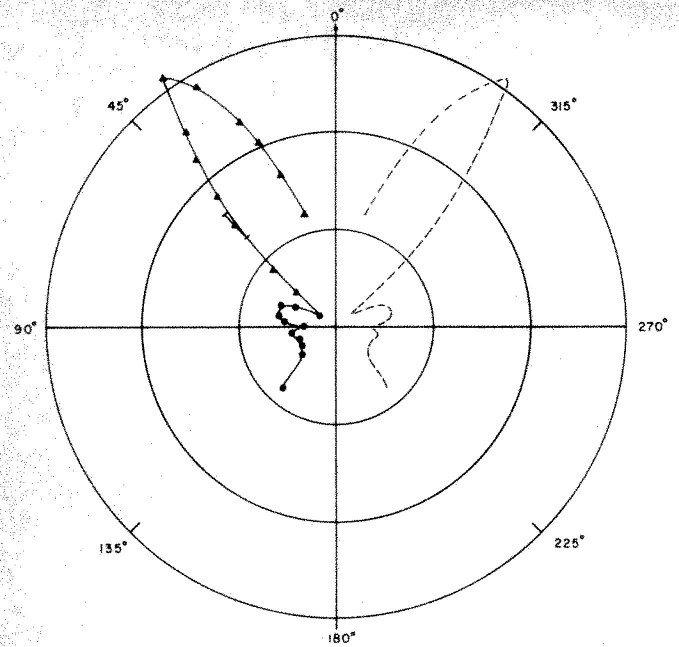

Fig. 3 Plot of CIDS $[(I_L - I_R)/(I_L + I_R)]$ versus scattering angle for *E. cirrhosa* sperm heads at a concentration of 0.25 mg ml^{-1} in the buffer of Fig. 2; the arrow illustrates the direction of incident beam (wavelength = 442 mm). ▲, Positive values; ●, negative values; ——, measured data; – – –, constructed by symmetry. The plot has a maximum positive value of 1.4×10^{-2} at about 35°; the positive value means left circularly polarized light is preferentially scattered.

in the back direction of the scattering envelope. The FDCD technique involves the use of a fluorescer molecule that is not optically active and that does not bind to the particle being measured. Each scattering particle is now surrounded by a cloud of fluorescent molecules which measure all the light that is not absorbed, including light scattered backwards along the incoming light beam. Considering the minor corrections to the measured CD by the fluorscat and FDCD techniques (Fig. 2), we conclude that the sperm heads mainly scatter light differentially in the forward direction.

The apparatus used to measure CIDS directs linearly polarized light from a He–Cd laser (442 nm) through a Pockels' cell (an electro-optical quarter wave plate) with an applied square voltage pulse which produces alternately pure left and right circularly polarized light. The circularly polarized light is incident on the sample cuvette, and the scattered radiation is measured by a detector mounted on a goniometer. The signal from the detector is processed by a modified Cary 60 spectrophotometer and analysed in terms of CIDS.

Figure 3 shows the resulting polar plots of CIDS versus scattering angle for the sperm heads; a reference sample of polystyrene beads shows no differential scattering in the same conditions. This plot shows that the CIDS does occur mostly in the forward scattering direction (with a maximum at 35° from the incident beam), and also that left circularly polarized light is scattered more intensely than right circularly polarized light, that is, the forward lobe is positive. There is evidence of small negative differential scattering to the sides (90°) as is predicted from the minor correction of the fluorscat method (Fig. 2). The results presented here are preliminary and have been obtained with a maximum angular resolution of 5°; however they are very reproducible. We are now working to improve the resolution of the apparatus to obtain more detailed information about the angular dependence of the differential scattering intensities.

The data shown in Fig. 3 are of the type expected from theory for a helix whose pitch or radius is larger than, but similar to the wavelength of incident light. The preferential forward scattering of left circularly polarized light indicates a left-handed helix. We have measured differential scattering from T4 and T7 bacteriophage[14] which are very different from each other and from the octopus sperm. We think that differential scattering of circularly polarized light can be very useful in determining the packing of DNA in bacteriophages[15,16], and the higher order structures of DNA in chromosomes[17].

We thank Dr Phillip Burns for help with some of these measurements. This work was supported by NIH grants AI08247(M.F.M) and GM 10840(I.T.) and by the Office of Health and Environmental Research of the US Department of Energy under contract 98, DE-AC03-76SF00098.

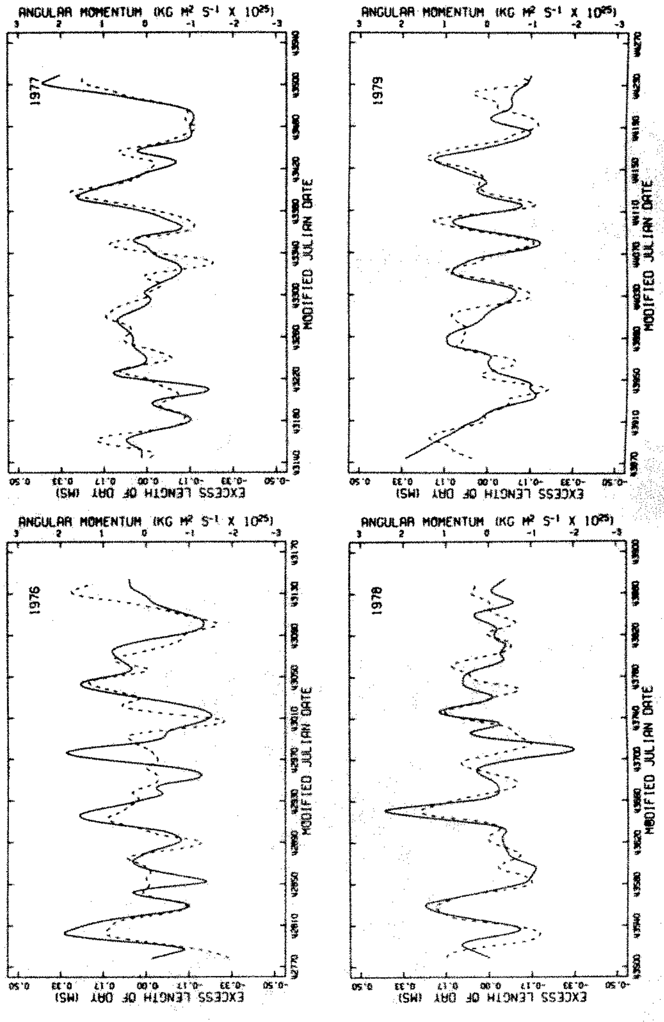
Erratum

In the letter 'Atmospheric angular momentum and the length of day: a common fluctuation with a period near 50 days' by R. B. Langley *et al. Nature* **294,** 730–732 (1982), the curves in a panel of Fig. 1 were rotated through 180°. The figure is shown correctly in reprints and (reduced in size) below.



BOOK REVIEWS

Blunders in the business of risk

Dorothy Nelkin

IN 1885 a British tourist in the United States was travelling on a train when it began to shake violently. Panicked, he asked the conductor to stop the train, but to no avail. The train jumped its tracks and most of the cars were smashed. Yet to his amazement, his fellow passengers applauded the conductor's efforts to arrive on time. So consumed were they by the idea of progress, they failed to recognize a near fatal disaster.

Clearly, attitudes have changed. Today, the United States has been described as a "risk-aversive" society, and some feel that our preoccupation with risks is threatening our commitment to technological progress and economic growth. In this environment the field of risk assessment has become a veritable industry. The assessment, management and adjustment to risk is estimated to cost between $200 and $300 billion per year, that is, from 10 to 15 per cent of the gross national product. The fear of risk is reflected in legislation and regulation. A programme within the National Science Foundation supports research on risk, hoping to provide a rational and reasonable basis for technical decisions. The availability of funds has encouraged a proliferation of consulting firms and academic research programmes. Indeed, the field of risk assessment, engaging geographers and engineers, economists and systems analysts, psychologists and anthropologists, has replaced technology assessment as the fashion of the day.

Risk analysts are preoccupied with two central questions: "How safe is safe enough?" and "What factors influence perception of risk?". Systematic efforts to estimate and evaluate the risks inherent in different technologies and then to quantify the acceptability of risk began to burgeon in response to environmental controversies, in particular over nuclear power. Hoping to develop a "rational" means to make decisions about hazardous technologies, a number of scholars from the field of engineering safety analysis sought to establish a quantitative basis to compare risks from different technological choices and to calculate their relative costs and benefits. They were encouraged by legislation requiring the risks of technological choices to be systematically weighed against social benefits. Their analytical approaches to risk, based on engineering and economic models, included a variety of forecasting and systems analysis techniques. They confronted serious methodological dilemmas. Indeed, the uncertainty about the nature and extent of the risks inherent in many technological choices seems to defy systematic and objective analysis. In any case, the various efforts to calculate the risks and benefits of technology proved to be poor indicators of the political and social acceptability of risk.

Risk and Culture: An Essay on the Selection of Technological and Environmental Dangers. By Mary Douglas and Aaron Wildavsky. Pp.224. ISBN 0-520-04491-6. (University of California Press: 1982.) $14.95, £11.25.

Difficulties in predicting public attitudes focused attention on the psychological and attitudinal factors that enter subjective perceptions of risk. Psychologists began to study risk perception through laboratory experiments, gaming situations and survey techniques in order to identify the subjective values that guide individual choices. Their work on the characteristics of risk that influence judgements about acceptability suggests that risks that are involuntary, uncertain, unfamiliar and potentially catastrophic are most difficult for people to accept. In their studies, psychologists try to arrive at a quantitative determination of risk acceptance. However, limited by their focus on the individual, they often fail to account for variations in the perception of risk in different social and cultural contexts. Why indeed did the British tourist perceive risks so differently from his fellow travellers?

These social dimensions of risk perception are the focus of *Risk and Culture*. Seeking to explain the preoccupation with risk in American society, the authors start with a provocative and promising premise — that it is inappropriate to define simply the problem of risk either in terms of objectively calculated physical risks or subjectively biased individual perceptions. Between subjective perceptions and physical science, they argue, lies a culture; and perceptions of risk are necessarily embodied in the complex system of beliefs, values and ideals which constitute this culture. This premise carries the debate about risk beyond the narrow technical questions of safety and into the domain of values and social choices.

This view of risk as a socially constructed phenomenon is a creative and refreshing addition to the risk analysis literature. It could lead to research into a variety of questions, shedding light on the social and political dimensions of risk perception. However, instead, the authors carry their argument in a direction that reflects their personal concerns with challenges to the *status quo*.

Their argument is as follows. Risk is a kind of euphemism for social and moral issues. Both modern and primitive societies select dangers to buttress their view of the social system. Risk becomes an explanation of failure, a way of attributing blame, a moral judgement about conduct inspired by a vision of the social and moral order. People predisposed to prefer different forms of social organization will perceive different dangers. Douglas and Wildavsky thus shift the critical question in risk analysis from "What are the real risks?" to "Why do different people perceive risks in different ways?" — "What issues of accountability or values are at stake?".

They build their argument by rejecting the conventional assumptions of most risk analyses. They dispose of explanations based on scientific evidence, pointing to the disputes among scientists and the real uncertainties surrounding many questions of risk. They observe how scientific judgements themselves are rooted in social expectations. Similarly, they account for the rigid categories of voluntary and involuntary risk underlying "objective" analyses by observing how the choices of risk assessment methods are themselves biased by underlying cultural assumptions. Then they turn to their own analysis, suggesting how different cultures with shared values and social institutions will select or highlight certain risks and minimize others.

The argument is built on Douglas's superb work on "pollution" — the idea that "pollution beliefs" are used by all societies to define boundaries that will preserve social categories and political relationships. It is a convincing thesis. The very language of those concerned with risks vividly reveals their social and political orientation. Why else would critics of nuclear technology talk of "electro-fascism" or "nucleocracy"? However, my enthusiasm for this approach to risk begins to wane when Douglas and Wildavsky develop a three-part typology of "risk portfolios" in American society. They assert that the evaluation of risk is based on (i) hierarchical assumptions, (ii) market or individualistic rationality, or (iii) sectarian values. The first two comprise a "centre" in which maintenance of the existing system is the primary goal. "Sectarian" rationality comprises a border, remote from the centre of power. The perspectives of sectarian groups on risks reflect their rebellion against the centre and their own needs to maintain group allegiance. Their views are marked by "disdain of the world, fear of pollution, of cancerous contamination" and are propelled by "moral fervor". The sectarian "wins adherence if he can threaten bigger dangers and associate them with the corruption of the system".

The authors develop their model of the sectarian society less from evidence than from their own opinion of the radical wing of the environmental movement. They quickly lapse into pejorative language that hardly masks their disdain. They portray such groups as self-indulgent and living in permanent and nagging opposition to the centre with no intention of assuming responsibility or power. And they denigrate the strengths of sectarian ideals suggesting that, when not allowed to enjoy government subsidy, such groups simply become part of the very system they reject.

The authors feel that such sectarian values are increasingly important in American society and have won "extraordinary success". They do, indeed, account for our preoccupation with risk. There are, however, many problems with their argument. After all, the "sustained assault" by public interest and environmental groups lasted but a decade. In the context of today's politics the "extraordinary success" of environmental groups as compared to business interests is hardly convincing. Moral fervour in the United States today comes from other directions, indeed from the centre itself. Concerned about challenges to the hierarchical and market values that constitute the centre, the authors ignore the usefulness of sectarian groups as a source of constructive criticism and countervailing power. They neglect, for example, the positive contributions of "border groups" such as the alternative technology movement who have put forward specific proposals for minimizing risk. And to suggest that such sectarian — i.e. powerless — groups could gain power if they really wanted it, is to totally ignore political and economic constraints. In their criticism of such groups, the authors describe "lobbying, litigation and non-violent obstruction" as "border strategies", forgetting that these are also conventional political actions exploited by bureaucracies and businesses.

The authors also dismiss the possibility that the reality of risk has changed in any significant way, essentially ignoring the increased scale and changing character of technology-induced risk. Associating the fear of risk with radical groups, their theory has no place for those who work in genuinely dangerous jobs, or the residents of Love Canal, or the 700,000 middle-class people who converged in New York City to protest against the risk of nuclear war.

A cultural theory of risk could be developed in a different direction with greater emphasis on the social position and the special vulnerability of certain groups with limited economic or political choice. It could call attention to the experience and perspectives of people who deal with risks as a fact of everyday life. Clearly judgements of risk reflect cultural values. But after all there is a social reality. If indeed the issue of risk has become an arena for disputes over power, why not take off from this approach to examine critically corporate perceptions and behaviour with respect to risk? Why not ask how factors at work and in daily life influence people's risk perceptions?

Douglas and Wildavsky end their book by frankly stating their own bias towards the centre. Basing their analysis on the acceptance of given institutional arrangements, they, along with other risk analysts, have masked many problems by avoiding critical questions about the very political and social relationships that they themselves admit are fundamental to the selection and perception of risks. ☐

An enlarged Universe

Owen Gingerich

The Expanding Universe: Astronomy's 'Great Debate' 1900–1931. By Robert W. Smith. Pp.220. ISBN 0-521-23212-0. (Cambridge University Press: 1982.) £19, $29.50.

ONE of the extraordinary developments of twentieth-century science has been the recognition and measurement of the great size of the Universe. The most dramatic moments in this revolutionary understanding took place from 1918 to 1924, primarily at the great mountain observatories in the American West, and a focal event was the debate on the scale of the Universe between Harlow Shapley and H.D. Curtis in Washington, in June 1920.

The Shapley–Curtis debate has achieved something of near mythological status among astronomers. Robert Smith capitalizes on the mystique of the specific debate in his subtitle to extend the argumentation over a broader time span; and well he might, for, as he informs us, the actual encounter before the National Academy of Sciences left a great deal to be desired as far as scientific depth was concerned. The main title is likewise stretched beyond its specific technical connotation, and in an almost punning fashion refers more to a Universe ever larger in man's conception than in physical expansion.

The Shapley–Curtis–Hubble era has attracted a variety of historical treatments in the past decade. Smith's in-depth research fills in the contemporary details too often blurred by our 20–20 hindsight. For example, the status of the globular clusters as possible external galaxies has been almost entirely neglected in modern historical accounts of the 1915–1925 period. Similarly, he fills in the story of the first faltering attempts in the 1920s to derive a relation between the velocities and distances of the spirals, without which certain aspects of Edwin Hubble's approach to the problem can scarcely be comprehended.

In giving us a near-definitive account of the fascinating and turbulent growth in astronomical knowledge, Smith has assiduously avoided the historian's sin of evaluating the past with today's standards. Yet it would have been illuminating, I think, for him to have allowed that Shapley's joining of the period–luminosity relations for cluster-type variables and the Cepheids, for which he was criticized at the time, was in fact incorrect. Equally, Shapley's own criticism of Hubble's assumptions about the similarity of certain galaxies and their components has today proved valid. In the event both Shapley and Hubble pushed on with their faulty programmes, to the considerable advance of science in their day. This may well be telling us something interesting about the nature of scientific progress, but Smith's strictly historical approach prevents any such speculation. ☐

Owen Gingerich is a Professor of Astronomy and History of Science at the Harvard–Smithsonian Center for Astrophysics, Cambridge, Massachusetts.

An experiment of Otto von Guericke (1602–1686), a predecessor of Robert Boyle, attempting to produce a vacuum by exhausting a sealed cask filled with water. The illustration is taken from a corrected reprint of A. Rupert Hall's *From Galileo to Newton*, first published in 1963. The new edition is published by Dover in the United States and Constable in Britain, prices $6, £4.50 respectively (pbk).

Polymeric molecules in motion

Warner L. Peticolas

The Theory of Vibrational Spectroscopy and Its Application to Polymeric Materials. By Paul C. Painter, Michael M. Coleman and Jack L. Koenig. Pp.530. ISBN 0-471-09346-7. (Wiley: 1982.) £44.50, $80.

A DISTINGUISHED figure in the field of vibrational spectroscopy, Professor Jack Koenig of Case Western Reserve University has collaborated with two of his younger colleagues to produce a book which should be, for some time to come, the definitive work on the application of the theory of molecular vibrations to polymeric materials. Starting with a clear treatment of the classical mechanics of the vibrations of small molecules using both Cartesian and internal coordinates, the book takes the reader in a logical way to calculations of the normal modes of vibrations of polymer chains.

Due to the exigencies of space, some short cuts have been taken. For example, although the book starts with a discussion of small molecules, there is no mention of the formulae for calculating molecular internal coordinates from molecular Cartesian coordinates. Instead, the general concept of internal coordinates and their relationship to Cartesian coordinates is worked out in detail using matrix techniques. If the reader would like to work out the G matrix for small molecules with a desk calculator, he will have to turn to one of the listed references.

However, one gets the feeling that this book is really for readers who wish to do their calculations using computers. With a good computer program, it is possible to carry out normal mode calculations without actually going into a detailed derivation of the precise mathematical formulae for calculating each type of internal coordinate. Computer programs are available which define the internal coordinates and then immediately give instructions for calculating them from the coordinates of the atoms, which must be supplied as data. This approach is stressed in Chapter 7, entitled "Solving the Vibrational Problem Using Computer Methods". The authors note that it is difficult to use a desk calculator to solve secular matrices whose dimensions are greater than 3 by 3 and that it is much easier to go directly to a computer. They conclude their discussion of simple molecules with a detailed analysis of the benzene molecule. This is an area to which they themselves have made an important contribution in elucidating the vibrational spectra of benzene and its two important carbon-13 isotopic derivatives, as well as those of numerous deuterium substitutive derivatives.

After giving a brief account of the quantum mechanical description of infrared and Raman intensities, the authors discuss the lattice dynamics of chain molecules. This is the strongest feature of the book. Starting with the simple linear diatomic chain, and going to a detailed mathematical discussion of the Wilson–GF method, they present a clear method for calculating the normal modes of helical polymeric chains. The theory is followed by consideration of the normal modes calculations of many common polymeric materials. The book closes with an introduction to biological polymers which includes a discussion of the normal modes of polyglycine I.

Anyone wishing to do research in the field of vibrational spectroscopy of polymeric materials, including biological polymers, or anyone interested in the force fields of macromolecules, will find this book a time-saving, helpful introduction to a very complex but fascinating subject. ☐

Alternative hosts for genetic engineers

Noreen Murray

Gene Cloning in Organisms Other than E. coli. Vol.96 *Current Topics in Microbiology and Immunology.* Edited by P. H. Hofschneider and W. Goebel. Pp.259. ISBN 0-387-11117-4/3-540-11117-4. (Springer–Verlag: 1982.) DM92, $42.90.

BIOCHEMICAL approaches to the molecular cloning of DNA became simple when, in 1972, it was shown that DNA digested with certain endonucleases yielded discrete fragments with cohesive ends. In the intervening decade, molecular cloning techniques using *E. coli* K12 as host have led to a detailed understanding of the mechanism of action of several prokaryotic genes and have revolutionized our concept of the organization of the eukaryotic genome. The full impact of this technology cannot, however, be realized just by cloning, sequencing and changing genes. A complete understanding of gene expression requires the cloned genes to be studied within the environment of their provenance, whilst commercial production of polypeptides may demand hosts free of endotoxins from which products can be exported across the cell membrane.

Volume 96 of *Current Topics in Microbiology and Immunology* surveys the current and potential use of *Bacillus subtilis,* pseudomonads, streptomycetes, fungi, animal and plant cells as hosts for molecular cloning. In many instances a more complete view of any one genetic system is achieved by including two chapters covering one system. For each system the following topics are documented: vectors; uptake of DNA into cells; the recognition of cells carrying recombinant DNA molecules; and the fate of the donor DNA following its uptake.

The development of alternative prokaryotic systems inevitably draws heavily upon experience with *E. coli* where the concepts of vector construction are well established. Consequently, novel information is often relatively specialized and likely to be of most interest to those readers who wish to use bacteria other than *E. coli* as hosts for cloning experiments. For *Streptomyces* much useful technical information, including laboratory methods and recipes, is provided. Of more general concern are the justifications for studying different bacterial species and the accounts of experiments relevant to the barriers preventing expression of heterologous genes.

The fungi are represented by a brief article documenting the beginnings of molecular cloning in *Neurospora crassa* and two chapters conveying some of the dramatic advances achieved in the molecular biology of *Saccharomyces.* The second of these two articles is in no way redundant, but the first (by Hinnen and Meyhack) is so clearly presented that it should be enjoyed by students of both genetics and molecular biology.

I approached the contributions on higher cells as an interested outsider, anxious to be informed of some of the more exciting developments in molecular biology. In the event I found them somewhat disappointing. The chapter on selectable markers for gene transfer was indeed useful, covering the systems and their use in transformation with some critical evaluation of the resulting studies of gene expression. However, a detailed diagram summarizing the relevant features of the Herpes TK gene and a chart indicating those aspects of nucleotide metabolism of relevance to the selective systems in use would have been welcome. In contrast, the short chapter on animal viral vectors, principally SV40, presents only a limited account of the field. Perhaps the authors anticipated the inclusion of a second and complementary article; certainly the space devoted to animal viral vectors is only a half or a third that for either *Bacillus subtilis* or pseudomonads. Unfortunately the volume was conceived too early to take account of recent success in the transformation of *Drosophila* cells.

A detailed survey of liposomes as a

NEW

FORAMINIFERA

J. R. HAYNES
Reader in Geology
University College of Wales

December 1981; £50.00;
480pp; 34pp plates; ISBN 0
333 28681 2

CONTENTS
Preface; The Scope of Foraminiferal Studies; Collection, Preparation and Examination (including Annotated Literature on Technical Methods); The Living Foraminifer; Test Morphology and Composition; Classification of the Foraminifera; The Agglutinating Foraminifera; The Fusulinida – The Miliolida; The Nodosariida; The Buliminida; The Robertinida; The Rotaliida (Smaller); The Rotaliida (Larger); The Globigerinida; References; Index.

This work is an advanced text covering the biology, morphology and classification of the Foraminifera and their use in stratigraphy and palaeoecology.

Superbly illustrated, the text draws on the author's experience in oil exploration and twenty years' teaching at both undergraduate and postgraduate level.

The main features of this work are:
- A new classification, illustrated by hand-drawn figures of the main genera, selected scanning electron micrographs and photomicrographs of thin sections.
- New theories linking the morphology of the foraminiferal shell with its adaptive function.
- The integration of the study of each of the orders which tend to succeed each other in time to illustrate their use in biostratigraphy and palaeoecology from the Cambrian to the Recent.
- It brings the student up against current problems and the dangers of an over- simplified approach to palaeoecology, evolutionary studies and biostratigraphy, and synthesises the result of recent research which is at present widely scattered in the literature.

SCIENTIFIC & MEDICAL M MACMILLAN PRESS LTD

carrier system is included but there is no chapter devoted either to microinjection, or protoplast fusion, as a means of DNA or RNA transfer. Plant systems are represented by comprehensive accounts of cauliflower mosiac virus and Ti plasmids of *Agrobacterium*. The former includes as appendices a computer print-out of the viral DNA sequence and derivative information.

The broad topic of genetic engineering in hosts other than *E.coli* should appeal to a wide audience, and I would hope to find a copy of this useful reference material in all university libraries. □

Pollution in context

Eirene White

Principles of Pollution Control. By Francis Sandbach. Pp.174. Pbk ISBN 0-582-30042-8. (Longman: 1982.) £5.95, $11.95.

THIS is not a book addressed to the serious natural scientist. To be fair, it does not pretend to be. It is the first study in a series entitled "Themes in Resource Management".

The manifold objectives of the series, as stated by the editor-in-chief, Professor Bruce Mitchell, are, first

> to identify and examine enduring resource management and development problems [and thence] to assess responses to these problems in a variety of world regions.

Of particular concern are research and action programmes. The former are to be evaluated in terms of the nature and adequacy of data, the theoretical and practical understanding displayed and the identification of special problem areas. Action programmes are to be reviewed in terms of their effectiveness in promoting "economic efficiency, social equity and environmental harmony".

> This orientation [writes Professor Mitchell] should provide a departure point for considering the transferability of experience from one jurisdiction to another.

A final objective is

> to explore the way in which resource analysis, management and development might be made more complementary to one another.

Set against these fairly demanding requirements, one may ask how far in his study of the principles of pollution control Francis Sandbach can be said to have complied with them, and in any case to what readership his book is directed. It would not satisfy a reader looking for a scientifically-based account of pollution control over the past few decades or the scientific outlook for the future. But that is not what Mr Sandbach envisages. As a lecturer in interdisciplinary studies at the University of Kent, it is natural that he should seek to paint with a broad brush. One needs to go no further than the introduction to realize that although he has indeed read widely and assiduously about pollution in its various manifestations and provides a great deal of helpful factual information about how it is handled in Britain and elsewhere, he is really turned on by social and political theory rather than by science or technology.

Anyone who wants a schematic view of pollution control would do better to turn to Martin Holdgate's *A Perspective of Environment Pollution*, published by Cambridge University Press in 1979. Nevertheless, there is some validity in Francis Sandbach's thesis, as he forcefully illustrates in his case study of asbestos, the classic example of the clash of interests between health and profits. He devotes another chapter to a not very satisfactory attempt to discredit what he describes as the pluralist/behavioural perspective of those such as Eric Ashby and Mary Anderson who in their historical account of air pollution control in Britain (*The Politics of Clean Air*; for review see *Nature* **298**, 207; 1982) pay less attention than he thinks fit to economic determinants.

The six preceding chapters comprise a rapid and necessarily superficial survey of risk/dose/response relationships; cost effectiveness; the alternatives of recycling or of using a less polluting technology; "the polluter pays" principle and the possible use of pollution taxes; the setting of standards or threshold limit values; the choice of strategies; and the administrative and legal framework for pollution control in the United Kingdom, the EEC and the United States, with glimpses of China, Japan and Scandinavia.

There is much of interest in the book, but it is all rather breathless, plucking a fact here and picking up a figure there. An extensive bibliography includes many useful references to periodical literature (including some that may be more emotive than scientific). The index, by contrast, is exceedingly thin and anyone wishing to look up Seveso or Minamata, for example, has to scan the text.

As a means of introducing students to the general problems of pollution control set in a comprehensive context, this study, in the hands of a well-informed lecturer, could be very helpful. For the more general reader, such as an elected member of a local authority, who might well be in need of guidance, it is likely to be too allusive and, at times, bewildering in its range of detail. □

Baroness White is a Member of the House of Lords Select Committee on Science and Technology (Water Sub-Committee), and was a Member of the Royal Commission on Environmental Pollution from 1974 to 1981.

Life as a wonderful one-hoss shay

In the next 20 years at normal fertility rates, the US population will age dramatically. Are science and medicine prepared for the challenge and will they respond in the best possible way?

It is a general human failing, or a failing of our culture, to turn a blind eye to the fact that one day we will be old and infirm. The search for eternal youth brings with it avoidance of the inevitability of old age. But a few researchers in the United States have been asking in recent years whether old age must entail senility, illness and loneliness or whether through research, people who are now in their 30s, 40s and 50s stand a chance of living out their lives in relative good health until the very end. Unfortunately, most biomedical researchers and doctors are merely human, they share the human preference to not think about old age — let alone about how to cure it.

Two who have held out this new goal, Lewis Thomas, chancellor of the Memorial Sloan-Kettering Cancer Center in New York, and James Fries of Stanford University Medical Center, invoke a poem by Oliver Wendell Holmes, called the "wonderful one-hoss shay". The one-hoss shay — American slang for a small carriage — worked without a hitch until one day it gave out all at once and died. Holmes wished that death would be so kind to us and spare us the gradual loss of our hubs, tyres, springs and thills.

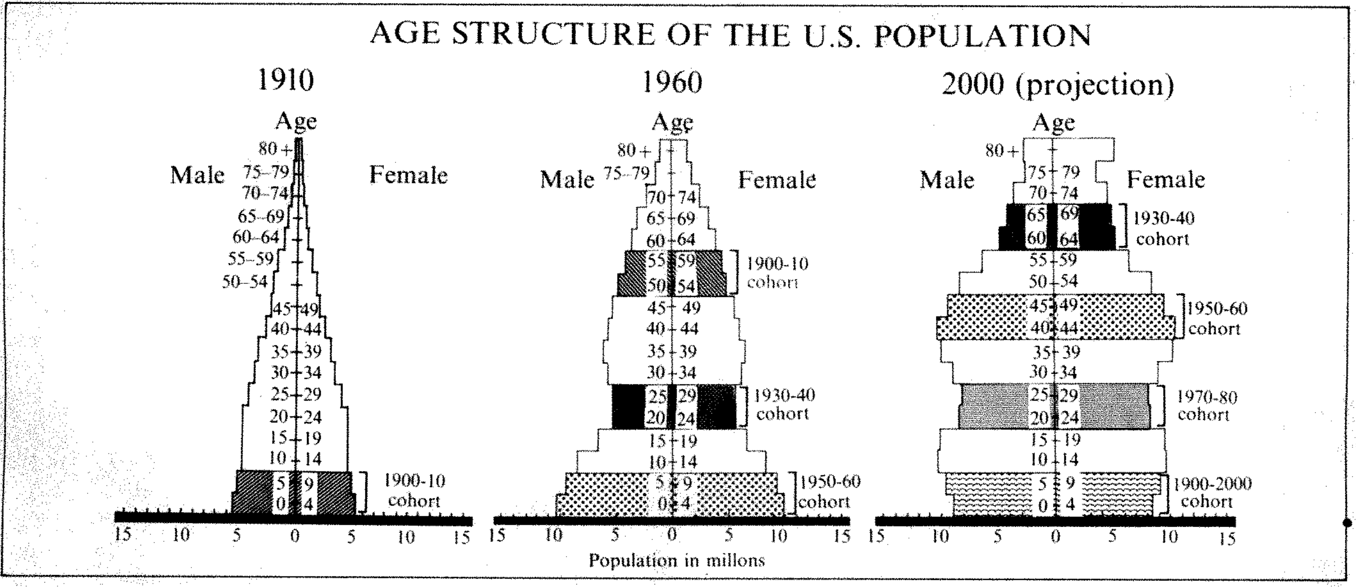
Thomas argues that basic biomedical research at the cellular level — the breakthroughs in Alzheimer's disease (presenile dementia) and work on the fundamental processes of memory, the ageing of cells, the possible switches that are key to vascular abnormalities and even cancer — may be found through a steady assault at the fundamental level in coming years. In 1978 he made a prediction: "I believe that the major diseases of human beings have become approachable biological puzzles, ultimately solvable. It follows from this that it is now possible to begin thinking about a human society relatively free from disease . . . What can we die of, if not disease?"

Fries has advanced the concept of the "compression of morbidity". Reduction in the acute illnesses from which people used to die continues to add to life expectancy in the United States. It is well known that a person celebrating their 65th birthday in 1953 could expect to live another 14 years; the person celebrating their 65th birthday in 1978 could expect to live another 16.3 years. On the other hand, Fries says that the life *span* of human beings will remain at 85. Medical science will enable more people to avoid premature death from an acute illness only to have them suffer from the familiar array of chronic diseases: cancer, emphysema and chronic bronchitis, vascular diseases, osteoarthritis and Alzheimer' disease.

The challenge of both arguments is the same: given the extraordinary increase in the numbers of old relative to the numbers of young in the future (see figure), can science make the lives of the old healthier, and relieve their dependence on younger family members, institutions, and the state? Although the challenge of the demographics is widely accepted, there are many arguments about how science and medicine should organize itself for this challenge.

One debate particularly among doctors is whether to establish geriatrics as a separate, licensed specialty, equivalent, for example, to pediatrics, cardiology and other medical fields. The debate going on in teaching hospitals and medical schools currently centres on whether a separate set of skills is required for dealing with the elderly and if so, what they are. In the United States, the problem is aggravated by the fact that a rather small proportion of doctors is family practitioners, and most are specialists. In the United Kingdom, which has a large proportion of old people, the problem is less serious, because most doctors are general practitioners, and treat the elderly as a matter of course.

Another debate is over whether or not to create new institutes within the US National Institutes of Health to focus attention on particular diseases of the elderly in order to attract money and political attention. There is already a National Institute of Aging, founded in 1976 and now consuming $82 million a year. And some diseases of the elderly are already encompassed within other institutes; arthritis, for example, is covered by the National Institute on Arthritis, Metabolism and Digestive Diseases. But with the prospect of a new National Arthritis Institute being foisted upon him by Congress, Dr James B. Wyngaarde, director



AGE STRUCTURE OF THE U.S. POPULATION

0028-0836/82/340779 02$01.00

of the National Institutes of Health, has been raising the kind of objection to focused institutes that is held by many serious biomedical researchers. Why fragment research, he argues, sensibly, just when the extraordinary interconnectedness of different diseases — for instance of the arthritis family with osteoporosis and systemic lupus erythematosus — is just becoming evident?

Typical short cycles for funding pose another obstacle to attacking the long-term, chronic diseases of the elderly. Most researchers (and doctors) prefer to work on problems that show quick, discernible results. But whether senile dementia is linked to nutrition or to early health, obviously cannot be answered in time for the next one- or three-year grant application.

Fortunately, more private benefactors are realizing that they can offer alternatives to traditional, government inspired approaches. Last week, Philippe Villiers, a Boston businessman, gave $40 million to endow a new foundation dedicated to research and study of the elderly. Robert N. Butler, who is leaving the directorship of NIA after six years, will take a privately endowed chair as head of the country's first department of geriatrics, also privately endowed, at the Mount Sinai School of Medicine. But the profession would be better off, obviously, with some overall plan for how to address these new problems, rather than letting the whims of benefactors or the political process shape the future.

A start will be made soon by the National Academy of Sciences, which has just designated a chairman (Robert I. Berliner, dean of the Medical School at Yale) for its Committee on the Aging, now being formed under the auspices of the Institute of Medicine. It should be no surprise that the government did not see the need to fund an overall study (hence much of it will be paid for with academy funds) and that assembling the committee and subgroups has taken time. Ageing is not exactly the status-ridden scientific bandwagon that cancer was 10 years ago. But the scope of the study is very broad, ranging from the impact of the demographics on society to the needs of science and medicine, so the study will be a step in the right direction.

In his diary in exile, in 1935, Leon Trotsky wrote: "old age is the most unexpected of all things that can happen to a man". But there is nothing unexpected about the ageing of US population, and the future, greyer constituency for the results of research and for health care. If Thomas is right, biomedical scientists may have it within their power to make life more comfortable for these people — indeed for themselves in their old age. But to do this they must look the problems in the eye and face up to certain organisational and philosophical choices. One choice is for the US biomedical science community to follow the path of least resistance and set up new 'advocacy' specialities and institutes that would focus political attention on the problems of the elderly. The alternative, harder, but probably sounder, choice is to inject knowledge of, and concern for, the diseases of the elderly into all biomedical research to maximize the chances of the unexpected discovery that would lead, ultimately, to improved treatment or even cure of the diseases. Similarly, for the medical profession it would be better to make the needs of the elderly part of all medical training than to establish yet more specialities.

Language of love

French scientists are under pressure to communicate in French. But can they afford to?

The English edition of *Scientific American* used to sell only 5,000 copies a month in France. But the new French edition, *Pour la Science*, sells 50,000, its editor, M. Philippe Boulanger has claimed. So a mere change from one language to another increased communication tenfold.

This is what preys on the minds of those in France who wish to re-establish "French as a language of science". While French scientists rush to the microphone at conferences to address their American colleagues in English (see this issue p.784), and while more and more French scientists publish in English rather than French (82 per cent of French papers were published in French in 1976, but only 67 per cent in 1980), a hunger — and a need — for knowledge among the rest of the French nation may go forgotten. Moreover, it is from this forgotten part of the nation that the next generation of scientists, technologists and technicians will emerge. What is more, it is imperative, from the point of view of a socialist government, that the same sector of the nation should, at the very least, be equipped to play an educated role in the democratic management of science and technology in the country. Meanwhile, many French primary scientific journals are declining — the best work being published in English — while few good textbooks are now published in French, and science is almost absent from radio and television. Is this the nation destined to become the technological leader of Europe?

One can therefore sympathize with M. Jean-Pierre Chevènement, Minister of State for Science and Industry, when he insists that French scientific culture must be based on the French language. His version of the French nation requires it. He does not decry international communications. There, he is the first to acknowledge, the universalism of English is a distinct advantage. Chevènement is determined to improve national communication and in pursuit of that goal Chevènement's scientist must look not only outwards, but inwards, towards his own countrymen and his own media.

But in practice, what can the minister do? He starts with the knowledge that most French scientists are against him. Professor Alfred Kastler, France's sole Nobel physicist, is a passionate Francophone, but he puts the Anglophone argument succinctly: "If we publish in French," the argument goes "the international scientific community doesn't read us. And if we speak in French at an international conference, most of the audience leaves the room". Briefly: to make contact with Americans, to keep in touch with his field, the French scientist must speak English. There is no simple solution to the dilemma that is posed for the French scientist sympathetic towards Chevènement's proposals but having to survive in a world dominated by the English language.

Professor Kastler has recommended "taking the offensive". But there is only one real offensive: to establish French science as a world force — just as the establishment of American science in the world (for whatever historical and economic reasons) led to the dominance of English. France can still dominate in one or two subjects — certain branches of mathematics, for example, and of social anthropology — but for the rest the battle will be arduous and the outcome must be gloomy.

Therefore, in most areas of science, French policy seems to grasp at straws. The provision of simultaneous translations at conferences has already been rejected as too expensive. The alternatives of partial translation by pre-print, transparencies or by a colleague (as now being suggested) seem artificial. In the matter of publication, to publish a paper in French as well as English is expensive and time-consuming; and will the editors of *Comptes Rendues* agree to become mere echoes of their counterparts on some English or American journal? Some have suggested more rigorous editing and selectivity in the French journals, and "vigorous marketing". This is a worthy proposal and can do no harm to the journals but if French scientists will not submit their best work to these journals anyhow, rigour and vigour are of little avail.

So is all lost for the French plan? Not entirely, insofar as early enthusiasms are now being tempered by reality. Certain small, but practical things are being done. Data banks and other forms of electronically stored information are being developed in French, for example, to make France independent of American data sources (there is a strategic imperative here also). And there are exercises to establish new, firmly edited journals in fields in which France does excel. Small things, perhaps, but the only practical ones. It is impossible to stage a complete revolution against English now. And as for French scientists: the measure of the success of the programme, in the end, will not be how many papers are published in French — but how many foreigners are forced to read them.

Vienna accord on remote sensing

Conference calls for bigger UN role

Vienna

New and expanded space-related activities, recommended to the United Nations by the Unispace-82 conference which ended last Saturday, should cost the United Nations $3.2 million annually — almost four times the 1980–81 budget of the existing Outer Space Affairs Division of the UN Secretariat. These activities, the conference proposed, should be funded voluntarily by the member nations, and the UN General Assembly should rearrange its budget so that the increase in personnel costs may be absorbed within the available resources.

The proposed activities are largely information related, including consultancy services to assist developing countries in selecting space technology systems, study tours, seminars, and training fellowships, the creation of an international space information service, expansion of the existing space library and the establishment of a regular newsletter on space.

The need for such services became abundantly clear during the two weeks of Unispace-82; remote sensing has been constantly hailed as the answer to environmental and resource problems, and a bewilderingly large range of systems was on display for developing countries shopping for hardware or know-how. Yet the suppliers of these products were often first to admit that their data are simply not reaching those who most need the information. One representative of the UK Natural Environmental Research Council quoted the case of a remote sensing programme which identified icebergs heading directly for a Canadian off-shore oil-rig — with no organizational framework through which a warning could be transmitted to the rig at risk.

The conference report called for the formulation of international principles on satellite remote sensing which would allow the "sensed" state "timely and non-discriminatory access under reasonable conditions" to primary data relating to its territory.

The conference also expressed "real concern" over the approaching saturation of the geostationary orbit with communications satellites in certain frequency bands. Research into ways of facilitating the closer siting of satellites is "imperative", and the feasibility of using highly elliptical orbits for communications satellites should be re-examined. The International Telecommunications Union was recommended to consider introducing into its future regulations a clause stating that a satellite owner was responsible for removing its hardware from orbit when it became inoperable.

Similarly, although the conference urged member countries to examine the feasibility of direct television broadcasting satellites for education in remote rural areas, it also urged them to consider the possibility of international or regional satellite space segments, shared by neighbouring countries.

In general, the conference confined itself to the specifics of space technology and its applications but there was also a full discussion of the problem of preserving peace in space. After the three main committees of the conference had failed to reach consensus on this issue, Dr Willibald Pahr, the Austrian foreign secretary and president of the conference, convened a 15-member drafting group, called the "Friends of the president" which represented all regional groups and which finally, and with the conference in extra time, found an acceptable consensus wording calling on all nations, "in particular those with major space capabilities" to "contribute actively to preventing an arms race in outer space".

Few winners in Australian budget

Sydney

The Australian government's latest budget, framed amid growing speculation about an early election, once again cuts back on funding for most areas of scientific research. The budget, released last week, was built around tax cuts and other handouts for the middle income earners. The government proved once again that they see very few votes in research funding.

Australia spends less than 1 per cent of gross domestic product on research, considerably less than most Western countries. The government provides about 70 per cent of this funding, which is an unusually large proportion by world standards. This year over half this money will go to the Commonwealth Scientific and Industrial Research Organization (CSIRO) and the rest to the other government agencies and the universities.

One of the few bright spots in the budget is the re-allocation of A$49 million (£27 million) to a scheme that favours research projects with product-oriented goals. This re-allocation came as a surprise because the scheme, funded under the Industrial Research and Incentives Act, was left up in the air last year when its budget was frozen after only A$24 million was spent.

In the budget, basic research in universities has been given A$19 million, around 4 per cent less in real terms than in 1981. This continues the steady decline which has gone on since 1975. The funds are channelled through the Australian Research Grants Scheme (ARGS) which now contributes only 15 per cent of the total national research spending compared with 24 per cent in 1975. If ARGS uses its reduced budget to maintain the top research groups, it will be unable to support about 100 projects that would otherwise have been accepted, according to Professor Max Brennan, chairman of the committee administering the scheme.

But there were some winners in the area of basic research. In astronomy, prior to the budget, two proposals were vying for patronage. One was the radioastronomers'

Canada's array poised

While Australian radioastronomers have just received the go ahead for their long baseline array of telescopes (see above) the fate of a Canadian counterpart is still in the balance.

The Canadian Long Baseline Array (CLBA) has already been approved in principle by the National Research Council (NRC) which has selected it over several competing big-science projects, such as the Canadian high energy electron ring and Starlab. A final proposal for the CLBA will probably be approved by NRC in September. The economic development committee of the Canadian cabinet will then have to decide whether it can afford the Canadian $70 million needed to construct CLBA — with $6.5 million per year running costs — in the midst of a recession.

The current proposal for CLBA calls for eight 32-metre dishes spread from British Colombia across to Newfoundland and one smaller dish in the North West Territories. Thomas H. Legg, the originator of the project, says the CLBA could be operating within four to five years of approval. The schedule is important, for the United States is planning its own very long baseline array that would stretch across the continent and include sites in Hawaii and Alaska. A proposal for building the system has been submitted to the US National Science Foundation (*Nature* 12 August, p.596) but whether it will be included in the US budget for fiscal 1984 is anybody's guess. There is a debate about the need for two separate systems of this size and both the Canadian and the US sides have thought about a possible link but nothing concrete has yet been proposed.

0028-0836/82/340781-02$01.00

"Australia Telescope", the other the optical astronomers' "Starlab" project.

With the news that the Australian Telescope has been funded to the tune of A$25 million, CSIRO can now proceed to develop a continental-scale, radio-linked interferometer network. When completed in 6 years' time, this should provide a Southern Hemisphere radio facility comparable to the most sophisticated interferometers in the north, complementing the activities in the optical and infrared bands of the Anglo-Australian Telescope.

The Australian Telescope will consist of a linear array of five 22-metre dishes at Culgoora in New South Wales, a 22-metre dish at Siding Spring (the site of the Anglo-Australian Telescope) and a 64-metre dish at Parkes. The total array will be equivalent to a dish 300 km across with a revolution of 0.1 seconds of arc — comparable to the US/European space telescope. It is also proposed that five other sites, covering much of the continent, can be radio-linked to the network, improving the resolution to one-thousandth of a second of arc.

The Starlab project has not been so fortunate. This joint Canadian, US, Australian scheme aims to place a 1-metre telescope in Earth-orbit by 1989. Australia's contribution was to have been the instrument package for the telescope. At this stage the government is not prepared to commit the full A$28 million that would be necessary if Australia is to participate. But it is keeping the project alive by providing A$3.3 million to local industry for some preliminary work.

Australian postgraduate research scholars were another notable group to gain in the budget. About one third of all full-time research students enrolled for higher degrees are supported on these scholarships. They have just been awarded a 50 per cent salary increase, presumably in recognition of the importance of their work as integral members of university research teams, and as Australia's future research scientists. Although this increase sounds impressive, the salary of a scholar has now only climbed from below the official poverty line to a generous A$40 a week above (A$6,850 a year). This is still less than half the average wage and no doubt a measure of the high esteem in which many Australian politicians hold Australian science.

Peter Hunt

US plant patent disputed

A fierce protest against the validity of a US patent dealing with plant breeding has been made public by Professor N.L. Innes, chairman of the British Association of Plant Breeders and a member of the staff of the British National Vegetable Research Station. The patent complained of was awarded in April this year to the Colorado based corporation Agrigenetics Research Associates, a seed firm with annual revenues of $100 million.

The invention for which the patent has been awarded is described in the published version (US patent number 4,326,358) as a technique for accelerated production of new hybrid strains of plants and rapid commercial production of seeds from such hybrids. The patent claims that seeds of desirable new hybrids can be readied for marketing in as little as three years rather than the present eight to twelve years.

In conventional hybrid production, the plant breeder first has to breed two different homozygous plant lines from which a hybrid is produced and tested. Not only can it take many years to breed the homozygous lines but homozygous plants often produce low numbers of seeds.

In its essentials the invention covered by the patent starts with the crossing of any heterozygous plant — of which there is a great variety of good seed producers — with a heterozygous or homozygous partner. The hybrid offspring of such a cross will not be genetically identical but, on occasion, the plants will still be sufficiently similar to be worth testing as a potential crop.

If they have desirable crop qualities, the breeder then returns to the parent plants and propagates them, asexually, as clones. The large numbers of each parent so generated are then crossed to produce large numbers of hybrids, equivalent to those of the original cross of the individual parents.

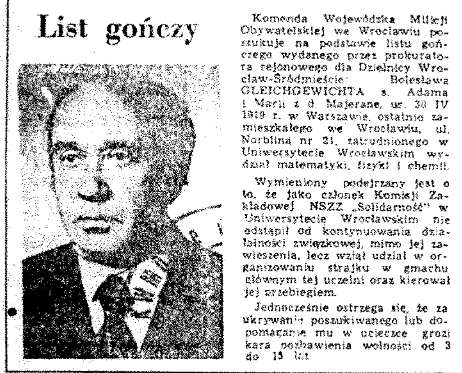
The protest from the British Association of Plant Breeders (published in full on page 786) boils down to the assertion that the use and advantages of heterozygous parental plants as breeding stock are well known and that clonal propagation of individual plants is now a standard technique in plant breeding, so that the particular combination of the two principles for which a US patent has been awarded must be obvious and thus not qualified for protection.

Even the combination of techniques described in the patent is very similar to that used in practice by, for example, British sugar beet breeders, says Dr Richard Macer, secretary of the British Association of Plant Breeders.

According to Rene Tegtmeyer, of the US Patent Office, to which Professor Innes has sent a copy of the letter, a formal request for reexamination can be filed after a patent is issued, but only on the grounds of a prior patent or publication that was overlooked by the patent office in its original examination. Prior public use or sale is not sufficient grounds for reopening an already-issued patent. Even in the original examination of an application, Tegtmeyer says, a foreign use would not bar patenting in the United States, although a foreign publication could.

"Any given detail or sequence may seem obvious, but the way they're put together may be original", so far as the patent law is concerned, says Dr David Padwa, chairman of Agrigenetics, who will shortly announce licensing terms that will be "fair and reasonable".

A second Agrigenetics patent, applying the techniques to a specific species, was recently allowed by the patent office and should soon be issued. Meanwhile Agrigenetics awaits the outcome of its application last January to the European Patent Office for a patent similar to the one issued in the United States.



List gończy

Komenda Wojewódzka Milicji Obywatelskiej we Wrocławiu poszukuje na podstawie listu gończego wydanego przez prokuratora rejonowego dla Dzielnicy Wrocław-Śródmieście Bolesława GLEICHGEWICHTA s. Adama i Marii z d. Majerane, ur. 30 IV 1919 r. w Warszawie, ostatnio zamieszkałego we Wrocławiu, ul. Norblina nr 21, zatrudnionego w Uniwersytecie Wrocławskim wydział matematyki, fizyki i chemii.

Wymieniony podejrzany jest o to, że jako członek Komisji Zakładowej NSZZ „Solidarność" w Uniwersytecie Wrocławskim nie odstąpił od kontynuowania działalności związkowej, mimo jej zawieszenia, lecz wziął udział w organizowaniu strajku w gmachu głównym tej uczelni oraz kierował jej przebiegiem.

Jednocześnie ostrzega się, że za ukrywanie poszukiwanego lub dopomaganie mu w ucieczce grozi kara pozbawienia wolności od 3 do 15 lat

"WANTED for continuing trade union activities under martial law, and for organizing a strike in Wroclaw University" says this notice from a recent issue of the Wroclaw daily *Gazeta Robontnicza*. Professor Boleslaw Gleichgewicht, the subject of this notice, is a leading Polish mathematician, a former organizer of the clandestine "Flying University" and one of the founder-members of the Wroclaw University chapter of Solidarity. He is now in hiding.

The notice includes a warning that the penalty for hiding or assisting the "fugitive" is from three to fifteen years loss of liberty.

Australian patents bill

Seeds of doubt

Canberra

The Australian government's first attempt to legislate for the protection of new plant varieties has blown up in its face. The Plant Variety Rights Bill, introduced a year ago and passed by the House of Representatives in April, is now the focus of a political storm. And the Senate has referred the bill to its Standing Commission on Natural Resources, a procedural device for postponing a decision.

The objective of the bill, of crucial importance in a country with a large agriculture industry, is to enable plant breeders to acquire the same kind of proprietary rights in new plant varieties as have long been available in some European countries. The present Patents Act, dependent as it is on the criterion of reproducibility, does not protect most plant varieties.

Five years ago, the Australian Agricultural Council (a political body representing federal and state ministers) recommended legislation on plant varieties protection with the objectives of stimulating the commercial plant breeding

0028-0836/82/340782-02$01.00

industry, giving Australian farmers access to varieties developed overseas under the proposed bill's protection and enabling Australia to join L'Union Internationale pour la Protection des Obtentions Vegetales (UPOV).

As amended during the past year, the bill offers protection to Australian plant breeders producing plant varieties, including hybrids, that are novel, distinctive, stable and uniform. Existing varieties will not be entitled to protection.

Both government and opposition have been surprised at the controversy the bill has aroused. Its opponents include farmers, scientists, church groups, environmentalists, alternative life-stylers and consumer organizations. Many people employed by the federal and state governments on plant breeding fear that the bill, by making commercial plant-breeding more profitable, will give the governments an excuse to reduce support for plant breeding and also increase competition from the private sector, perhaps by the production of "cosmetic" varieties.

Even the claim that protecting plant varieties will stimulate the Australian private sector is disputed on the grounds that Australian farmers are at present only buying in one per cent of the seeds they sow each year — too little to generate much revenue. Some critics say that the most probable result will be to flood the market with seeds imported from overseas.

The fate of the bill is at this stage unclear. Hitherto, it had been thought that the fate of the bill would depend on the votes of the Australian Democrats, the minority party that holds the balance of power in the Senate and which sees its role as a watchdog over the machinations of the major parties. ("Keep the bastards honest" is its motto.) But several government senators now have cold feet about the bill.

One possibility is that nothing is decided until after the next election, particularly if that is called as early as the beginning of 1983. If there is an early election, everything will depend on which party is returned to Canberra. The present government might simply reintroduce the bill. The Labour Party, if elected, would probably let it die a natural death — and then find that it had to devise an alternative of its own.

Vimala Sarma

German nuclear power

Modest advance

Heidelberg

Four new nuclear power plants at a go may seem like a boom but appearances are deceptive. The Federal German atomic power industry has problems. Although work began recently on the sites at Isar II (Bavaria) and Emsland, Lingen (Lower Saxony) and approval for Biblis C (Hesse) and Neckar-Westheim (Baden-Würtemburg) seems little more than a formality, all four reactors are of the same conventional high pressure light water, type — defensive planning that aims to expedite technical approval and confine local enquiries to siting and radioecology.

The electricity industry in West Germany is private, with a legal monopoly position based on laws dating from the 1930s. Most new power stations are financed by consortia, usually combinations of power companies and local government. The two-stage Federal–Land vetting procedure which keeps nuclear issues in political focus, stringent safety regulations, lengthy planning processes, and battles with environmentalist groups have turned the construction of atomic power plants in the West Germany into an obstacle race. Costs are now double those in France. Electricity prices are disappointingly high and industries now renegotiating 20-year contracts signed in the optimistic 1960s may consider importing from France. It is suggested that heavy industries may eventually emigrate to sites close to the French power plants. While West Germany has only 11 functioning nuclear power plants and 14 awaiting approval or under construction, *Electricité de France* has 24 functioning units and 26 in various stages of planning and construction.

Atomic power is controversial in West Germany: The CDU/CSU accuse the government of damaging the industry by ambivalence, imposing unnecessary controls, and dragging its feet on the reprocessing facility. The SPD is divided on the issue and the Greens (*Nature* 17 June) oppose use of atomic power categorically. Not only is the Bonn SPD/FDP coalition shakey and the SPD losing votes on the right to the CDU and on the left to the Greens, but the CDU itself is on the brink of a leadership conflict. With the Greens set to gain 10 per cent in the House election on 26 September and over 5 per cent in the Bavarian elections on 10 October, the major parties want to play down the nuclear power issue. For the time being there will be no decision on Biblis C which will add 1,300 megawatts to what at 2,500 megawatts is already the biggest atomic power complex in the country.

The Federal government participates financially only in prototype reactors. The fate of the fast breeder at Kalkar on the lower Rhine and the high temperature reactor at Schmehausen in the Ruhr await a meeting of the *Nuklearkabinett* on 31 October. In June this year, escalating costs led research and technology minister Andreas von Bulow to advocate halting both these projects. They were reprieved by Helmut Schmidt, chairman of the *Nuklearkabinett*, who insisted that for reasons of national prestige the projects should be retained.

Meanwhile the future of the Federal German nuclear industry looks as unclear as that of the Bonn government.

Sarah Tooze

Belgian nuclear fuel

Plant to restart

Waalre, The Netherlands

Eurochemic, a nuclear fuel reprocessing plant in Mol (Belgium) which was closed in 1974, is likely to begin work again. The international project shut down when Britain, France and Germany decided to go their own way, but on 2 July one of the two chambers of the Belgian Parliament voted to reopen the plant and it is expected that the Senate will do the same, at the earliest in October.

If the Senate agrees, a new fuel cycle company will be formed covering the whole nuclear cycle, with the Belgian government and the utilities taking equal shares. One or two subsidiary companies will take care of reprocessing and fuel fabrication. A new fuel will be produced: a mixture of uranium and plutonium.

The capacity of the reprocessing plant, which is now 60 tonnes per year, will probably be doubled. Without the plant, Belgian nuclear power stations would have had no place for spent fuel after 1985. A 120-tonne capacity at Mol also provides an opportunity to reprocess spent fuel from other countries.

The Belgian plant at Mol is now — after decontamination — cleaner than many experts thought possible, according to Dr Jacques van Gell. Radiation levels in the cells are only slightly higher than natural background levels, after 200 million curies have passed through them. "This is a world achievement", says Detilleux.

The reprocessing process will be changed at Mol, from the dissolving method to the mechanical chop and leach process. The existing fuel fabrication company Belgonucleaire, on the same site at Mol, will become part of the second subsidiary company and will produce plutonium for fast breeders but also for thermal reactors. Although Dr Detilleux considers that breeder reactors will not be needed for the next 15 years, using plutonium in conventional thermal reactors should give Belgium a more secure supply of fuel.

There has been considerable criticism of the Belgian vote in the Netherlands. The plant is only 15 km from the border, and after a number of ex-employees had told of incidents at the plant between 1966 and 1974, Dutch public interest groups protested against reopening and regional authorities asked for more information and for early warning systems in case of accidents. The Dutch under-minister for the environment, Mrs Ineke Lambers, was disappointed about the Belgian decision. Only the previous day, she had recommended in the EEC Council of Ministers that arrangements should be made for the European Parliament to settle such trans-border pollution issues. "This is a proof that such settlements are far away", she said.

Casper Schuuring

0028-0836/82/340783-01$01.00

Language of science

French plans

The French government's campaign to re-establish French as a language of science is under severe stress — as thousands of foreign scientists descend on France for the 1982 conference season, attracted by the climate, the food and wine and, of course, the science. But these scientists mostly wish to speak English, not French, and there are not enough technical translaters to go round (nor money to pay them.)

Breaking point came a couple of weeks ago at the 21st international conference on high energy physics in Paris, where even the French spoke English.

Government determination to push on with the language programme is unbowed. But there has been a shift of emphasis from the tone of the circular sent out to researchers last September, which spoke of the need for French scientists to make presentations "in our language". For at the high energy conference participants were faced with a questionnaire in four languages (French, German, English and Spanish) asking them what they thought of simultaneous translation, multilingual posters and other means of dealing with the language barrier. The point is that the government is now supporting not just French as a language of science, but also Italian, Russian, Japanese, Spanish, Arabic, Chinese and the rest. "We will do all we can to demolish the monopoly of English", said the programme director.

The objection to English is that — outside Anglophone countries — it leads to the creation of an artificial barrier between those scientists who can cope easily with the language and those who cannot, so that English is used as a matter of status and hence of isolation of one group from another. English thus militates against "democracy" in French science. Moreover, in France the government has taken an overriding interest in all means of increasing communication between scientists and industry, and this "snobbish" division is seen as a real barrier to industrial development.

Government determination, however, is not enough. Money is also required. To provide simultaneous translation for a number of languages at a major conference is expensive — about FF350,000 (£30,000) for a conference of 1,500–3,000 participants for three or four days, estimates MIDIST, the Mission Interministerielle de l'Information Scientifique et Technique in which the "French as a language of science" programme is based. Short of the necessary wherewithal, and of technically-trained translators who can deal with immunology on the one hand or high-energy physics on the other, MIDIST this year is resorting to experiments on means cheaper than simultaneous translation.

For a total cost of FF600,000 at 20 conferences over the next couple of months, MIDIST will therefore try out:

- Simultaneous translation at plenary sessions, but not at working groups, which would be divided by subject and language.
- Distribution of a typed resumé of presentations in various languages.
- Bilingual transparencies, to be prepared before each talk.
- Paragraphy-by-paragraph translation of a talk by a bilingual colleague.
- The résumé on request, by a participant, of the essential points of a talk in the language requested.

The results of these experiments will be tested in part by questionnaire, and may result in more positive action during the conference season of 1983. **Robert Walgate**

Astronomer on fast

Patras, Greece

Professor Leonid Ozernoi of the P.N. Lebedev Physical Institute in Moscow began a hunger strike on 17 August in the face of the refusal of the Soviet authorities to grant him and his family visas for emigration to the United States. His case was being widely publicized at the General Assembly of the International Astronomical Union at Patras, Greece which finishes on 26 August.

Professor Ozernoi is well-known for his work in high-energy astrophysics including theoretical studies of processes in quasars and the nuclei of active galaxies. He applied for emigration in June 1979. Following the application, his wife lost her job as a sociologist and has since been unable to obtain another postion; he was barred from attending international conferences, removed from the board of *Letters to the Astronomical Journal of the USSR* and prevented from teaching. A paper of his was omitted from a book for which it was scheduled. Nearly 2½ years after applying to leave the country he was refused, his departure being "considered inexpedient at this time".

The Harvard-Smithsonian Centre for Astrophysics has invited Professor Ozernoi to work there, while the executive committee of the International Astronomical Union (IAU) will be considering whether or not to become involved officially at its next meeting in September.

A petition on behalf of Professor Ozernoi was cirulated at the IAU Assembly. Addressed to E.R. Mustel, Chairman of the Astronomical Council of the USSR Academy of Sciences, it also concerned Dr Alpert of the Institute of Terrestrial Magnetism Radio Research and the Ionosphere of the USSR Academy of Sciences, who has experienced demotion and restrictions on his work since his application for exit in 1975.

Philip Campbell

Drug promotion

FDA steps in

Washington

"A new choice for freedom from arthritis pain. . . Coming soon from Geigy."

This advertisement, accompanied by a colour illustration of a dove flying from a pair of outstretched hands, appeared in medical journals last autumn. At first glance, it seemed much like the many other eye-catching advertising pieces that the drug companies invest in so heavily to promote their wares in their highly competitive business. The strange thing about this advertisement, though, is that nowhere is the name of the drug mentioned. In fact, the drug had not yet received approval from the Food and Drug Administration (FDA).

Over the past year or so, this tactic and others for the pre-approval promotion of drugs have become increasingly common. Recently, FDA has been trying to do something about it.

FDA has broad powers under the federal drug laws to regulate the labelling of prescription drugs it has approved. By extension, this has been applied to advertising and other promotional literature. Any advertisement for a prescription drug must, for instance, include complete information on side effects, precautions and proper dosage. FDA also scrutinizes headlines and claims made in promotional material for accuracy and proper balance. A false or misleading promotion can render a drug "misbranded" and liable for seizure — a remedy FDA has occasionally used.

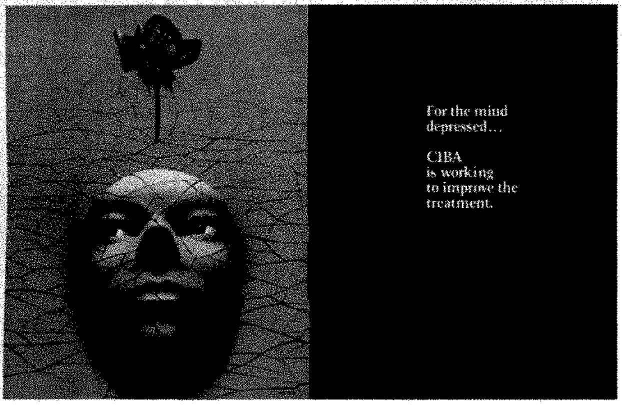
FDA regulations also prohibit the promotion of a drug's safety or usefulness before approval, since it is the safety and usefulness that FDA is attempting to determine in its review of a new drug application. But what if the drug's name is not mentioned in pre-approval advertising? That was apparently what the drug companies asked themselves; and thus a loophole was opened.

Possibly the most effective of these pre-approval advertisements are of the variety shown opposite. A graphic motif is introduced in the pre-approval advertisement, which is carried over to the post-approval — and, the advertiser hopes, the favourable first impression is carried over as well.

No warnings, precautions or contraindications encumber the pre-approval advertisements. But neither does the drug's name, and that puts FDA in an awkward position. "Without the mention of a drug product, it becomes difficult for us to say that is an advertisement" under FDA regulations, says Kenneth Feather, acting chief of FDA's drug advertising regulation branch.

Now the agency hopes to set limits on pre-approval advertisments. Last month, FDA issued a list of "recommendations" aimed to stop what it sees as infringements of the spirit of the law.

0028-0836/82/340784-02$01.00



For the mind
depressed…

CIBA
is working
to improve the
treatment.

An impressionistic pre-launch . . .

In particular, the agency said, it will object to any advertisements that "make claims of safety and efficacy even if the new drug is not specified". On the other hand, if the name is specified, FDA says, advertising copy may not suggest the drug's indications, uses, safety or effectiveness, nor may any other advertisements or even the graphics that appear. In other words, the advertisement can say only "Fribulate, coming soon from Wonder Drugs, Inc.".

Pre-approval advertisements such as that shown here for Ciba's Ludiomil fall in a middle ground. The FDA says they are in general acceptable, but the dividing line is fine.

A case that came nearer to that line was Marion Laboratories' pre-approval campaign for Carafate, an antiulcer drug. The advertisements proclaimed the new, unnamed drug "a new era in ulcer therapy", a claim that FDA might well take exception to if it appeared in post-approval advertisements naming the drug.

Another loophole that concerns FDA is pre-approval promotion of drugs at scientific meetings. The FDA regulations specifically exempt seminars and scientific publications from its ban on representing a drug as "safe or useful" prior to approval; this is to allow a full exchange of scientific information concerning the drug. But according to Kenneth Feather of FDA, some firms have been stretching their interpretation of this exemption. He says he has seen several "scientific exhibits" at meetings that had all the hallmarks of promotional exhibits of the "flashing lights variety".

At the recent Pan-American Congress of Rheumatology, for example, Lederle Laboratories, had an exhibit which offered to visitors who stopped by free computer photographs along with a flyer with the headline "Fenbufen: a highly effective non-steroidal anti-infammatory drug with an unusually low incidence of serious GI complications". According to a letter that Feather sent Lederle, the exhibit was promoting Fenbufen, which the FDA has not yet approved for sale in the United States, although it is sold elsewhere.

After FDA objected, Lederle issued a statement that it "regarded the congress as an international meeting" and that "since requirements and practices differ from country to country . . . it does not appear equitable to adhere to those of any single country". FDA officials say, however, that it is nothing new for US laws to apply within the United States to US companies.

A similar incident occurred last year at the American Rheumatism Association meeting in Boston, where Pfizer Pharmaceuticals showed a film promoting Piroxicam, an anti-arthritis drug not yet approved. FDA said that the film hardly qualified as a "scientific exchange" since it was shown at a cocktail and buffet reception sponsored by Pfizer and that there was virtually no scientific discussion. According to FDA, the only question from the audience following the screening was, "When will the drug be available?"

FDA's recourse in these cases is unclear. They may order the companies to stop an advertisement or not to show a film again, but this, says Feather, is "shutting the barn door after the horse has bolted", since most of these pre-approval promotions are designed to be one-shot campaigns. And the remedies available after a drug is on the market, such as seizure, do not apply beforehand.

The recent Oraflex case, though, may cast a chill over the industry's own eagerness to pursue aggressive promotional campaigns. In late July, shortly before sales of Oraflex were suspended following reports of 61 deaths among users in Britain, FDA notified Lilly that a press kit prepared for Oraflex contained false or misleading statements. FDA said it seriously understated the drug's side effects and implied that Oraflex had a unique ability to fight the underlying disease in arthritis patients. In fact, FDA says, Oraflex is just another non-steroidal anti-inflammatory agent, and any claims about its disease-fighting ability are based solely on speculative inferences from animal studies.

After such a hard sell, the backlash that came when the reports of adverse effects started accumulating was all the greater. If the drug is ever cleared for sale again, FDA will probably require stiffer labelling designed to counter the false impression that Lilly's press campaign created.

FDA officials have raised the spectre of stiffer labelling requirements to counter pre-approval claims as well, a threat that will probably weigh heavily in the industry's decisions on future promotions.

Patents and plant breeding

SIR — In the United States a patent (No. 4,326,358 of 27 April 1982) has recently been granted to Agrigenetics Research Associates Ltd of Denver, Colorado for the use of tissue culture (micropropagation *in vitro*) for the multiplication of parental plants to produce hybrid seed of crop varieties. The patented procedure is intended for the rapid development, evaluation and commercial production of hybrid seed from pairs of parental plants chosen for their specific combining ability and uniformity of the hybrid between them irrespective of their degree of homozygosity. The specific example describes the application of the technique to tomatoes. It is understood that equivalent patents in other countries have also been sought.

Both public and private plant breeders must feel concern that this patent purports to give rights over the use of techniques that have been part of the stock-in-trade of plant breeders for some considerable time and have already been used commercially. We would therefore like to draw attention to the conditions governing the validity of patents on plant tissue culture in the United States, as well as to evidence in the scientific literature on the widespread use of tissue culture techniques by plant breeders before the US patent application was made.

Bagwill[1] has summarized the validity of patents on plant tissue culture techniques in the United States. Among the key points made by Bagwill are:

- A person shall be entitled to a patent unless — (a) The invention was known or used by others in this country, or patented or described in a printed publication in this or a foreign country, before the invention thereof by the applicant for patent.
  (b) The invention was patented or described in a printed publication in this or a foreign country or in public use or on sale in this country, more than one year prior to the date of the application for patent in the United States.
- A patent may not be obtained . . . if the differences between the subject matter sought to be patented and the prior art are such that the subject matter as a whole would have been obvious at the time the invention was made to a person having ordinary skill in the art to which said subject matter pertains.

In the light of Bagwill's remarks it is pertinent to observe that: (1) The essential principles and techniques in the patent were known and practised by others well before the patent application was filed. (2) The practical value of the particular combination of pre-existing principles and techniques outlined in the application had been recognized previously by others. (3) The value of the approaches outlined in the application to variety development and production were already obvious to any person having ordinary skills in the relevant disciplines.

The case for patentability is based on a number of premises which merit comment:

Utilization of hybrid vigour in developing crop varieties: The value of hybrid vigour in developing superior crop varieties has been recognized and exploited by plant breeders for more than 100 years. Beal was the first to recommend the use of hybrid varieties of maize; recognition of their commercial worth in other crops followed later. This principle is now universally acknowledged by biologists and is discussed in most textbooks on plant breeding[2].

Phenotype uniformity obtained from specific combination of heterozygous parents: The concept that first generation hybrids of acceptable phenotype can be obtained by crossing two heterozygous stocks has been known and used for a very long time. For example, varietal hybrids of maize were exploited commercially at least 150 years ago[3]. Controlled experiments on varietal hybrids of maize were reported in the 1870s[3] and interest in them was revived in the 1960s[4]. The difference between a varietal hybrid and the type of hybrid described in the patent is one of degree rather than of kind.

In the description of the patented procedure it is noted that some, but not all, hybrids of pair-crossed heterozygous plants are sufficiently uniform in phenotype to be acceptable as commercial varieties. This is not a new idea. Differences in uniformity for important traits were noted among double-cross hybrids of maize more than 40 years ago[5]. To any person with a knowledge of genetics it is obvious that if there are differences in phenotypic uniformity among double-cross hybrids, they would also occur among hybrids produced by crossing heterozygous single plants because the same genetical principles apply in both cases.

Progeny testing and specific combing ability: In the patented procedure, selection among potential parents of hybrids is based on the field performance of their hybrid progeny. It acknowledges that the best way to exploit specific combining ability is to make and test the hybrid that will eventually be released as a new variety. The concept of exploiting specific combining ability in this manner is not new. It was the basis of Hull's[6] recommendation that an inbred tester be used in developing new single-cross hybrids and is also an important feature of the full-sib selection systems developed by Hallauer[7], Lonnquist and Williams[8] and Hallauer and Eberhart[9] for maize. The only significant difference between these methods and the patented method is the manner in which selected heterozygous plants are propagated.

Seed yields from heterozygous parents: The principle that greater yields of good quality hybrid seed are obtained if the parents of a hybrid are themselves heterozygous has long been known to breeders of cross-pollinated crops. It was embodied in Jones'[10] proposal of 1918 that double-cross hybrids of maize should be used as commercial varieties. The same principle was later exploited in three-way cross hybrids and again in modified single crosses and sister line crosses[2]. It has also been used in the production of kale hybrids[11] and is a concept used in the breeding of hybrid Brussels sprouts[12] and onions[13].

Vegetative propagation: The vegetative propagation of heterozygous plants to provide adequate stocks of genetically identical plants for hybrid seed production is crucial to the procedure patented. However, the idea that cloning can be used to perpetuate and increase unique genotypes that cannot be maintained without genetic change by sexual methods of reproduction is common knowledge[2,14–17]. Its particular use in the production of hybrid seed has also been repeatedly recommended[2,11,14,18–25]. The special value of micropropagation *in vitro* as a potentially more efficient substitute for vegetative propagation *in vivo* is also generally acknowledged[14,15].

On the basis of our interpretation of Bagwill's paper[1] and the evidence presented here, we find it difficult as scientists to see how the conditions recited by Bagwill can have been satisfied in the process of obtaining this patent. We strongly urge the United States Patent and Trademark Office to re-examine this particular patent and if similar applications are made elsewhere to consult specialist opinion more widely before granting other plant patents that may similarly restrict the use of techniques and combinations of techniques that are common currency among plant breeders worldwide.

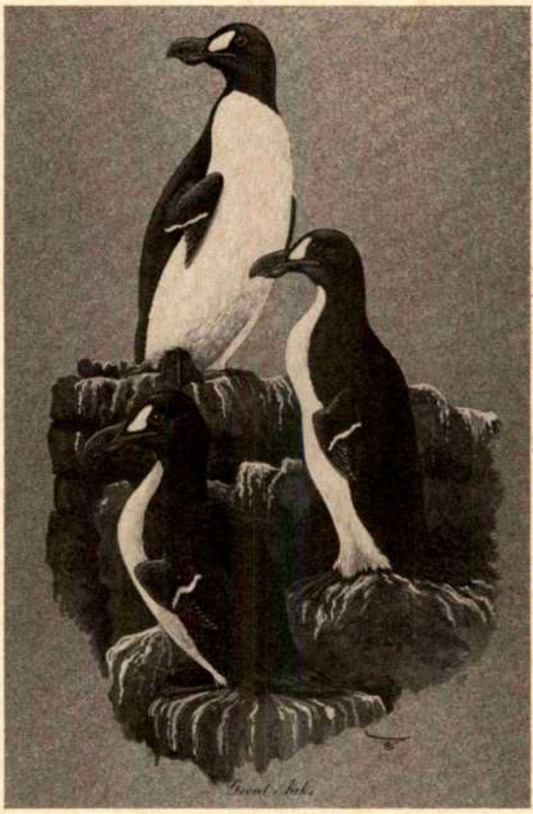
Man the exterminator

from Jared M. Diamond

THE spread of European populations over the globe that followed the discovery of America soon led to the extinction of many species and local populations, including populations of man himself. Among the best known cases are those of the Dodo, Passenger Pigeon, Steller's Sea Cow, Tasmanian Wolf and Tasmanian humans. The colonizing Europeans often encountered local hunting groups who obeyed taboos that effectively promoted conservation of the wild life on which they depended. So arose the legend that man the hunter-gatherer is prudent, and only civilized man is an exterminator. Accumulating evidence, much of it recent or controversial, suggests that the truth may be very different.



From Tim Halliday *Vanishing Birds* (Sidgwick & Jackson, 1978).

Hunter-gatherers and neolithic agriculturalists seem now to have played the part of exterminator whenever they occupied new areas of the globe. That the areas occupied by man in the past 50 millennia have suffered extinctions, especially of large animals, is undisputed. What remains controversial is which extinctions preceded and which followed man's arrival and how the latter extinctions took place.

Many other waves of human migration preceded that of the Europeans. Only in Africa and Eurasia is man's antiquity measured in millions or hundreds of thousands of years. Present estimates suggest humans reached Australia and New Guinea 50,000 yr BP, North and South America 20,000 yr BP, the West Indies 5,000 yr BP, outer Melanesia (New Caledonia and Fiji) 3–4,000 yr BP, and Madagascar, New Zealand and Hawaii 1–1,500 yr BP.

The best understood of the early extinction waves occurred on New Zealand. In the 200 years since Europeans arrived, eight bird species are known to have become extinct. The discovery of moa bones, however, testifies to earlier extinctions. Until about 25 years ago, it was generally thought that moas had been dying out naturally[1,2], and that few remained when Polynesian colonists arrived around AD 1000. Excavations and radiocarbon dating have now shown that these colonists encountered at least 30 bird species, including the 13 moas and 9 other flightless species, that had vanished by the time Europeans began surveying the avifauna in the 1800s[3–8]. The moas disappeared in a north-to-south wave ending at the south of New Zealand's South Island in the 1600s[9]. In the same period, breeding fur seals became extinct on North Island (now confined to South Island), and large lizards, frogs and flightless insects became extinct on the New Zealand mainland (now confined to offshore islands).

Graphic witness to a role of overhunting in at least some of these extinctions are archaeological sites with stone ovens and hundreds of butchered moa skeletons[5]. But overhunting could hardly explain the extinctions of frogs and flightless insects. Even for the moas, it is hard to accept overhunting as the sole explanation on South Island, where human population densities were very low. Other causes, including the clearing of forest, predation by introduced Polynesian rats and introduced diseases, must also have contributed to the Polynesian-linked extinctions[5–7,10–12].

In New Zealand, both the arrival of man and the extinctions are very recent and well documented. Yet it was long uncertain whether the New Zealand extinctions were even contemporary with human settlement, and it is not clear exactly how they took place, as is indeed often the case even for extinctions occurring under biologist's eyes today. No wonder then that the facts are disputed for earlier extinctions that are less accessible archaeologically, elsewhere in the world.

Around the time that Polynesians reached New Zealand, two other isolated islands with rich biotas were also first settled by man: Hawaii and Madagascar. When Europeans surveyed the Hawaiian avifauna in the nineteenth century, they found 49 land and freshwater bird species (two of them flightless), of which at least 15 are now extinct. This European-linked extinction wave is well known, but studies of subfossil bird bones reported in the current issue of *Science* show that it was preceded by an even larger Polynesian-linked extinction wave[13,14]. At least 39 recent fossil species have been discovered that had disappeared before European arrival. Bones of most of these species have been found either in Polynesian archaeological sites or in deposits contemporary with these sites, proving that the extinctions followed the arrival of man. The lost prehistoric avifauna includes at least 7 species of goose, many of them flightless, plus two flightless ibis, seven flightless rails and at least fifteen subfossil species of the Hawaiian endemic tribe Drepanidini (the Hawaiian finches or 'honeycreepers'). The radiation of Hawaii's geese, as of New Zealand moas, presumably filled grazer niches in the absence of mammals other than bats.

Madagascar also had a remarkable subfossil fauna that disappeared before the Europeans arrived[15–18]. It included about 14 large or giant lemurs, which together with about 19 surviving species constituted the richest sympatric primate community on Earth; 6–12 species of the giant flightless elephant birds (Aepyornthidae); 2 giant tortoises; and a hippopotamus, aardvark and large viverrid. The elephant birds and tortoises would have been the dominant terrestrial herbivores, equivalent to the moas and Hawaiian geese. Humans

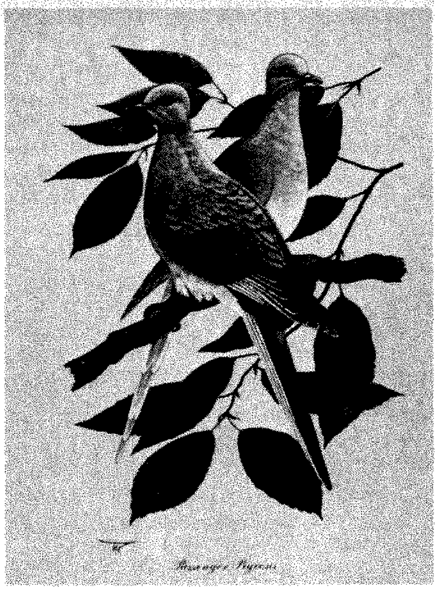
arrived around AD 500, and extinction of most of the megafauna apparently followed in the next six centuries.

For New Zealand, Hawaii and Madagascar the arrival of man was so recent, and (at least for New Zealand and Hawaii) the occurrence of extinct species in archaeological sites or levels so well documented, that the extinctions are obviously due to man rather than to late-Pleistocene climate changes. In the West Indies[19,20], the story becomes more complicated, because humans arrived earlier (about 5,000 yr ago) and fossil extinctions have yet to be dated. Fossil mammals included about nine ground sloths, numerous rodents up to the size of a bear, insectivores and a distinctive but enigmatic monkey. Carnivorous birds radiated in the absence of carnivorous mammals: a condor, giant eagle, barn owls of three different sizes (normal, giant and enormous), and an enormous and possibly flightless strigid owl. Other extinct species include lizards and giant tortoises, as well as other birds. When each species went extinct is largely unknown, but there seems to have been at least three stages: late-Pleistocene extinctions due to moister climate and rising sea level and especially affecting species of dry habitats; a wave of extinctions when Amerindians arrived five millennia ago; and another, continuing wave that began with the arrival of Europeans in 1492.

On the North and South American continents a wave of extinctions peaking around 10,000–12,000 yr ago eliminated about three-quarters of the genera of large mammals (weight > 100 lb)[15,21-26]. Although there is now no dispute that the extinctions occurred after man arrived, the question of whether the extinctions were due to man or to the late-Pleistocene climate changes remains controversial for several reasons. First, the New World differs from the previously discussed cases in that the arrival of a wave of human hunters around 12,000 yr BP (the Clovis hunters)[26] coincided with the rapid climate changes at the end of the Pleistocene. Second, most archaeologists believe that other humans had already reached the New World well before 12,000 yr BP, so that those who maintain the extinctions to be man-related have to postulate that the earlier colonists were either inefficient or indifferent big-game hunters. Third, clear associations of human artefacts with extinct fauna are very few, a fact which Mosimann and Martin[23] explained by a 'blitzkreig model' of extinction — that is, hunters encountering native large animals decimate them so quickly that the period of coexistence between animals and man is brief, leaving few remains for archaeologists to distinguish from carcasses of animals that died naturally. This reconstruction seemed daring when first proposed, but it now appears to describe exactly the speed of extinction in New Zealand, Hawaii and Madagascar.



From Tim Halliday *Vanishing Birds* (Sidgwick & Jackson, 1978).

The alternative, climate-based interpretation of New World extinctions also faces difficulties. For instance, the Shasta ground sloth disappeared abruptly when Clovis hunters reached its range around 11,000 yr BP, yet radiocarbon-dated dung samples show it to have been common during the five centuries immediately preceding its extinction, and the plants on which the sloth fed still occur today at its fossil sites[24].

The other continent colonized by Pleistocene man, Australia, lost a bigger fraction of its megafauna than any other continent[27-29]. Along with a giant snake (*Wonambi*), giant lizard (*Megalania*), giant tortoise (*Meiolania*) and giant flightless birds (*Genyornis*), Australia lost all its large mammals (>100 lb) except 4 kangaroos: 17 extinct genera and 46 extinct species of marsupials up to the size of the rhinoceros-sized herbivore *Diprotodon* and the lion-sized carnivore *Thylacoleo*, plus several species of giant kangaroos. As in the New World, the relative roles of climate and man in the extinctions are controversial. Evidence for association of megafaunal remains with human artefacts has yet to be found in Australia. Unlike the New World, Australia gained humans and lost megafauna long before the end of the Pleistocene. Humans arrived at least by 30,000 yr BP, and evidence for survival of megafauna much after that time is inconclusive.

These changes on land produced secondary effects at sea. It is likely that the populations of pelagic turtles[30] and birds[31] that we see today are a tiny fraction of those existing before breeding colonies on oceanic islands were decimated by the first human colonists. Evidence includes abundant remains of subfossil petrels on Hawaii[14] and in Polynesian middens on the Chathams[32], and the recent discovery of breeding petrels in the remote interior of the Solomon island of Bougainville[33].

Evidence of man-linked faunal extinctions remains to be sought on many islands that have been little explored by palaeontologists but that were reached by man before the European expansion of the past 500 yr. Such islands include New Caledonia, New Britain, Fiji, the Solomons, Canaries, Comoros and Mediterranean islands. Of equal interest will be islands such as Lord Howe, the Galapagos and the remote islands of the Indian and Atlantic Oceans, that were not reached by man until the recent European expansion. Such islands will be controls that show the 'pure' effect of climate changes in the absence of man.

Man's hand fell especially on species that were large, flightless, or both. Large animals fared badly as the preferred prey of hunters, and because they tend to occur with low population densities and low reproductive potentials. Flightless birds fared badly as the easiest prey, whether to man or to his accompanying mammalian pests. For example, New Zealand lost its 19 largest birds; Madagascar, 14 of its 15 largest lemurs; Australia, 37 of its 41 largest marsupials; the New World, two-thirds of its largest mammals. An exception is Hawaii, whch lost 15 small drepanidine finches along with large geese, crows and an eagle (see below). The Chathams lost all 6 of their flightless birds; Hawaii lost all but 2 of its 14–18 flightless birds to the Polynesians, and the remaining 2 to Europeans; and New Zealand lost 22 of its

29 flightless birds to Polynesians, and has lost or nearly lost 4 of the remaining 7 to Europeans. Dozens of other remote islands lost flightless birds to Europeans.

While the fact of human-related extinction waves is clearly established for some areas, at least six different mechanisms have been proposed, and their relative importance is debated. The most obvious is overhunting, the mechanism by which modern European hunters exterminated the Greak Auk and Steller's Sea Cow under the eyes of other Europeans. For example, the last two Great Auk were clubbed to death at Eldey Rock off Iceland on 3 June 1844. Animal populations that had never experienced man did not fear him, and this helps explain why extinction waves proceeded so quickly when man first reached remote islands and continents. Today one can still glimpse a surviving fragment of the world of 50,000 yr ago in New Guinea's isolated, completely uninhabited Foja Mountains. Here large marsupials are abundant and tame, in contrast to their rareness and shyness even in areas of New Guinea with only sparse populations of nomadic hunter-gatherers.

A second, related mechanism of man-linked extinction is the impact of predators introduced by man, such as rats, cats, dogs, weasels and mongooses, especially on nesting birds and ground-dwelling animals. Notorious examples include the extinctions of four birds, a bat and numerous invertebrates on Big South Cape Island off New Zealand within three years of the arrival of rats[3]; and a similar extinction wave after rats reached Lord Howe Island[34]. The correlation between the spread of rats and the post-European extinctions of Hawaiian birds also suggests such an explanation[35]. Even large animals can fall victim to man's pests: rats have been seen to kill adult albatross on the nest[36], and young of Galapagos Giant Tortoises are destroyed by feral pigs unless reared in captivity to a pig-proof size. Numerous species of New Zealand birds, reptiles, frogs and insects have disappeared from the mainland and now survive only on rat-free offshore islands.

A third mechanism attested by innumerable examples is destruction of habitat, whether by fire, by clearing or draining for agriculture, or by introduced browsing animals. Clearing of Hawaii's lowland forest probably explains why the Polynesian-linked extinction wave carried off at least 15 small songbirds not worth hunting, as well as 'game' birds such as geese[14]. Deforestation by fire and introduced animals eliminated much of the habitat on which Madagascar's megafauna depended[18]. By the time that the first European biologists arrived, Easter Island had no land birds at all, and St Helena only one species: their original complement disappeared with the cutting of the forests by Polynesians and Europeans respectively, before the biologists came.

Three other suggested mechanisms of extinction involve introduced competitors, disease and social disruption. While man has exterminated native species, he has also introduced exotics that may compete with surviving natives. Disease is the primary mechanism by which colonizing Europeans have exterminated or reduced many non-European human groups they encountered in the last 500 yr. (Disease in the form of avian malaria may also have eliminated native Hawaiian forest birds from surviving forest below the malaria ceiling of 3,000 ft.) Finally, breeding in colonial species depends on social stimulation, so that a remnant population with its social structure disrupted may be incapable of recovery. This is probably why surviving Passenger Pigeons[34], and surviving human Tasmanians, dwindled to extinction after the hunting that had decimated their numbers ended.

What can past history teach us about future risks? We risk more of the same, in different places: overharvesting of the cichlid fish fauna of East African lakes; arrival of rats at still rat-free Rennell Island, which has 5 endemic bird species and 17 endemic subspecies; and continuing destruction of Himalayan hill forest. But the major extinction wave of the near future will surely be through the swiftly advancing destruction of the continental tropical rainforests, the most species-rich habitats on Earth. While extinction waves cost New Zealand, Hawaii and Madagascar a considerable fraction of their biotas, these biotas were tiny compared with the biotas of Amazonia and tropical south-east Asia. The rainforests are already gone in much of the mountains of Colombia, and in coastal south-east Brazil. At present rates of destruction they will be virtually gone in lowland Malaysia, west Africa, Cambodia, Sri Lanka, Guatemala and Chiapas by the year 2000. Man the exterminator risks eliminating more species in the next few decades than in all his previous history. □

Twinkle, twinkle quasi star . . .

from Marek Abramowicz

WAS our Galaxy a quasar? Could it become a quasar in the future? In a recent issue of *Monthly Notes of the Royal Astronomical Society* (**200**, 247; 1982), Bailey argues that the Galaxy has indeed undergone at least one event of quasar-like activity in the recent past and may do so again.

Short, active periods recur in most galaxies. In Bailey's picture of galactic evolution, the mass lost by stars slowly settles in a central rotating disk. This continues quietly until the disk density exceeds M/r^3, where M is the mass of the galactic nucleus and r is the disk radius. At this point the self-gravity of the disk becomes important and local instabilities, similar to the Jeans instability, develop. According to Paczyński[1], if the optical depth is so large that the cooling time scale is much longer than the rotational period, the instabilities will not produce condensations but will increase the velocity dispersion in the gas. Without condensations no star formation is possible. Velocity dispersion produces turbulence, thereby enhancing viscous stresses, which drive accretion by transporting angular momentum outwards and producing heat.

Bailey modifies this idea: he assumes that condensations will form and a sequential star formation occur. He suggests that this will produce turbulent motions in the gas which in turn increase viscosity. As in Paczyński's model, the rapid viscous evolution of the disk fuels the activity of the nucleus by accretion of gas onto a supermassive central black hole. Alternatively, in the absence of such a hole, a massive central cloud may form which eventually collapses to form a black hole or spinar.

The evolution goes through the sequence of long, quiet phases interrupted by short periods of high activity; the quasars twinkle, very much like cataclysmic variables in our Galaxy. But does this idea agree with what we know about quasars?

Despite the substantial progress in our understanding of the nature of active galactic nuclei, a few fundamental problems have not yet been solved: (1) The supply problem — how can a galaxy supply enough matter to fuel the activity of its nucleus? (2) The efficiency problem — what physical mechanism provides a high enough efficiency of accretion? (Efficiency is the number of ergs of energy radiated per gramme of matter swallowed by the nucleus.) (3) The verification problem — how can observations confirm or rule out the different theoretical models (black hole/spinar)?

The supply problem

The galaxy supplies fuel to its nucleus either through mass loss from stars, or by more exotic processes of star captures and disruptions which can be very effective near the central black hole. Some questions remain open — among them, how to compute the stellar capture and disruption rates, and how to determine the fate of the resulting debris. As pointed out by Rees[2] and others, the classical estimations of

Hills are over-optimistic because they do not allow for the fact that once all the stars whose orbits pass close to the central hole have been destroyed, further capture can occur only when dynamical interaction between the stars repopulates the orbits, that is, on a time scale longer than 10^{10} yr. This means that the rate of supply from the galaxy may be insufficient to fuel continuously the activity of the nucleus. Obviously, Bailey's scenario gives an opportunity to solve this problem: the disk deposits a large mass by accumulating a low income over a very long time — it can therefore afford short time losses at a rate much higher than the income.

The efficiency problem

Black holes, once formed, cannot be destroyed. Soltan[3] uses this fundamental fact to discuss the masses of quasars and the efficiency of accretion. If quasar-like events are common and if they involve black holes, then there should be black holes in most galaxies. The mass of the hole must be smaller than that of its host galaxy. Since we know the masses of galaxies from observation, we can set an upper limit to the black hole masses, which is also the upper limit for the mass of the fuel swallowed by the hole during the active phases. Soltan also estimates (from quasar counts and bolometric luminosities) an absolute lower limit for the total energy produced by the quasars per unit volume. His estimate is independent of cosmological model and agrees with a similar estimate of Schmidt. The upper limit for mass, together with the lower limit for energy, give the lower limit for efficiency, which is close to 0.1. Such a high efficiency cannot be consistent with very thick, stationary accretion disks. However, there are strong arguments in favour of very thick disks as models of active galactic nuclei. Thick disks can generate huge, super-Eddington luminosities observed in some BL Lac objects and produce long, jet-like structures in which matter moves with apparently superluminal velocities. It was suggested (by myself, Paczyński, Blandford and probably by others) that non-stationary disks can radiate away most of their energy while being geometrically thick from time to time. Between these flare-ups most of the matter is accreted onto a black hole from $r = 3\,r_G$. Such disks may be both efficient and thick. Their behaviour resembles the short, active, recurrent events advocated by Bailey.

The verification problem

Bailey shows that the observations of several nearby galaxies are consistent with his theory. However, in the case of our Galactic Centre, his theory agrees with both the black hole and the spinar models, thus leaving unanswered the question, raised by Lynden-Bell, is there a black hole in the centre of our Galaxy? Previously Bailey has argued[4] that the Galactic Centre may contain a compact object (black hole?) with a mass greater than $10^6\,M_\odot$. Other authors, particularly Ozernol[2], maintain that in this case the Galactic Centre would have a much higher luminosity than is observed. This controversy will probably last for some time to come, because its source lies mainly in genuine difficulties of theoretical interpretation and cannot be resolved by progress in technology.

Bailey discussed some indirect observational tests of his theory. A direct test is also possible. Preliminary, unpublished results of Sikora and Soltan, who have analysed statistically the observed ratio of the radio luminosity of extended sources to the bolometric luminosity of their central nuclei as a function of redshift, seem to indicate that the galactic nuclei do indeed twinkle. The intensity and frequency of twinkling falls off with time.

Some of Bailey's calculations employ astrophysical theories that are still likely to experience new developments and substantial revisions. In addition, a few of his results are in conflict with those of other investigators. This may indicate that some details of Bailey's theory will need reconsideration. However, the main idea, that active galactic nuclei switch on and off, or that 'quasars twinkle', is, in my opinion, both very important and correct. Some elements of this idea have been discussed by other authors before Bailey. However, he presented it for the first time in a wide context of galactic evolution and endowed it with astrophysically realistic scenarios. The richness and complexity of Bailey's theory will guide many theoreticians and observers in their work on active galactic nuclei in years to come.

Opioids at Cape Cod

from Brian M. Cox

A DECADE ago the presence of a specific receptor activated by opiate drugs was accepted, but those who sought direct measures of drug binding to the receptor were still struggling to reduce background binding to acceptable levels. Only a few visionaries had begun the search for the endogenous ligand, and it was always referred to in the singular, if mentioned at all. Now the occurrence of at least three sets of endogenous opioids derived from three different genes is clearly established and, as emerged at the recent International Narcotics Conference*, evidence of an extraordinary degree of complexity in endogenous opioid systems is rapidly accumulating.

Conference sessions on the endogenous opioids were dominated by rumours that Numa's group in Kyoto had characterized a common precursor for dynorphin and the neo-endorphins. Now these rumours have been confirmed and the precursor sequence recently published in *Nature* (**298**, 245). Much evidence presented at the conference was consistent with Numa's findings. Measurements of tissue levels of dynorphin and α-neo-endorphin revealed closely similar anatomic and subcellular distributions (B. Seizinger, Max-Planck-Institut, Munich; C. Molineaux, Uniformed Services University, Bethesda). Immunocytochemical studies by E. Weber (Stanford University), recently discussed in these pages (*News & Views* **298**, 221), were strongly suggestive of co-localization of these peptides in the same neurones. However, processing of the dynorphin precursor appeared to be differentially regulated in different tissues; both Seizinger and Weber provided evidence for the presence of substantial amounts of the dynorphin fragment dynorphin$_{1-8}$ in hypothalamus. The distribution of dynorphin in brain differs from that of the enkephalins and β-endorphin, although there are several areas where dynorphin and enkephalin precursors are both present (S. Watson, University of Michigan). Several studies emphasized that in the magnocellular neurones of the hypothalamo-hypophyseal tract, dynorphin and vasopressin are localized in the same cells, while K. Voight (University of Ulm) reported that enkephalins are present in the oxytocin-containing cells.

But what of the roles of the products of the three opioid peptide genes? There is now general agreement that opioid receptors can be classified into at least three types, designated μ, κ and δ. The enkephalins have long been known to have preferential affinity for δ receptors. Over the past year it has become apparent that dynorphin has selective affinity for κ receptors; at the meeting, evidence was presented that the other products of the dynorphin gene, α-neo-endorphin, dynorphin B and dynorphin$_{1-8}$, also show marked κ-receptor selectivity (W. Fischli, Addiction Research Foundation; A. McKnight, Unit for Research on Addictive Drugs, Aberdeen). Thus the dynorphin gene generates opioids with preferential κ

0028-0836/82/340790-02$01.00

activity and the enkephalin gene agonists with preferential δ activity. β-Endorphin is, however, more promiscuous, interacting with comparable affinity at μ, κ and δ sites. There is no known endogenous opioid with selective affinity for the μ sites, although both β-endorphin and the enkephalins have good affinity and could well function as physiological ligands at μ receptors.

Whether these various receptor forms represent different molecular entities or result from conformational changes of a single receptor species is still unclear. C. Pert (NIMH) argued that μ- and δ-binding sites in the striatum were interconvertible, the conversion being regulated by local Na^+ and GTP concentrations. However, I. James (Addiction Research Foundation) was unable to demonstrate any re-equilibration of receptor types in isolated brain membranes after the selective inactivation of one or more classes by the alkylating opioid antagonist β-chlornaltrexamine. Autoradiographic studies suggest that the distributions of the μ- and κ-receptor forms in brain are different. S. Snyder (Johns Hopkins University) reported the presence of a particularly prominent band of κ receptors in the deep layers of the rat cerebral cortex, which he postulated might be linked to the sedative properties of κ receptor agonists. F. Leslie (University of California, Irvine) found the neonatal rat brain contained predominantly μ and κ receptors, with few δ receptors demonstrable. In the adult rat, the proportion of κ receptors falls substantially, while the proportion of δ receptors increases to levels comparable with μ-receptor densities. The rat, however, is apparently atypical in the low proportion of κ receptors observed in the adult animal. Higher levels have been observed in other species, and Y. Itzhak (New York University) reported that relatively high levels of κ receptors were observed in most regions of human brain.

The analysis of the functions of the different receptor classes has been facilitated by the development of several new drugs and reagents. The alkylating agents with opioid receptor affinity, such as β-chlornaltrexamine, initially developed by P. Portoghese (University of Minnesota), have been found useful by several groups. G. Pasternak (Memorial Sloan-Kettering Cancer Center) reported the use of another irreversible receptor ligand, naloxazone, in the discrimination of opioid receptor subtypes. However, all these irreversible ligands have proved to have lower affinity for δ receptors than other receptor forms. The development, therefore, of a peptide analogue with selective competitive antagonist activity at δ receptors, reported by J. Shaw and M. Turnbull (ICI), promises to be very useful in identifying functions mediated by this receptor class. An approach to the identification of the roles of specific opioids in physiological processes is the use of selective inhibitors of degradation. R. Greenberg (Squibb) and R.E. Chipkin (Schering) reported that thiorphan, an inhibitor of enkephalinase, potentiated analgesia induced by restraint or foot-shock stress. Interpretation of these results was complicated, however, by the observation that thiorphan also potentiated the analgesic effects of peptides not subject to degradation by enkephalinase.

Some progress has been made in identifying functions regulated by specific receptor subtypes. P. Wood (Douglas Hospital, Quebec) demonstrated that analgesia induced by opiate injection into the periaqueductal gray region of the midbrain is mediated by activation of μ receptors, while κ receptor-selective opioids are relatively inactive. However, M. Piercey (Upjohn) reported that injection of either dynorphin or a κ receptor-specific drug, U50488H, into the spinal cord in mice produced pronounced analgesia. The analgesic action of dynorphin in spinal cord was also confirmed by J. Han (Beijing Medical College). A possible role for dynorphin in the physiological regulation at the spinal cord level of the perception of noxious stimuli is suggested by Han's demonstration that electroacupuncture analgesia was suppressed by the localized administration to the spinal cord of dynorphin antiserum. The presence of relatively high concentrations of dynorphin in the dorsal horn of spinal cord has previously been reported.

The role of opioids in the nigrostriatal system has been much studied because it is known that there is a very close relationship between dopaminergic and opioid systems in this part of the brain. Wood reported that μ- and δ-receptor agonists increased the levels of dopamine metabolites in the striatum, while κ-selective agonists, such as ethylketocyclazocine, had little direct effect, but antagonized morphine action. M-F. Chesselet (College de France) showed that the selective δ ligand D-Ser^2-Thr^6-Leu-enkephalin, injected into the fluid perfusing the caudate nucleus, induced a localized release of dopamine. Selective μ agonists such as morphine produced a weaker effect which was followed by inhibition of release. Since the enkephalin analogue, but not morphine, enhanced the release of dopamine from striatal slices *in vitro*, it was suggested that δ agonists act directly, while μ agonists act indirectly, to promote the release of dopamine in the caudate. The induction of muscular rigidity by morphine in the rat, probably by an inhibitory action of γ-aminobutyric acid neurones in the zona reticulata of the substantia nigra, was discussed by U. Havemann (Max-Planck-Institut, Gottingen). Thus in this, as in so many systems, several component structures seem to be influenced by one or other form of opioid. □

Do antigen-presenting cells distinguish self from non-self?

from Martin C. Raff

THERE is substantial evidence suggesting that helper T cells recognize a foreign antigen only after it has been taken up by specialized antigen-presenting cells (APCs) and that the antigen is recognized on the surface of the APC in association with class II (Ia) MHC glycoproteins[1]. But this view of antigen presentation is fundamentally incomplete in that it does not provide answers to two central questions: how do APCs recognize antigens, and do they distinguish foreign molecules from self molecules?

If APCs do not discriminate between self and non-self, why are their recognition and processing pathways not saturated by the high concentration of self macromolecules in the extracellular fluid? If they do distinguish self from non-self, how do they do so? How can they pick out a molecule of tetanus toxin from a sea of self proteins? One possibility is that they use a non-immunological recognition mechanism akin to those used by certain invertebrate cells for distinguishing self from non-self: although the molecular mechanisms involved are still poorly understood, it is clear that such discrimination operates when, for example, yeast cells mate[2], or a mixture of cells dissociated from two different species of sponges reaggregates in a species-specific way[3], or invertebrate haematocytes react against foreign particles, cells or organisms[4]. However, the discrimination required of APCs, were they to distinguish the many thousands of different self molecules from the many millions of different foreign antigens that are capable of stimulating an immune response, would be far more demanding than that required of invertebrate cells. Teleologically, therefore, it seems more likely that APCs would take advantage of the sophisticated antigen recognition mechanisms evolved by the vertebrate immune system. For example, APCs might only efficiently bind and/or process molecules that are complexed to antibodies secreted by T cell-independent B cells. However, some APCs, such as splenic dendritic cells, apparently do not have Fc receptors with which to bind antigen–

0028-0836/82/340791-02$01.00

antibody complexes[5], and B cell-deficient animals seem to be able to make helper T cell-dependent immune responses[6]. Therefore, if APCs require lymphocyte help to recognize foreign antigens, this help might be in the form of antigen-specific T cell products (which must themselves be made without the aid of APCs). The recent report that suppressor T cells can inhibit the function of APCs[7] is consistent with the view that communication between T cells and APCs is bidirectional.

The idea that antigen binding and/or processing by APCs is lymphocyte-dependent would be untenable if pure APCs (especially antigen-presenting cell lines) were found to be as efficiently 'loaded' with antigen in the absence of lymphocytes as in their presence. It would also be unlikely if the recent evidence (cited but not documented in ref. 8; and G. Sunshine, M. Cyrus and G. Winchester, unpublished results) that APCs do not discriminate between self and non-self forms of the F serum glycoprotein is confirmed for other molecules. In either case, an important question in antigen presentation, which has so far been ignored, would remain unanswered: why are APCs not saturated by self molecules?

Iron-sulphur cluster interconversions and the activation of aconitase

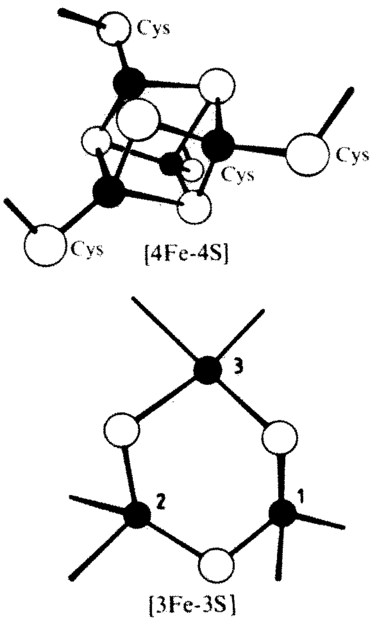
from Richard Cammack

IRON-SULPHUR clusters in proteins may not always be such static entities as has been supposed. Recent experiments have shown that some of the newly discovered [3Fe-3S] clusters can be converted reversibly into [4Fe-4S] clusters. H. Beinert's group, working in Madison, Wisconsin, has proposed that an interconversion of this type is the key to the activation of the mitochondrial enzyme aconitase. It has long been known that aconitase, when isolated, is in an inactive form and can be activated by incubation with iron salts. Some authors have suggested that this iron atom is involved in the catalytic centre of the enzyme. Now it is recognized that aconitase contains an iron-sulphur cluster, of the recently discovered three-iron type (see *News and Views* **286**, 442; 1980). The additional iron appears to convert this to a [4Fe-4S] cluster which somehow is required for the activity of the enzyme.

Recent advances in the use of spectroscopic techniques, including ESR, magnetic circular dichroism (MCD), ^{57}Fe-Mössbauer and resonance Raman (RR) spectroscopy, have made it possible to observe the individual clusters in the iron-sulphur proteins. Though each technique provides different information about the type of cluster in a protein (paramagnetism, vibrational modes, and so on), they all provide ways of comparing an unknown iron-sulphur protein with the 'benchmark' proteins whose structures have been determined by X-ray crystallography. A series of ferredoxins is now known which contain [4Fe-4S] and [3Fe-3S] clusters in various combinations. The advantage of studying these instead of proteins such as aconitase is that their relatively low molecular weights means that there is relatively more iron to observe.

The [4Fe-4S] cluster can be visualized as a cube, with iron and sulphide atoms at alternate corners. The [3Fe-3S] cluster is more like a flat hexagon of alternate iron and sulphur atoms[1]. In each cluster, the iron atoms are also bound to ligands from the protein; in the [4Fe-4S] cluster, they are four sulphur atoms of the amino acid cysteine; the [3Fe-3S] cluster requires six ligands, which in ferredoxin of *Azotobacter vinelandii* are provided by five cysteine sulphurs and possibly a water or glutamate oxygen atom[1]. Cluster interconversion therefore requires a considerable rearrangement of the protein structure.

Atomic arrangements in the four-iron and three-iron clusters. Iron atoms are the solid circles.



The function of the clusters in most iron-sulphur proteins is to transfer electrons. (This cannot, however, be the case in aconitase, which is not an oxidoreductase.) A major class of iron-sulphur proteins has clusters that undergo oxidation–reduction between the [Fe-4S]$^{2+}$ and [4Fe-4S]$^{1+}$ oxidation levels. When such proteins are isolated, they often contain small and variable amounts of material which gives an ESR signal in the oxidized state of $g = 2.01$. The amount of this material can be increased by treatment with the artifical oxidizing agent ferricyanide. At first this was thought to be due to conversion to the [4Fe-4S]$^{3+}$ oxidation level; however, if this occurs, the cluster is probably unstable and undergoes further modification, because the process cannot be reversed by simple reducing agents. The material which results from this modification, and which gives the $g = 2.01$ signal, has recently been shown by MCD[2], RR[3] and Mössbauer[4] spectroscopy to contain [3Fe-3S] clusters. Evidently oxidative treatment results in the loss of an iron atom from the [4Fe-4S] cluster, and rearrangement.

The change was referred to as 'oxidative damage'[3], implying that the [3Fe-3S] clusters found are artefacts caused by the exposure of [4Fe-4S] proteins to oxygen during isolation. The question then arises as to whether any of the [3Fe-3S] clusters observed in isolated proteins are of physiological significance.

A test case is provided by the ferredoxins isolated from *Desulfovibrio gigas* by J. Le Gall (University of Marseille), J. J. G. Moura, I. Moura and A.V. Xavier (University of Lisbon). Although designated ferredoxins I and II, these are in fact two different assemblages of the same polypeptide of molecular weight 6,000. Fd I is a trimeric unit in which each protein subunit contain a [4Fe-4S] cluster; Fd II is a tetrameric unit in which most of the subunits contains [3Fe-3S] clusters. Both ferredoxins are obtained in substantial quantities when the bacteria are extracted. They have different redox potentials and different activities with the enzymatic systems of *Desulfovibrio*. Fd I is active in the phosphoroclastic cleavage of pyruvate while Fd II is more active in sulphite reduction[5]. Various treatments have been found to interconvert the ferredoxins. Incubation of Fd II with cell extracts and pyruvate (reducing conditions) causes the appearance of Fd I, as seen by ESR. Oxidation of Fd I with ferricyanide

---

Richard Cammack is a lecturer in the Department of Plant Sciences, King's College London, 68 Half Moon Lane, London SE24 9JF.

converts it into something resembling Fd II. The protein has six cysteines and thus can readily accommodate a [3Fe-3S] cluster. The finely tuned balance between the cluster types was shown by reconstitution experiments in which the iron and sulphide were removed entirely and then replaced[6]. With an excess of iron present (5 per protein molecule), only [4Fe-4S] clusters were produced. With limiting iron (3 per protein molecule), up to 50 per cent of the clusters formed were of the [3Fe-3S] type.

Moura *et al.*[6] have developed a procedure to add the extra iron atom to Fd II and produce [4Fe-4S] clusters. This provides a unique opportunity to examine a specific iron atom in a [4Fe-4S] cluster. Using Mössbauer spectroscopy one can observe the isotope ^{57}Fe (which has an abundance of only 2.2 per cent in natural iron), so that by adding either enriched ^{57}Fe or ^{56}Fe to Fd II it is possible to obtain spectra from either the added iron atom, or the average of the other three. The studies were carried out by E. Münck and coworkers in Minnesota.

The spectra show that the added iron atom probably goes into a specific site in the [4Fe-4S] cluster, though the possibility of two equivalent subsites cannot be excluded[7].

The inequivalence between the iron atoms in this type of cluster is not understood at present. For example, in the reduced cluster, when the valence state corresponds to one Fe III and three Fe II atoms, the iron atoms as seen by Mössbauer spectroscopy appear to be present in two equivalent pairs[8]. A theoretical understanding of these clusters can now be assisted by the determination of the electron distribution and hyperfine field at the individual iron atoms.

Similar experiments have been carried out on the iron-sulphur cluster in aconitase[9]. The enzyme is activated by reductive treatments in which an iron atom is introduced into a particular site in the [4Fe-4S] cluster. The incorporated iron atom is relatively loosely bound, since added ^{56}Fe will exchange in a few minutes with ^{57}Fe-activated enzyme. By contrast, in *D. gigas* Fd I, the incorporated Fe will not readily exchange. Oxidative treatments, which reconvert the cluster to the [3Fe-3S] form, inactivate the protein, but it is still not clear why.

It has not yet been demonstrated that this interconversion occurs *in vivo*, apart from an early report[10] that the ESR signal at $g = 2.01$ resembling that of the aconitase [3Fe-3S] cluster can be observed in mitochondria. If it does, it would represent a totally new form of covalent modification of enzyme activity. It may not be unique; other enzymes, notably some hydrogenases, exist in inactive forms and show $g = 2.01$ ESR signals. □

Evolution and molecular biology

from Andrew Leigh Brown

DESPITE the flush of publications commemorating the centenary of Darwin's death, those outside the field could be forgiven for believing that evolutionary biology has lost its way. While the horizons of the rest of biology are being dramatically extended by new technologies, evolutionary biology seems to be becoming more and more introspective. A recurrent discussion of 'tempo and mode' in evolution has reached such prominence that 'punctuated equilibria' appear to constitute the only issue of importance. In fact, this is far from being the case.

A more fundamental problem raised by developments in molecular biology has so far passed almost unnoticed: the concepts and language of population genetics, in which the behaviour of genes in populations is described in the terms of classical genetics, are no longer adequate. The very words 'locus' and 'allele' have become almost meaningless. A new phraseology is required which can accommodate data on both restriction site polymorphisms and nucleotide substitutions, as well as more radical types of genetic variation: insertion polymorphism, 'concerted evolution' and transposition of repeated elements. Some of the first steps in erecting this new framework could be seen at two recent meetings* intended to foster understanding of the relationship between molecular and evolutionary biology.

The mitochondrial genome was used for the first essays in the molecular study of evolution because of its small size and ease of isolation. Population structure was analysed by restriction site variation and detailed phylogenetic trees were constructed. Now the first results of DNA sequence analysis of mitochondrial (mt) DNA are becoming available. In 900 base pairs (bp) of DNA sequence around the D-loop region of human mtDNA from seven individuals, nucleotide substitutions were found at 45 sites and DNA insertions at three positions (C. Aquadro, National Institute of Environmental Health Sciences, North Carolina).

Nucleotide substitutions were almost always transitions (that is, A→G or T→C changes), transversions accounted for only four per cent of the total. A phylogenetic tree, constructed by a maximum parsimony procedure that minimizes the number of changes between each sequence in the finished tree, reveals that convergent or parallel substitutions have occurred in at least five positions. In addition, the distribution of substitutions along the sequence was highly non-random because multiple substitutions occur at certain sites. These results raise doubts about the estimation of genetic variability from DNA sequence data that depend on pairwise comparisons, for these would greatly underestimate the sequence change inferred by the phylogenetic approach. Perhaps more worrying is that a restriction enzyme analysis would produce quite incorrect trees, because of the localized occurrence of base substitution.

Turning to nuclear genes, more is known of the evolution of the mammalian β-globin gene family than any other system. In man, these genes are arranged in the order:

$$5'\ \psi\beta_2,\ \varepsilon,\ {}^{G}\gamma,\ {}^{A}\gamma,\ \psi\beta_1,\ \delta,\ \beta\ 3'$$

Sequence homology between the δ- and β-globin genes in man suggested that they arose by duplication about 40 million years ago. However, DNA sequence analysis shows that the 3′ portion of the mouse βH2 gene has nearly 80 per cent homology to the human δ gene but only 58 per cent to the human β gene (M. Edgell, University of North Carolina). In addition, part of the single pseudogene in the lemur β-globin cluster appears to be a δ-globin sequence that has undergone gene conversion with an embryonic gene (A. Jeffreys, University of Leicester). These results strongly suggest that the β/δ-globin duplication predates the mammalian radiation of 80 million years ago. Where gene conversion can occur, overall sequence homology cannot be used to estimate the times of gene duplication events.

A large body of data collected on variants in the human β-globin gene cluster has revealed some remarkable aspects of the relationship between linkage disequilibrium and recombination distance (H.K. Kazazian, Johns Hopkins University). Thirteen polymorphic restriction site markers have been studied in several hundred individuals. Seven are located in a

0028-0836/82/340793-02$01.00

32-kilobase (kb) region on the 5′ side of the δ-globin gene which includes the γ, ε and ψβ$_1$ genes. Six sites are found in a separate 20kb block across and to the 3′ side of the β gene. Theoretically, the variants at the seven restriction sites might be found in over one hundred different combinations in the 5′ region. Remarkably, only three combinations are common, all of which are distinguished from each other at at least two sites. Similarly, in the 3′ block, only three more combinations are found. This high degree of linkage association would be unsurprising in view of the short distance separating the markers, but for the observation that across an 11 kb region spanning the δ gene, random association between 5′ and 3′ haplotypes is found. However, this recombination hot spot is unlikely to be a function of the δ-globin gene itself, as the flanking blocks include all the other genes in this cluster.

In surveys of the β-globin region, few DNA insertion variants have been found. In contrast, studies of restriction site polymorphism at two genes in *Drosophila* indicate that insertion/deletion events are an important source of variation. In a 12 kb region around the alcohol dehydrogenase (*Adh*) gene in *D. melanogaster*, five insertion/deletion variants were discovered in 18 lines from natural populations (C.H. Langley, NIEHS, North Carolina). However, the commonest restriction map in *D. melanogaster* showed little divergence that could be ascribed to DNA insertion from those obtained for two other species, *D. simulans* and *D. mauritiana*. Similar results are seen for the *87A* heat-shock locus in *Drosophila* (A. Leigh Brown, Imperial Cancer Research Fund). It is not yet known whether these other *Drosophila* species also show insertional variation but it could be that 'the spaces between the genes' are important in as yet undefined ways such that insertions or deletions are generally screened out by natural selection. The strong conservation of the distances between genes in the β-globin cluster of higher primates has prompted similar speculations (Jeffreys).

The *Adh* gene in *D. melanogaster* is also the first nuclear gene to be used for a systematic survey of variation in natural populations using DNA sequencing (M. Kreitman, Harvard University). Of 1,750 bp which have been sequenced in 11 isogenic strains, 36 nucleotide positions are variable. Unlike mtDNA, transitions and transversions are equally frequent. No amino acid substitutions were detected apart from the Thr-Lys substitution which causes the well known 'fast-slow' electrophoretic polymorphism. If it is assumed that the only substitutions permitted are silent ones whch do not result in an amino acid change, the frequency of polymorphic nucleotide sites relative to the number of silent sites in exons is very similar to the total frequency found in the introns. A much lower frequency was found in the 5′-non-coding regions of the transcripts, suggesting that some constraints on nucleotide substitution may be acting upstream of the protein-coding region. However, these apparently do not extend to the transcription start point, around which substitutions were quite frequent.

Finally, population genetics theory is now being applied to the behaviour of transposable elements in eukaryotic populations. A simple mathematical model has been developed that gives the expected frequencies of occupation of a particular chromosomal site by a mobile element in a natural population under the action of random genetic drift (J. Brookfield and C.H. Langley, NIEHS). Testing this model with data on the sites of hybridization to *Drosophila* polytene chromosomes of three mobile elements, *copia*, *412* and *297*, Brookfield and Langley showed that the data give a good fit for a high transposition rate. The result may be unexpected given that some mutations due to *copia* insertions (for example *w*^{a}) are very stable. It was also observed that the frequency of co-occupancy of a site by more than one type of transposable element was much higher than expected. This suggests either that insertion is not random and occurs after strand breakage or some similar event, or that the total number of occupable sites is restricted.

The P factor is a transposable element whose movement is responsible for a syndrome of germ-line aberrations in *D. melanogaster* known as hybrid dysgenesis. These aberrations are only found when wild males are crossed to females from long-established laboratory strains. Wild-type strains from the USA almost without exception carry this factor (P strains) while old-established laboratory strains do not (M strains). It had been thought that this loss was a consequence of inbreeding but new data on the relative frequency of such strains in collections from Europe and the Far East give a very different picture (M. Kidwell, Brown University). Here 'Q' strains, which are compatible with both P and M strains but contain many copies of the P element, are common, while M strains are of intermediate frequency and P strains are rare. In addition, some wild M strains are now known to contain some copies of the P element. The P element is known to be highly labile and it is not known whether any of the elements in these strains are functional. This complex pattern suggests that the element is itself undergoing rapid evolutionary change and possibly indicates an invasive rather than a symbiotic history.

Speculation that transposable elements may be involved in speciation has flourished following the discovery of their role in hybrid dysgenesis. If, however, the germ-line incompatibility is a consequence of a transient process of invasion, such involvement is much more difficult to envisage. It is hardly reasonable to propose a new invasion for each speciation event. Similarly, no clear pattern can yet be discerned on the general significance of insertional variation, which is apparently common in *Drosophila*, but is very rare in the human β-globin region. It seems more reasonable that the current difference between the mammalian and *Drosophila* data is due to the particular genes which have been studied in each organism to date [for example, the *dilute* coat colour mutation in the mouse is due to an insertion of retro-viral sequences (Jenkins, N. *et al. Nature* **293**, 370; 1981) and insertional polymorphism has also been found in man (Wyman & White, *PNAS* 77, 6754; 1980)].

These studies are beginning to reveal some of the processes which take place in the genome during evolution. It should be nevertheless recognized that the pursuit of detail is not a satisfactory end in itself. However much is learnt about a single gene, if the knowledge cannot be generalized we will not have discovered much about evolution. The greatest interest in the new developments stems from the fact that the whole genome has been rendered accessible by these techniques, and that is something that evolutionary biologists have waited a long time for. □

100 YEARS AGO

THE two Swedish gunboats which conveyed the circumpolar observation party to Spitzbergen, have just returned to Tromsö. Capt. Palander states that it was impossible to approach Mossel Bay, he having made two attempts, on account of heavy pack-ice, and that the party had therefore settled on Cape Thordsten as their residence, where observations commenced on the 15th inst. He further reports that all the Norwegian fishermen he met complained of the unfavourable season and the enormous quantity of ice this summer, no vessel having been able to get higher than Amsterdam Island, from where no opening could be seen by telescope in any direction.

The steamer *A.E. Nordenskjöld*, belonging to M. Sibiriakoff, left Tromsö on the 18th inst. for the Jenisei. The vessel has on board a cargo of English merchandise, two steam launches, and an engine for the Siberian gold works. The vessel will attempt to save some of the cargo lost in the *Oscar Dickson* in Gydaviken, and return next year with a full cargo of tea, which will be brought from China across the Baikal sea to Kureika on the Jenisei.

The death is announced of Count Lutke, well known in connection with Russian Arctic exploration, especially in the Novaya Zemlay region.

Detectors in astronomy

Optical astronomy

from Alec Boksenberg

It is now more than a century since the invention of the gelatin photographic emulsion, but the photographic process still has many deficiencies, including nonlinear response, restricted dynamic range, reciprocity failure, adjacency effects, and a detection efficiency of only a few per cent. It does, however, have the advantage over all other detection media when a huge number of picture elements is required. However, for most detection and recording applications in astronomy it has been superseded by more efficient methods.

Direct interaction of photons with the recording medium occurs in photographic emulsion, electronically-scanned silicon devices such as the charge-coupled-device (CCD), and electron-beam-scanned television camera tubes of the simple vidicon type. In all other devices a photocathode is used to produce an intermediate electron image, which then is accelerated to relatively high energy to enable the signal to be enhanced by some gain process before recording.

Electronographic cameras

In 1934 Kiepenheuer proposed that an efficient detector could be made by accelerating and focusing electrons from a photocathode onto a photographic emulsion. This would give a considerable gain in sensitivity over a simple photographic emulsion because every high-energy electron entering the emulsion produces developable grains and there is no reciprocity failure. The overall efficiency should therefore depend mainly on the efficiency of the photocathode. Modifications to the technique, particularly by McGee, who in his 'Spectracon' used a mica barrier membrane to protect the photocathode and also allow the emulsion to be used in air (fine-grained nuclear emulsions are used in modern devices), and the later variant by McMullan, have resulted in more convenient operation.

Photocathodes are now fundamental in certain television camera tubes and in image intensifiers. The most commonly used photocathode in optical astronomy, trialkali, has an efficiency of about 20 per cent in the blue falling to about 1 per cent at 8,000 Å. Recently a new class of 'negative electron affinity' photoemitting materials, such as GaAs(Cs), have been discovered which have a high efficiency in the red and near infrared.

Integrating television camera tubes

Conventional television camera tubes can in principle be used to detect and record astronomical images, however, television broadcast cameras are severely limited by noise (from the video pre-amplifier) at low light levels. It is therefore important to use a camera tube with high internal gain and the capability to integrate a weak signal over a long period before readout. Two tubes having these properties are the SEC and SIT vidicons, both originally developed for the military market as night vision devices. A photocathode generates photoelectrons which are accelerated to a few keV in the image section and focused at the target. Electron multiplication takes place in the target and, at the end of the exposure, the amplified electron image is read by a scanning electron beam in the readout section. The SIT target has an electron amplification up to 2,000 but requires strong cooling (to –60°C) in order to reduce the dark current sufficiently to permit long integration times. The SEC target has lower gain (~100) but can integrate and store charge images indefinitely at room temperature without degradation, but it has the disadvantage of lower storage capacity and produces 'grainier' images. Notwithstanding, the SEC tube has been used successfully in several astronomy programmes, and is the prime detector on the International Ultraviolet Explorer observatory satellite where its operational simplicity is fully exploited.

Image intensifiers

Image intensifiers come in several forms, all using a photocathode for the initial conversion of photons into an electron image. They have arbitrary input and output spectral characteristics, for example a device may accept a UV image but convert it to an enhanced optical image. In the simplest case electrons from the photocathode are accelerated onto a phosphor screen to produce an enhanced optical image. A blue-light gain of 50 is typical for a simple device of this kind, but several such stages can be arranged in cascade to give a very high overall gain, a four-stage intensifier produced by EMI having a blue-light gain of about 10^7.

The microchannel plate (MCP) can also be employed as an image intensifier capable of extremely high gain. It consists of an array of fine, slightly conducting glass tubes having a secondary emission coefficient greater than unity. An accelerated electron entering one of the channels and striking the wall produces secondaries, which are accelerated by an internal electric field and in turn strike the wall, eventually producing an avalanche of electrons which emerges from the output of the channel.

The MCP can also be built into a very compact double proximity-focused structure using a conventional photocathode on its input window to give a 'wafer' intensifier with high gain and no distortion. Although the electron gain of a MCP with straight channels is limited by the onset of positive ion feedback, several techniques have now been introduced to suppress this, the most satisfactory being to curve the channels, which can give an electron gain greater than 10^7 without difficulty. Additionally, the output pulse sizes at such high gains are confined to a sharply peaked distribution which substantially decreases the added noise in the image compared to the low gain performance. Although the output of an image intensifier may be recorded photographically, this combination still suffers from non-linearity and small

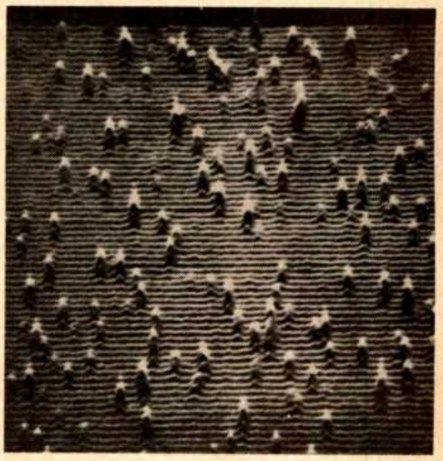

Fig. 1 Single photon events detected with a high gain image intensifier viewed by a television camera, as employed in the IPCS. This isometric display represents less than half of one per cent of the available television field.

Alec Boksenberg is Director of the Royal Greenwich Observatory, Herstmonceux Castle, Sussex.

0028-0836/82/340795-02$01.00

dynamic range. Coupling to a photoelectronic detector such as a television camera tube is far more satisfactory. This is exploited in the widely used technique of 'image photon counting' first developed by Boksenberg, who employed an EMI four-stage intensifier lens-coupled to a Philips 'Plumbicon' television camera tube.

Image photon counting systems (IPCS)

The basic idea of image photon counting is to amplify a faint image to a level where single photon events can be discerned above the readout noise of a television camera used to view the output screen of a high gain image intensifier (Fig. 1). The television camera acts as a spatially sensitive one-frame buffer store and passes the photon signals to a special pattern processor which records their central positions, and then passes these to the digital electronic memory of an on-line computer. Photon events registered in each television frame are then accumulated digitally. There is no limit to the length of exposure attainable because the system has no saturation capacity (unlike photographic emulsion or television camera targets). The technique shifts the emphasis from the detailed performance of the individual devices themselves to the real-time data processing of the fundamental signals delivered by the initial photon conversion layer in the system.

Recording only the central positions of each detected photon has two major advantages. Maximum efficiency is attained because each photon event is accorded equal statistical weighting, unlike the raw signals delivered by the television camera which are variously sized due to unequal gain processes associated with the coupled image intensifier. This would otherwise lead to uncertainty in the number of detected events. Second, a markedly sharper image is obtained because the image smearing inherent in the devices is removed in the processing of the photon events. Also, since all amplifier noise is rejected, there is no low-level threshold for very faint images, so images containing even a few photon events can be recorded accurately. Another major advantage of the system is the real-time display of the accummulating image on a monitor, which results in high operating efficiency in astronomy; considerable time may be saved by terminating exposures as soon as the required image signal-to-noise ratio has been achieved.

Two other systems also in routine use are the Robinson and Wampler image dissector scanner, and the intensified Reticon scanner developed by Shectman. These have more restricted channel capacity than a full IPCS but are excellent for many one-dimensional spectroscopic applications. Several more forms of image photon counting (or quasi-counting) detector are now being developed, employing various forms of intensification and readout, some resulting in very compact devices.

Solid state detectors

Various types of solid state imaging detectors based on silicon photodetectors have become available for astronomy in the past few years. Silicon is particularly efficient in the red and near-infrared compared to photoemissive surfaces, reaching about 80 per cent between 5,000 and 7,000 Å and extending beyond 11,000 Å. The various devices such as the Reticon and the charge-coupled device (CCD) are distinguished by the method of reading out the stored image. The detection efficiency is more or less limited by readout noise and build-up of charge background, and is highest for the CCD.

CCD devices all contain a two-dimensional array of sensitive elements (typically of dimension 15-30 μm), and arrays of up to 1,500 × 1,500 elements are under development. The device is essentially a silicon integrated circuit of MOS type and comprises an oxide covered silicon substrate upon which is formed an array of closely spaced electrodes. Each electrode is equivalent to the 'gate' of an MOS transistor. Signal information is carried in the form of an electric charge which is localized beneath the electrodes with the highest applied potentials. Charge accumulates in these potential wells and is released for conduction in the silicon by the action of the incident photons. 'Charge coupling' is the technique by which this signal charge can be transferred from beneath one electrode to the next. This is achieved by sequentially pulsing the voltages on the electrodes between high and low levels. Charge can therefore be made to pass down an array of many electrodes with hardly any loss and very little addition of noise. By this means the entire charge image can be shifted out bodily, and entered into a line readout section which delivers the now sequentially arranged signals to an on-chip video amplifier. The noise in this amplifier represents a limit to the minimum detectable signal, but in current devices can be as low as six electrons per image element. Cosmic ray events represent another limitation as silicon is an efficient detector of high-energy charged particles. For use in astronomy the devices must be cooled to avoid the build-up of thermally-induced charge, which would otherwise mask the signal. Exposures of several hours can then be achieved without excessive interference due to dark current.

Future improvements in image detection are likely to come at least as much from the application of new electronic processing and data reduction methods as from the development of better devices. The CCD is taking an increasing role in astronomy, and in future all detector devices may be of this type. Vast arrays might be built up of CCD configurations and internal gain might be achieved by avalanche processes already implemented in discrete diode structures. The technique of image photon counting, with its superior low light level performance, may then be achieved entirely in solid state. □

Infrared astronomy

from Erick T. Young

SINCE the first detection of infrared (IR) radiation from a celestial source by Sir William Herschel[1] in 1800, the sensitivity of IR detectors has improved by many orders of magnitude. However, the true revolution in IR astronomy came in the 1960s with the advent of cooled semiconductor detectors. With these devices, the barrier to detecting ever fainter sources became the natural backgrounds from the atmosphere and telescope rather than the detector itself.

The astronomical IR spans the wavelength range from just below 1μm to 1,000μm. Although groundbased observations are limited to a few atmospheric windows of below 30μm and at 350 and 450μm, observations from balloons, aeroplanes, and spacecraft have now opened the entire range to study. Detection techniques vary from optical methods at the shorter wavelengths to quasi-radio methods in the submillimetre range. The choice of detector for a system depends on cost, required sensitivity, wavelength coverage, backgrounds, cooling capabilities, and time resolution. The requirements of IR astronomy are quite distinct from most applications. Most importantly, astronomical sources are exceedingly faint, and consequently sensitivity is the most important detector parameter. To this end the detectors are usually operated cooled with restricted fields of view to keep the background noise to a minimum.

Sensitivity limits for detectors

The sensitivity of an IR detector is the ultimately limited by noise both in the detector and in the associated electronics. Thermal detectors are subject to phonon noise associated with the finite temperature of the sensing element. Photon detectors can have noise due to the random generation

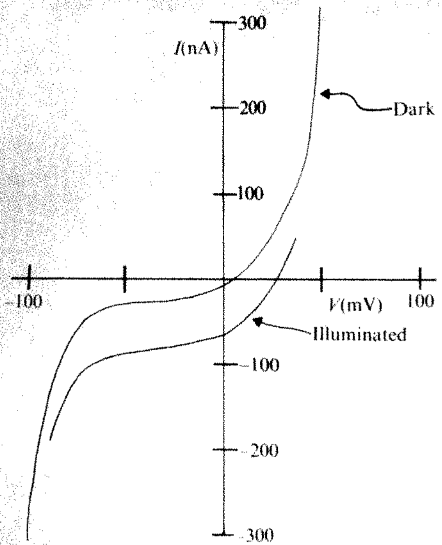

Fig.1 Current–voltage curves for an InSb photovoltaic detector operating at 77K. The two curves represent the case with background irradiation and the case without background irradiation.

and recombination of charge carriers, and all detectors suffer from Johnson noise due to the thermal motions of the charge carriers. Additionally, noise due to the fluctuations in the background photons seen by the detector can contribute significantly, and indeed are the most important source of noise with the current generation of IR detectors. The great promise of space experiments is the elimination of backgrounds due to the atmosphere and the telescope.

For an IR astronomer, the two most important parameters for detectors are the noise equivalent power (NEP) and the quantum efficiency η. The NEP gives the power incident on the detector which yields a unity signal-to-noise ratio in one second of integration time, and is therefore an indication of the required integration time for detecting an astronomical source at a given signal-to-noise ratio. The responsive quantum efficiency η is the ratio of electrons generated in the detector to incident photons. Of more use is the detective quantum efficiency η_D, first applied to IR detectors by Jones[2], $\eta_D = \mathrm{NEP}_{BL}^2/\mathrm{NEP}^2$, where NEP_{BL} is the noise equivalent power of a perfect detector, limited only by the background photon fluctuations, and NEP is the actual noise equivalent power for those conditions. η_D is therefore a measure of how closely a detector approaches the theoretical limit. The detective quantum efficiency is especially useful when the photon background fluctuations are the dominant noise source. In the absence of spurious noise, η_D has the same value as η.

Thermal detectors

Herschel's first IR detector was a thermal detector, a thermometer. Thermal detectors utilize the temperature dependence of some physical parameter for the detection of IR energy. The IR energy is converted into thermal energy of the lattice which is subsequently sensed. Currently, the most sensitive thermal detectors are liquid helium cooled germanium or silicon bolometers. With suitable doping, the impurity conductivity in silicon and germanium shows a very strong dependence on temperature[3]. By carefully mounting the semiconducting element so that the thermal conductance to the helium bath is small, minute amounts of IR energy will cause measurable changes in the conductivity of the device. Clearly the thermal fluctuations in the device can be a significant noise source, and it is highly advantageous to cool the detector. The gallium-doped germanium bolometer invented by Low[4] was the first device to approach the theoretical sensitivity limits at liquid helium tempertures. In the background conditions where the noise due to photon fluctuations is greater than the thermal fluctuation noise, the Ga-doped Ge bolometer is a virtually ideal detector with almost unity quantum efficiency. This detector is widely used in astronomical observations, and its application to photometry has been described in detail by Low and Rieke[5]. Typically these devices are cooled with superfluid helium to below 1.5 K, and NEPs as low as 7×10^{-15} W Hz$^{-1/2}$ have been realized. Because bolometers are thermal detectors, the wavelength limits to the response are set by the efficiency of coupling the radiative energy into the lattice. Using special absorbing materials, sensitive detectors into the millimetre wavelength range have been made. Current directions in research include developing bolometers for use at the much lower temperatures available with He III refrigerators and dilution refrigerators. NEPs better than 10^{-16} WHz$^{-1/2}$ appear to be realizable.

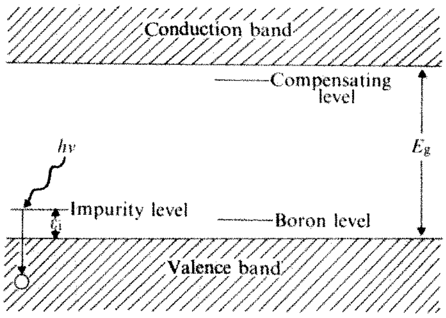

Fig.2 The band diagram of a typical extrinsic semiconductor with a shallow p-type dopant.

Photovoltaic detectors

At wavelengths below 5μm, the most commonly used IR detector is the InSb photodiode, which has generally replaced the older PbS detector in high performance applications. In groundbased observing conditions, the InSb detector offers excellent performance, with quantum efficiencies in excess of 60 per cent. In a photodiode, charge carriers are generated by photons in the depletion region and are swept out by the p–n junction voltage. Figure 1 shows the current–voltage curve for a high performance InSb photodiode. In the presence of photons, a current is generated across the junction that is proportional to the irradiance. These detectors became astronomically useful with the incorporation of the transimpedance amplifier (TIA)[6]. This amplifier acts as a current to voltage converter, and by maintaining a zero potential across the detector, noise contributions due to leakage currents are eliminated. The Johnson noise of the detector and noise in the associated electronics become the ultimate performance limitations. By cooling the detector to liquid helium temperatures and by using very low noise junction field effect transistors (J-FETs) in the amplifier, Rieke *et al.*[7] have attained background-limited performance at wavelengths as short as 2μm. NEPs of 7×10^{-17} W Hz$^{-1/2}$ have been reached, with operation limited to low frequencies.

Photoconductive detectors

When electron–hole pairs are created in a semiconductor by the absorption of photons, the conductivity of the material is temporarily increased until these charge carriers recombine. Application of a bias voltage allows the external detection of these carriers in an amplifier. Intrinsic photoconductivity can occur if the energy of the ionizing photon is greater than the bandgap of the material. As the intrinsic bandgaps of Si and Ge are 1.166 and 0.75 eV, respectively, these materials are not suitable for detection beyond 1.5 μm. Recent work has included the development of intrinsic materials such as HgCdTe with narrower bandgaps. To date, however, there has been little application of these materials in IR astronomy. Extrinsic photoconductivity utilizes energy levels due to impurities that lie within the forbidden gap. Figure 2 illustrates the energy bands of a typical semiconductor

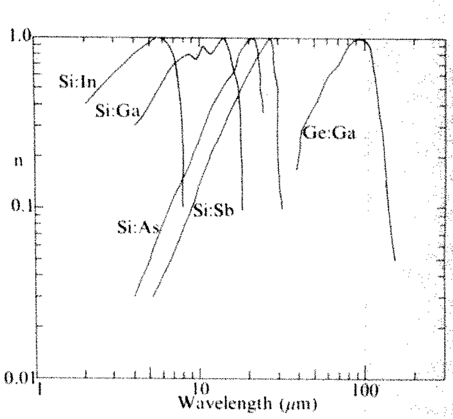

Fig.3 Normalized spectral response curves for some of the more important extrinsic detectors.

with a p-type dopant. In both silicon and germanium a wide variety of dopants with small ionization energies have been investigated[8], and spectral responses of some of the more important ones are illustrated in Fig. 3. By choosing a suitable dopant, the spectral response of the detector can be tailored to the specific requirements of the experiment. Since extrinsic photoconductors have a definite long wavelength cut-off, they are not subject to noise due to thermal fluctuations in the cooling bath. As long as the temperature is low enough to prevent thermally excited carriers, the only important noise source is the background.

Extrinsic photoconductors are currently the most sensitive detectors available for operation under reduced backgrounds. Consequently, they are the principal detectors in the current generation of low background space IR astronomy experiments, including the Infrared Astronomy Satellite (IRAS) and the Spacelab 2 Infrared Telescope[9] (SL-2 IRT). These space experiments will achieve greatly reduced background levels by cryogenically cooling the telescope. For example, the 12 μm band of IRAS will have $\sim 10^5$ times lower background power than with a comparable groundbased system. The better than 100-fold improvement in NEP translates to a 10^4-fold reduction in integration time.

Current extrinsic photoconductors have typical quantum efficiencies of 30 per cent, although values as high as 80 per cent have been reported[10]. Noise equivalent powers in the 10^{-17} to 10^{-16} W Hz$^{-1/2}$ range are attainable with TIA amplifiers and feedback resistors of $\sim 10^{10}\,\Omega$. These detector systems are adequate for the present generation of space experiments, where NEPs are limited by the thermal background from the interplanetary dust. Future IR astronomy experiments, such as the Shuttle Infrared Telescope Facility (SIRTF), possibly with diffraction-limited pixels and narrow bandwidths will require significant improvements in sensor technology to remain background-limited. In particular, amplification techniques will play a critical role in realizing the potential sensitivity.

A second exciting area of development is in large detector arrays. This technology has only recently become declassified, and much work remains to make arrays that are suitable for astronomical use. By the early 1990s, when SIRTF is hoped to be in operation, highly sensitive arrays of thousands of pixels should be available. ☐

X-ray astronomy

from Brian Taylor

THE very rapid advance of X-ray astronomy through the 1970s has produced demands for new detector developments with emphasis on large energy bandwidth (within the total range from tens of eV to tens of keV) spectral resolution, background rejection and position sensing capability if the momentum of the 1970s is to be maintained through the last two decades of the century. In particular position resolution is crucial given the advent of grazing-incidence imaging optics capable of providing arc second image quality at low energies, and coded aperture masks providing arc minute image quality at the upper end of the energy range.

Proportional counters

The state-of-the-art in mechanically collimated gas-filled proportional counters, the traditional work-horse for X-ray astronomy above 1.5 keV, is probably best exemplified by the eight, multiwire detectors of the Medium Energy Experiment[1] to be flown later this year on the EXOSAT mission[2]. These detectors give an effective area of 1,600 cm^2, are collimated to 45 arc min full-width half maximum (FWHM) and cover the energy range up to 50 keV. Use of five-sided anticoincidence and risetime rejection techniques provide background rejection efficiencies >99 per cent in the range 1–6 keV, with an energy resolution of 22 per cent FWHM at 6 keV.

These collimated detectors, however, have a sensitivity limit of 0.3 millicrabs (10^{-11} erg cm^{-2} s^{-1}) due to source confusion in the field of view. For the study of the spectral and temporal characteristics of the bright X-ray sources (from the UHURU or Ariel 5 catalogues) this is not a draw-back, but for the determination of the high-energy spectral tails of weak sources detected by imaging telescopes better sensitivity is required. Conversely, the upper energy limit of current grazing-incidence optics (the Einstein observatory[3], EXOSAT[2], ROSAT[4]) is typically a few keV and collimated proportional counters are unsuitable for the spectral mapping of extended objects (SNRs, clusters of galaxies) or resolution of confused regions.

This has lead to the development of coded aperture mask telescopes for use with large area proportional counters with two-dimensional position sensing capability. Instruments to be flown[5] on Spacelab 2 in 1984 and those considered for the potential ESA mission[6] X-80 in 1988 are examples. In the case of Spacelab 2, the detector has a window area of 32 cm square, is filled with Xe-CH$_4$ to 1.5 atm and with multilayer, multiwire arrays a position resolution of ≤ 1 mm is achieved, using delay line readout from orthogonal cathode wire planes. The anode wires provide the energy signal; an overall resolution of ~ 25 per cent being achieved at 6 keV. With a mask/detector separation of 3 m, mask elements 2.5 mm square and a field-of-view of about 5°, an angular resolution of ~ 3 arc min is achieved for a telescope covering the energy range from 2.5 to 25 keV — well suited to the study of temperature variations, iron line emission (near 7 keV) and non-thermal emission over clusters of galaxies.

Brian Taylor is at the European Space Research and Technology Centre, Noordwijk, the Netherlands.

Proportional counters with position sensing in essentially one dimension may be used in conjunction with Bragg Crystal Spectrometers. Such instruments were flown on the Solar Maximum Mission[7] to study the solar X-ray spectrum, and Spherical Crystal Spectrometers[8] are specified for the X-80 mission[6] for the study of oxygen, silicon, sulphur and iron spectral features in cosmic x-ray sources. Resolutions $E/\Delta E$ of $\sim 10^3$ can be achieved, determined largely by crystal choice and geometry, and counters with a position resolution of ≤ 1 mm over a length of some 25 cm, achievable with the resistive wire anode, charge division technique are required. The spherical crystals allow the mapping of extended sources and position resolution in the plane orthogonal to the plane of dispersion is also required. The long, narrow counters require five-sided anticoincidence for good background rejection, given the relatively small crystal area contributing to a given energy and the long observation times of 10^4–10^5 s.

Proportional counters required to be sensitive above 1.5 keV normally employ thin (~ 50 μm) Be foil entrance windows. For observations below 1.5 keV thin plastic windows must be used. Polypropylene has been widely used, for example the position sensitive proportional counter[9] on EXOSAT has a 0.8 μm, 28 mm diameter window supported with a fine wire grid and withstands a pressure differential of 1.2 atm. However, to probe the XUV waveband at energies below 100 eV thinner windows are required and Lexan windows with thicknesses of ≤ 0.3 μm have been developed[10].

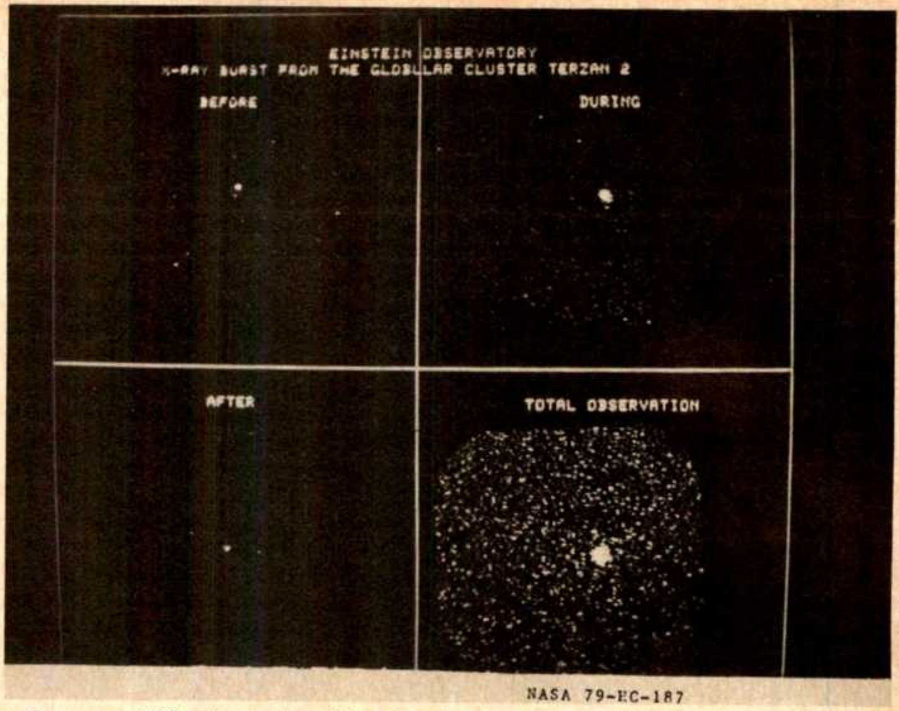
At these low energies imaging telescopes are used to provide a large X-ray collecting area, requiring relatively small detectors. However, the planned Advanced X-ray Astrophysics Facility (AXAF)[11] with its 10-m focal length and 1.2-m diameter outer mirror requires an imaging proportional counter with a window aperture of 18 cm diameter to cover its 1° field of view.

Numerous methods have been developed for determining the position of the photoelectric absorption of X rays in

0028-0836/82/340798-03$01.00

proportional counters in order to simplify the quantity of associated electronics. In the case of the Einstein IPC[12], the anode wire plane was sandwiched between two cathode planes, each comprising a resistive wire. A position resolution of 1.5 mm (FWHM) was achieved at 1.5 keV, corresponding to 1.5 arc min resolution through the optics. In the case of the EXOSAT PSD[9], the anode is a resistive disk with four orthogonal pick-offs at the circumference. Pre-launch calibration of the argon/20 per cent methane filled detector has shown an on-axis position resolution of 0.2 mm (FWHM) at 1.5 keV, with a gas gain of 6×10^4, equivalent to 40 arc s through the optics. The position resolution degrades off-axis with noticeable non-linearity, however, essentially distortion-free resistive anodes have been modelled[13] and are under development. The energy resolution in the EXOSAT PSD is ~35 per cent FWHM at 1.5 keV.

Position accuracy in a proportional counter is ultimately limited by lateral diffusion of the primary electron cloud in the absorption region, but noise and the configuration of the readout system play significant roles, however a figure of 100 μm FWHM at 1.1 keV has been achieved in a prototype XUV camera[14]. Such a detector performance coupled with a plate scale of the AXAF optics (50 μm/arc s) would yield a spectral mapping capability down to 2 arc s.



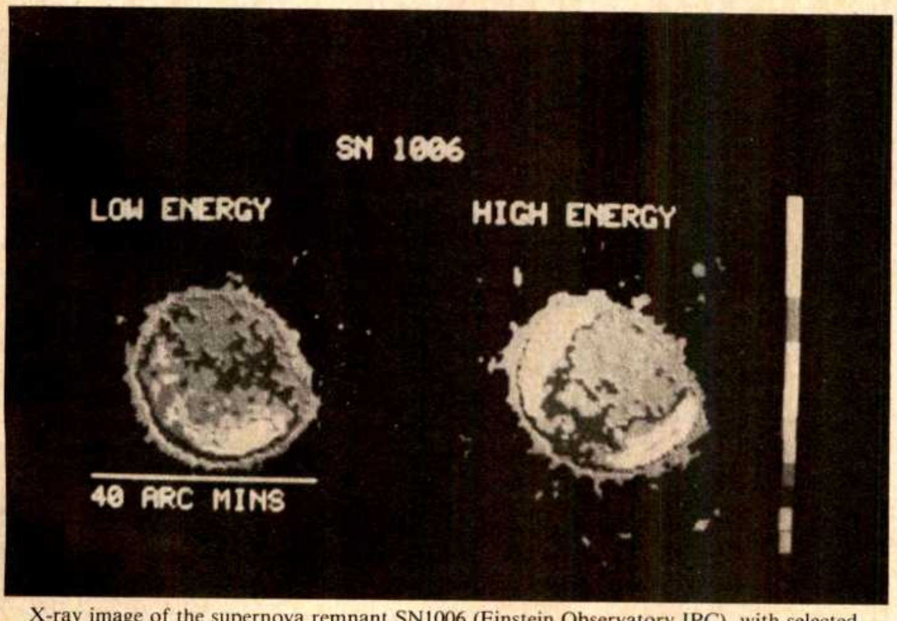
Sequence of 150-s observations of the X-ray burster in globular cluster Terzan 2 made with the Einstein Observatory IPC.

Gas scintillation proportional counters

The energy resolution of practical proportional counters is typically 20–25 per cent at 6 keV with a $E^{-0.5}$ energy dependence. The statistics of the photoabsorption process and electron multiplication at the anode wire contribute about equally to the resolution. The past few years has seen rapid development of the gas scintillation proportional counter (GSPC) as a practical detector for spectroscopy in X-ray astronomy. In this device, electron multiplication is avoided; the primary photoelectrons are accelerated by an electric field, typically 4 kV cm^{-1}, through pure xenon. Copious quantities of UV photons are released from molecules, and are de-exciting following collision of the accelerating electrons with the gas. These UV photons (1,600–1,900 Å) can be observed directly with UV sensitive photomultipliers.

An energy resolution of 7.5 per cent FWHM at 5.9 keV has been achieved with a small non-imaging detector[15] suitable for use with X-ray optics. The first flight of a 2×200 cm^2 effective area, spherical field GSPC took place in September 1980 with a 180 second rocket observation of the SNR Cas–A[16]. These detectors with 10 per cent FWHM were able to resolve the iron line emission feature at ~7 keV from the continuum in the raw data — amply demonstrating their potential as broad-band spectrometers. Generically similar detectors will be flown on EXOSAT[17], Spacelab 1 in 1983 (ref. 18) and the Japanese mission ASTRO-B[19] (1983). Background rejection within these first generation detectors relies exclusively on UV burst length discrimination, analogous to risetime discrimination in conventional proportional counters. On the basis of laboratory simulations and the results of a preliminary rocket flight, it is estimated that the EXOSAT GSPC will achieve 97 per cent background rejection efficiency in the range 2–10 keV (ref. 17).

A number of methods have been examined to provide position sensing in GSPCs, including the use of multiple photomultipliers[20,21], on the principle of the Anger camera[22], the coupling of a position sensitive photoionization detector (PID) using TMAE[23,24] (tetrakis [dimethylamine] ethylene with a photoionization potential of about 3.5 eV) and the coupling of a microchannel plate[25,26]. In the two former cases, the energy resolution performance of the GSPC is maintained while position resolutions of about 1 mm at 6 keV have been achieved. The first rocket flight of a GSPC/PID coupled to X-ray optics took place in 1981 yielding multicoloured images of the Cygnus loop from which the distribution of oxygen and temperatures across the shock-front could be determined[27]. Preliminary work with the coupled microchannel plate[26] and the use of coded TMAE as a liquid photocathode



X-ray image of the supernova remnant SN1006 (Einstein Observatory IPC), with selected energy range 0.01–0.3 keV (left) and 1.2–4.0 keV (right). (X-ray Astronomy Group, University of Leicester/Harvard-Smithsonian Center for Astrophysics.)

in conjunction with a very low pressure proportional counter[28], indicates that 300–500 μm position resolution at 6 keV should be achievable. This apparently modest position resolution, however, has to be seen in the context of the off-axis performance of the associated optics. Indeed, the half energy width of the AXAF optics could be as much as 1 arc min at the edge of the field of view[11].

The problem of background contamination becomes very severe for observations above 20 keV where up to now the 'Phoswich' detector has been employed largely in balloon-borne instrumentation. Such an instrument was successful in discovering the spectral feature in Her X-1 at ~ 60 keV ascribed to cyclotron emission[29]. Alternatives to the phoswich are being developed including position sensitive proportional counters[30] and GSPCs[31] for use with coded aperture masks. These detectors are filled up to 5 atm of xenon to provide adequate stopping power and incorporate 'fluorescent gating', in which an event qualifies only if the initial photoabsorption is detected in conjunction with the detectors of a xenon k_α or k_β fluorescent photon. With fluorescence gating applied to a non-imaging GSPC a background rejection of between 99.3 and 99.8 per cent was achieved over the energy range 35–100 keV coupled with an energy resolution of 2.7 per cent FWHM at 60 keV (ref. 32).

Recently the intriguing possibility of combining the spatial resolution of proportional counters with the energy resolution of GSPCs has been investigated[33]. By employing a low drift field in a parallel plate proportional counter, the electron cloud is allowed to diffuse so that each individual electron produces its own independent avalanche, the light pulse from which can be detected and counted. As in the GSPC, energy resolution is determined by the statistics of the initial photoabsorption event and 19 per cent FWHM at 1.5 keV has been measured. Diffusion-limited position resolution has been achieved with an image intensifier.

Microchannel plates

The lower energy limit for gas-filled detectors is, of course, determined by the entrance window. Measurements into the EUV and XUV bands may be made using imaging optics in conjunction with the microchannel plate[34], an array of small (10–50 μm) channel electron multipliers. An energetic photon incident at the entrance to a channel liberates an electron which initiates an avalanche through secondary emission from a continuous dynode on the inside of a channel. By putting two or more plates in series and employing different bias angles (the angle of the channel to the plate surface) high charge gain (up to 10^8) can be achieved without ion feedback. Because the quantum efficiency of a microchannel plate is low it is customary to coat the surface of the front plate. In the case of the EXOSAT channel multiplier array (CMA) focal plane detector[9], a magnesium fluoride coating is used which provides 30 per cent efficiency at 0.05 keV falling to 10 per cent at 1 keV, much smaller than the position sensitive proportional counter.

Several methods have been developed for MCPs including charge division readout of crossed wire grids as in the case of the Einstein observatory's high resolution imager[35], the resistive disc readout method for the EXOSAT CMA[9] and various configurations of multi-anode readout arrays[36]. The position resolutions achieved with MCPs are independent of energy and are largely governed by the readout method. It is anticipated that 15 μm will be achieved in the case of the AXAF HRI (≡0.3 arc s) while 50 μm (≡ 10 arc s) is achieved by the EXOSAT CMA (plate diameter 50 mm, channel diameter 50 μm). Due to its saturated mode of operation, the microchannel plate has no intrinsic energy resolution, and offers the ultimate in 'black and white' imaging.

Focal plane detectors developed to date have been planar in section. However, the focal surface of grazing-incidence X-ray optics tends to be far from planar as one goes off-axis. The microchannel plate, by virtue of its construction, may be formed to adopt the contour of the focal surface. Such a development may be pursued for the wide-field, XUV camera of the ROSAT mission[37].

The detectors described above, the proportional counter, the gas scintillator and the microchannel plate are by no means the only ones employed or with potential in X-ray astronomy. Charge coupled devices (CCDs) have been adapted for the X-ray waveband[38], and with sizes of up to 25 mm square may achieve 15 μm position resolution and energy resolution comparable to the GSPC. A number of solid state detectors without position sensing properties and available in relatively small areas but with energy resolutions of 'a few per cent' cover the range from 1–100 keV, and include cooled Si(Li), intrinsic germanium[39], and mercuric iodide detectors[40], and finally there is the coded mask/sodium iodide crystal/Anger camera combination studied for the SIGMA mission[41].

Operation of the proportional counter

To be detected in a proportional counter an X-ray photon must pass through the window and be absorbed in the gas inside the device. All the photon's energy is used in producing electron–ion pairs and the number of electrons liberated is proportional to the energy of the incident photon. The negatively charged electrons drift towards the anode wires under the influence of the electric field. Anode wires with radii of 10–30 μm are used so that the electric field near the wires is large enough to cause the electrons to ionize the gas molecules further. This process causes an avalanche of electrons, and the number of electrons reaching the wire may be several thousand times the number produced in the initial ionization. This multiplication factor is independant of the original number of electrons and so the size of the pulse sensed by electronics connected to the anode wire is "proportional" to the energy of the incident photon. However, because of statistical variations in the initial ionization and avalanche, the response of a counter to X rays of a single energy is broadened, resulting in a finite energy resolution.

With a more complicated internal configuration and sophisticated electronics the location of the avalanche within the counter may be determined. By placing such a counter at the focus of an X-ray telescope it is therefore possible to obtain X-ray images. Unfortunately proportional counters are prone to many unwanted effects that may greatly degrade their performance. For this reason the choice of gas filling (usually based on an inert gas such as argon or xenon), and physical characteristics, are quite critical.

REVIEW ARTICLE

The inflationary Universe—birth, death and transfiguration

John D. Barrow

Michael S. Turner
Astronomy and Astrophysics Center, University of Chicago, Chicago, Illinois 60637, USA

A number of exciting new experimental and theoretical developments have recently made a dramatic impact on the interdisciplinary study of cosmology and elementary particle physics. The Nuffield Foundation recently sponsored a 3-week workshop in Cambridge where theoreticians worked intensively on some of these problems. A brief review is given of the progress that was made as a result of the workshop, something of the background to the problems tackled, and the likely course of future developments.

FOR the past four years the Nuffield Foundation has sponsored a workshop devoted to related aspects of gravitation and particle physics. Last month's workshop, organized by Stephen Hawking and Gary Gibbons at Cambridge, focused on the theory of the very early Universe (events occurring during the first second of its expansion history). The spectrum of participants was international with five particle physicists and cosmologists from the Soviet Union and the remaining 25 from Europe and the United States. It transpired that the conference organizers could not have chosen a better topic for detailed collective scrutiny. During the past six months there have been a number of dramatic theoretical and experimental developments on the interface between particle physics and cosmology that threaten to revolutionize our thinking about the large-scale structure of the Universe and link together our studies of the very large and the very small more closely than ever before. Early this year Linde[1], in the Soviet Union, Albrecht and Steinhardt[2] in the United States and Hawking and Moss[3] in the UK proposed a model of the very early Universe (dubbed the 'new inflationary Universe') in which, through a phase transition soon after the big bang ($t \sim 10^{-35}$ s), a number of longstanding and outstanding cosmological problems seem to be simultaneously and naturally resolved. Then, last March, Cabrera of Stanford University, reported[4] experimental evidence consistent with the detection of a single magnetic monopole. If, and this has not yet been confirmed, he has indeed seen the magnetic monopole predicted to exist by new grand unified gauge theories[5] of elementary particle interactions at high energy (GUTs), then his result could provide a most dramatic and direct witness to the fact that the Universe was once at least as hot as 10^{27}K. Just to make things more interesting, it appears that Cabrera's monopole is inconsistent with the existence of the Galaxy's magnetic field; if these monopoles exist they should have discharged large-scale cosmic magnetic fields long ago[6–8]. In addition, monopoles would themselves provide microscopic 'laboratories' for the study of particle physics down at length scales $\sim 10^{-25}$ cm and a confirmation of the overall philosophy of grand unification. During the past year there has also emerged a growing interest in particle physics theories that not only unify the description of the three basic interactions (strong, weak and electromagnetic) but which are also supersymmetric (supersymmetry is a symmetry which relates the particles of integer spin (bosons) which do not obey the exclusion principle to those of half-integral spin (fermions) which do). The cosmological implications of such schemes are substantial but, so far, only partially explored. Almost all the work done and talks presented at the workshop involved aspects of one or more of these three exciting developments.

Symmetry breaking and unification

The study of the very early history of the Universe amalgamates two seemingly unrelated disciplines: cosmology and elementary particles. So far, gauge theories have been very successful in describing and predicting the behaviour of fundamental particle interactions: the strong (or colour) force controlling quarks is successfully described by an unbroken SU(3) symmetric gauge theory; the weak and electromagnetic forces are conjoined in an SU(2) × U(1) symmetric gauge theory (the Weinberg–Salam–Glashow model) which is spontaneously broken at an energy of about 10^3 GeV. The point of spontaneous symmetry breaking (SSB) is that although the laws of physics may be intrinsically symmetrical, that symmetry is not manifest below a certain temperature or energy level because the lowest energy state of the system (the vacuum, as it is called) is a particular solution of the equations that does not possess their symmetry. In spontaneously broken gauge theories the properties of the vacuum state are of vital importance and are described by the vacuum expectation value of a scalar field—the Higgs field[9]. The appearance of a non-zero vacuum expectation value signals SSB.

The mathematical elegance and experimental vindication of the SU(3) and SU(2) × U(1) models has led to their incorporation within proposals for the grand unification of the strong and electro-weak interactions. In such models a spontaneous breakdown of complete symmetry between the strength and properties of these three interactions occurs when the temperature falls to 10^{28} K, an energy of about 10^{15} GeV. Clearly, if we are going to check such ideas by experiment we need energies of $\sim 10^{15}$ GeV to probe the symmetric vacuum. Such energies are never likely to be attained by terrestrial accelerators; so far only energies up to 1,000 GeV have been attained. There are very few low-energy consequences of GUTs that we can test but there are two generic predictions which are both extraordinary and accessible to current technology. It is predicted that the proton will be unstable with a lifetime $\sim 10^{31\pm 2}$ yr and that stable, magnetic monopoles exist with a mass $\sim 10^{16}$ GeV (that is, about 10^{-8} g). At present about a dozen experiments are either operational or soon to be so and tuned to search for the characteristic proton decay events[10]. The Indian–Japanese collaboration, which is examining the stability of protons within about 140 tonnes of iron buried

0028-0836/82/340801—05$01.00

below the Earth's surface in the Kolar Gold Fields, has already reported six candidate events for proton decay[11,12] within the last two years, corresponding to a lifetime of about 10^{31} yr. Also, in the last month another claim to detect proton decay has been made by the CERN group experimenting inside Mt Blanc. They have detected a single candidate event.

The early Universe was not subject to the type of budgetary and technological limitations that we encounter today. According to the hot big bang model, temperatures corresponding to average particle energies as large as 10^{19} GeV should have been reached in the early Universe. So, it is clear that the early Universe provides an ideal 'theoretical laboratory' for the study of grand unification. By way of a corollary, grand unification can have remarkable consequences for the expansion and evolution of the Universe. Already, a key cosmological contribution has been made[13-19]: the same interactions that mediate proton decay today allow an initial universal state which is symmetric between matter and antimatter to evolve into one with an excess of matter which translates, after the antimatter annihilates, into one like our own that contains, on average, about 10^{10} photons for every nucleon of matter. Grand unified theories are able to explain both the origin of matter (rather than just radiation), the non-existence of antimatter in space, as well as the relative abundance of photons and nucleons—previously all unsolved puzzles.

Birth of the inflationary Universe

In 1981 Guth[20] proposed a new picture for the early stages of the hot big bang model which provided a 'natural' explanation for a collection of cosmological conundrums. The picture was christened the 'inflationary Universe'. Guth pointed out that if the Universe got 'caught' in the symmetric vacuum early on, when the temperature was below that at which the asymmetric vacuum was energetically more favourable (a lower energy state), then because of the large energy density associated with this state, the Universe would expand exponentially and 'supercool', erasing its previous history. (Such an exponential expansion was first discussed by de Sitter[21] for other, mathematical reasons.) When the transition to the asymmetric vacuum state does occur, an enormous 'latent' heat (the energy difference between the two vacuum states) is released, reheating the Universe so its subsequent evolution is that of the standard hot big bang model. As a result of this 'de Sitter' phase in its early evolution, the portion of the Universe that is observable today should be extremely uniform and expanding at a critical rate (that is, the ratio of the potential to the kinetic energy in the Universe, Ω, should be equal to 1). Without this de Sitter phase, in which the size of the Universe is greatly 'inflated' over what one would expect early on, the present uniformity of the Universe and the proximity of its expansion rate to the critical value remain a mystery. Our only 'explanation' would be to appeal to very special initial conditions which does not, of course, explain anything. Guth's inflationary Universe dispensed with the need for special initial conditions. Furthermore, it solved an embarrassing problem: the over-production of magnetic monopoles during the SSB phase transition of the GUT. In the earlier, more conventional models of the GUT phase transition so many monopoles were predicted to arise that they would contribute a density more than 10^{12} times larger than the maximum allowed by the observed deceleration of the Universe[22-23]. In the inflationary model, the period of accelerating expansion during the de Sitter phase dilutes the monopole density to a small and observationally permissible level. Unfortunately, as Guth and others realized, his original inflationary scenario possesses one fatal flaw: models in which the Universe gets trapped in the symmetric phase early on, end up with it caught there forever! If we are certain of nothing else, we can be sure that we do not live in a symmetric GUT vacuum—if we did then our protons would all decay in seconds.

Death and transfiguration

Six months ago Linde[1], Albrecht and Steinhardt[2] and Hawking and Moss[3] analysed a different class of GUTs (those which undergo SSB of a characteristic type first studied by Coleman and E. Weinberg[24]), and discovered that in these models the advantageous features of Guth's inflationary model could be retained whilst the difficulty of escaping from the symmetric vacuum of the de Sitter phase could be overcome. In their second generation model—the so-called 'new inflationary model'—the Universe never gets trapped in the symmetric vacuum state but instead simply takes a very long time to evolve from the symmetric to the asymmetric vacuum state, and while the Universe is evolving from the symmetric to the asymmetric state it expands exponentially due to the large energy density of the symmetric vacuum. In this new model the evolution to the true vacuum takes long enough for sufficient exponential expansion to occur to explain the uniformity, expansion rate and monopole-free composition of the present-day Universe.

Guth, Hawking, Linde, Moss and Steinhardt were all in attendance at the Nuffield Workshop and because of its potential explanatory power and topicality the 'new inflationary Universe' was the focal point of considerable critical scrutiny during the 3-week period. One exciting issue was actively investigated by four different research groups throughout the workshop (J. Bardeen, P. Steinhardt and M. Turner; A. Starobinskii; S. W. Hawking; A. Guth). They sought to calculate the form of the matter inhomogeneities that are spontaneously generated during the de Sitter phase and decide whether they explain the pattern of irregularity we see throughout the Universe today in the form of galaxies and clusters. In the new inflationary model the Universe emerges from the de Sitter phase too smooth to allow the subsequent development of objects like stars and galaxies. The four groups all considered the form of the density inhomogeneities that arise from spatial fluctuations in the scalar field that leads to the SSB of the GUT. Although by the second week of the workshop there was radical disagreement amongst the groups as to the magnitude of the final fluctuations—but complete agreement, both amongst themselves and with observation, as to the relative change in the magnitude from one length scale of the Universe to the next—by the end they were in agreement, and by very different methods had arrived at essentially the same result (testimony to the stimulating atmosphere of the programme). The result was bad news for the 'new inflationary Universe'—or at least for the simplest version studied so far: the resulting inhomogeneities were found to be far too big to lead to galaxies, rather everything would evolve to form superdense objects or black holes—not the type of Universe we live in. Linde[25] also reported that fluctuations in the scalar field might actually prevent the phase transition from occurring slowly enough to resolve the cosmological puzzles in the first place; again in the simplest model. The simplest model of new inflation was officially pronounced dead, just 6 months old.

However, the work done on this problem before and during the Cambridge meeting has been crucial. It has spelt out exactly what type of GUT is needed to have both a de Sitter phase and a resulting inhomogeneity spectrum in accord with present astronomical observations. By the end of the workshop Bardeen, Steinhardt and Turner had proposed a candidate supersymmetric model which satisfied these necessary criteria. At the moment, the basic idea of 'new inflation' still seems to possess attractive features. If an even 'newer' inflationary model can be constructed which is both a phenomenologically acceptable particle physics theory and without cosmological defect, then the marriage of GUTs and cosmology will have achieved a remarkable consummation. At a stroke a cluster of the most fundamental cosmological problems could be solved.

Lest anyone get carried away on the wave of euphoria surrounding inflation, the final summary talk of the workshop by Wilczek drew together several critical assessments that had been made earlier. The inflationary models 'predict' that today the density parameter Ω should be equal to unity to a very high degree of precision; certainly no measurements we can now make should be able to measure the difference from unity. But, as Rees and Efstathiou reminded the particle theorists, the best astronomical determinations of Ω all consistently suggest a much smaller value, less than 0.2. A possible way out of this conflict is if the Universe is dominated ($\Omega \sim 1$) by non-baryonic matter which coalesces only on very large scales so that the observations made to date would not have been sensitive to the presence of this matter. Candidates for the closure density of dark matter include massive neutrinos, or one of the zoo of new particles postulated in supersymmetric gauge theories. Earlier in the week, Sciama[50] had stressed the attractiveness of photinos (supersymmetric fermionic partners of the photon) for providing the closure density and dark matter in the galaxy.

In the inflationary models the only relic monopoles which are present in the Universe today should be those produced shortly after the de Sitter phase by particle collisions[26,51] and their abundance should be very small. This was one of the original virtues of the inflationary scenario. However, if Cabrera's observation of a monopole is correct and is representative of the typical flux in the Milky Way, then his observation appears to be in conflict with the inflationary model. Finally, Wilczek stressed that underlying the inflationary model is the value of the energy density associated with the vacuum. At present, particle physics calculations do not set the absolute scale of this energy density, only the difference in energy between the symmetric and asymmetric vacua. Our observations of the total mass density of the Universe show that, compared to this energy difference, the energy density of our asymmetric vacuum must be at least a factor 0 (10^{20}) smaller. If we define the energy density of the symmetric vacuum as the zero level then we can calculate the energy density of the asymmetric vacuum. Unfortunately, at present, we have no idea why the energy density of our vacuum should turn out to be so infinitesimal. An understanding of this 'fact' or a recasting of the problem ought to reveal a deep connection between particle physics and gravity—and that may even spring a few surprises of its own.

Monopoles

Ever since 1931, when Dirac[27] showed that the existence of magnetic monopoles requires the quantization of both electric and magnetic charge, physicists have continually searched for (and occassionally even claimed to have found) magnetic monopoles. The advent of GUTs has revived interest in monopole-hunting. These theories always predict the existence of magnetic monopoles with a mass close to the energy scale of grand unification[28,29]. Last March, Cabrera[4] reported experimental evidence consistent with the detection of a single monopole. He utilizes a SQUID to monitor the current in a superconducting loop surrounded by a superconducting magnetic shield which in turn enables him to detect magnetic charges. If a magnetic charge passes through the loop it induces a persistent current whose amplitude is proportional to the magnetic charge. Unfortunately, sources of noise and systematic error might also induce such flux jumps and only time will tell whether this event is a real monopole. Cabrera's event has the Dirac charge value and corresponds to a 'flux' (one event in 150 days) of about $10^{-9}\,\mathrm{cm}^{-2}\,\mathrm{sr}^{-1}\,\mathrm{s}^{-1}$. In his review of the 'monopole problem' at the workshop Preskill described several new types of experiment planned by Cabrera and others which will both increase the effective capture area of the detector and use independent cross-checks to eliminate many possible sources of systematic error. Within a year his 'observed flux' should be confirmed or disproved. Unfortunately, Cabrera's experiment (as well as all the other monopole searches planned or in operation) can give no indication of the monopole mass. To measure that, its path through a very strong magnetic field would have to be tracked very accurately as superheavy monopoles are not easily deflected from straight lines.

As mentioned above, if this measurement is really of a magnetic monopole, its implications for cosmology and particle physics are extremely significant. Astrophysically, Cabrera's flux contradicts everything we know about the magnetic field of the Galaxy. Monopoles should move along magnetic field lines in the Galaxy, thereby gaining kinetic energy at the expense of the magnetic field energy. A monopole flux in the Galaxy exceeding $\sim 10^{-15}\,\mathrm{cm}^{-2}\,\mathrm{sr}^{-1}\,\mathrm{s}^{-1}$ (the so-called Parker[6-8] limit) would rapidly dissipate the entire galactic field on a time scale shorter than that on which it can be regenerated. Our observation of an interstellar field of a few microgauss means that Cabrera's flux cannot be indicative of the average galactic flux of monopoles. However, we clearly occupy a special position in the Galaxy[30]—very close to a star, the Sun. Wilczek and Preskill discussed the possibility that the average galactic flux is close to, or less than $\sim 10^{-15}\,\mathrm{cm}^{-2}\,\mathrm{sr}^{-1}\,\mathrm{s}^{-1}$ but the Sun captures a cloud of monopoles by gravitational attraction leading to a flux in the solar neighbourhood that exceeds the average value in the Galaxy by a factor that can be as large as the required value $\sim 10^{6}$.

The GUT monopole is a remarkably interesting object. It has a size close to that of other elementary particles but an enormous mass (by microscopic standards), close to that of a bacterium. This means monopoles are not easily stopped and they pass through the Earth without significant energy loss. The monopole interior and outlying periphery has an onion-skin structure. Very close to its centre the vacuum is the GUT symmetric vacuum, a little farther out it is the $SU(2) \times U(1)$ symmetric vacuum. A single monopole thus provides a potential laboratory for studying grand unification and SSB.

The rich internal structure of a monopole also means that physics close by is likely to be extremely interesting. Callan[31], Rubakov[32] and Wilczek[33] have all pointed out that monopoles should catalyse proton decay, for example, via $M + p \rightarrow M + e^{+} + X$ where X = other particle debris. Callan and Rubakov argued that the cross-section for these exchanges should be large, comparable to a typical hadronic cross-section ($\sim m_{\pi}^{-2}$). At the workshop Ellis[34] discussed an interesting terrestrial consequence of this: terrestrial protons exposed to a Cabrera monopole flux should, on the average, decay with a lifetime of $\sim 10^{28}$ yr. The present experimental evidence on proton places a limit on the proton lifetime, $\geqslant 3 \times 10^{30}$ yr, which rules this out. Preskill and Wilczek also pointed out that if the Callan–Rubakov estimate is correct then neutron stars would present an even more serious problem[35,36]. Neutron stars are very effective at capturing monopoles because of their high densities and gravitational field strengths. Once captured by the neutron star, the monopoles would begin catalysing neutron decay and, unless the monopole flux were less than 10^{-8} of Parker's bound (and 10^{16} times smaller than Cabrera's flux) neutron stars would emit far more X-ray and UV radiation than is observed. This leads to an unfortunate conclusion: if the cross-section for this interesting process is large, then the flux of monoples must be undetectably small.

However, Preskill and Wilczek sharply disagree with the Callan–Rubakov estimates of the cross-section for monopole catalysis of proton decay. They presented convincing arguments that the cross-section should be a weak interaction cross-section, or something even smaller, and this means it is at least 10^{10} smaller than the estimates of Callan and Rubakov. The problem of computing this catalysis cross-section is a formidable mathematical task and its value must still be regarded as uncertain.

Monopoles are not the only esoteric structures that can emerge from the peculiar vacuum physics of GUTs. At the workshop Shafi and Vilenkin discussed the possibility that strings or walls of vacuum energy could be produced at phase transitions where SSB occurs and these structures could persist until the present[37-40]. (Strings, walls and monopoles are all topological structures associated with the direction in group space that the Higgs field responsible for SSB has in different regions of our physical space.) Unlike in the case of monopole production at the moment of SSB in GUTs there seems to be no problem in creating too many strings and walls. The possibility of wall structures appears to be ruled out by observation—the presence of one stretching across the observable Universe would create an anisotropy in the temperature distribution of the microwave background radiation much larger than is observed. Vilenkin argued that, by way of contrast, vacuum strings could have a very significant astrophysical role. A network of string-like structures might provide a natural explanation for the level of inhomogeneity necessary to create galaxies later on[52]. Also, the oscillation of strings that close upon themselves to form isolated loops could give rise to an observable flux of gravitational radiation. However, this conclusion seems to rest on an axiom of faith that the strings would dissipate their energy into gravitational waves rather than photons which would leave no trace if they were produced early enough in the history of the Universe. Finally, to give some feel for what a string is like, a vacuum string arising from the era of GUT would have a thickness of the order of the Compton wavelength of the Higgs scalars involved in the SSB ($\sim 10^{-27}$ cm) and a calculable mass per unit length such that a piece of vacuum string stretching 15 thousand million light years across the observable Universe would have a mass roughly equal to that of 10 million galaxies.

Supersymmetry

One of the most important unsolved problems of modern particle physics is the gauge heirarchy problem—the difficulty of constructing a theory that explains why SSB takes place on such widely separated energy scales, 10^3 GeV and 10^{15} GeV. One possible resolution which has been the focus of growing attention[41–44] is super-symmetric grand unification (SUSY). Supersymmetry requires the existence of a bosonic partner of identical mass for every known fermion and vice versa. As no such supersymmetric partners of the known quarks and leptons exist (they would have been seen), supersymmetry, like some of the gauge symmetries, must be a broken symmetry. Supersymmetry has its own intrinsic appeal for other reasons[26]: it is the only way to unify the description of particles with different spin statistics, and it is the only way to unify internal symmetries (that is, those associated with the gauge symmetries of particle physics) with the space-time symmetries of general relativity (and hence is a very good candidate for unifying gravity with the strong and electro-weak interactions). However, there appear to be a number of substantial cosmological hurdles in the path of supersymmetric GUTs. Ellis, Lazarides and Nanopoulos each discussed some of these difficulties and possible ways of overcoming them. In particular it seems to be difficult to arrange things so that our asymmetric vacuum is the lowest vacuum energy state, and even if this can be achieved, it is hard to guarantee that the Universe evolves into the asymmetric vacuum rather than the cul-de-sac of the symmetric state where it remains stuck forever. Furthermore, it is difficult to construct a grand unified SUSY model which generates the observed matter–antimatter asymmetry and specific entropy of the Universe because it is harder to get baryon non-conserving interactions out of equilibrium than in conventional GUTs. At present it is premature to accept or reject such models and SUSY remains an attractive idea for resolving the heirarchy problem and a possible pathway to a theory of quantum gravity since gravity can be incorporated when the supersymmetry is made a local rather than a global (as in SUSY GUTs) symmetry.

Gravitation

General relativity is a gauge theory although not a quantum theory but it has long been realized that quantum corrections to the classical equations of Einstein must arise at energies exceeding about 10^{19} GeV, or, in the cosmological problem at times, $t \lesssim 10^{-43}$ s. These energies exceed even those required for grand unification and as yet there has appeared no way of testing theories of quantum gravity by experiment. A full-blooded quantum theory of the gravitational field, including therefore the space–time geometry, is not yet on offer. A more modest programme is being undertaken to determine how quantum fields behave in a classical gravitational field[45,46] and progress in this area was reviewed in Cambridge by Hartle and Hu. As yet there is no 'standard' model in this work. To illustrate this, consider the problem of how quantum effects determine the evolution of the Universe before 10^{-43} s. In some models the singularity of infinite density at zero time remains, whilst in other, equally likely variants, it is removed and the Universe bounces; the pre-bounce state also admits a variety of possibilities and it is still premature to try and draw definite conclusions as to the first instants of the big bang.

Two topics of interest to quantum gravity pundits were presented at the workshop: the first, by Starobinskii[47], who showed how an inflationary phase of de Sitter expansion may have occurred at the Planck time, 10^{-43} s, rather than later at the time of grand unification. Of particular interest is the possibility that such an event might leave an observable imprint on the gravitational wave background in the Universe which we could one day detect. The other contribution by Novikov described how, close to the Planck epoch, the propagation of sound waves in the Universe may be described by a wave equation that is not conformally invariant. These sound waves can be amplified by interacting with the curvature potential created by the expansion of the Universe and give rise to a characteristic spectrum of irregularities today[48,49].

The fundamental cosmological puzzles—the expansion rate of the Universe, its isotropy, homogeneity, irregularity spectrum and specific entropy—all involve the very special *initial* conditions we seem to require at 10^{-43} s. It may be that these puzzles will be explained by events occurring at the Planck epoch rather than through inflation at the time of grand unification, and that a resolution of our quandaries must await the much sought synthesis of relativity and quantum field theories. What we have investigated so far is by no means the end but hopefully it is the beginning of a true story with a happy ending.

The consensus among the participants was that they had attended a significant and productive scientific gathering in which real scientific progress was made during its extent. The organizers and sponsors were largely responsible for this; without their efforts it would not have been possible for all the protagonists in the early Universe debate to meet and exchange ideas. The simplest 'new inflationary' Universe appears to be defunct; however, perhaps reports of its death 'have been greatly exaggerated' and a newer version will emerge to fulfil the criteria for success that were drawn up at the workshop. Important experimental and theoretical issues regarding the existence and behaviour of magnetic monopoles have emerged. Supersymmetric grand unification has been subject to significant scrutiny and has been pushed near the brink of viability. Many of these exciting developments have emerged only during the last year and no one has any doubt that this trend is going to continue for some considerable time.

We thank all the participants in the Nuffield Workshop for conversations and the Nuffield Foundation for support.

ARTICLES

Phase transitions and dynamics of the Universe

Vahé Petrosian

Institute for Plasma Research and Department of Applied Physics, Stanford University, Stanford, California 94305, USA

The restoration of symmetry at grand unification in a closed contracting Robertson–Walker universe could slow down and halt the contraction, causing the universe to bounce and avoid the singular state or the big crunch. During subsequent expansion the symmetry is broken and the universe reverts back to its present (normal) state. A scenario is presented whereby the present entropy of the substance (resulting in $\sim 10^{90}$ photons) is created through a series of such bounces along with three possible initial states. The monopole, horizon and flatness difficulties faced in ordinary big bang models are also solved by the model presented.

DESPITE astronomical discoveries during the past half century, the basic and simple nineteenth century questions, such as age and size of the Universe, remain essentially unanswered. The open and flat models of the Robertson–Walker metric are unsatisfactory because of the need to extrapolate the local observations to infinity. The closed and finite (and therefore more appealing) model suffers from the fact that it will eventually collapse into a singular state. Although introduction of a positive and constant cosmological term will solve the collapse problem, there still remains (for all big bang models) the difficulty of dealing with the singular initial state which took place in a finite past. There is always the hope that quantum gravity will solve this problem around the Planck era (energies $\sim 10^{19}$ GeV). In this article, recent developments in microphysics are used to propose a possible scenario for the bounce of a collapsing closed universe occurring at the grand unification era (energies $\sim 10^{15}$ GeV) before it reaches the Planck era.

One of the intriguing results from the unification at high energies of various forces of nature is that as the expanding universe (or any system in thermal equilibrium) cools below some critical temperature the symmetry is spontaneously broken, the universe undergoes a first-order phase transition which induces a change in the vacuum energy density[1]. Without considering the details of the microphysics, most of which is still open to speculation, I take a phenomenological approach and investigate the modification of the dynamics of a Robertson–Walker universe due to a transition from a higher (or false) to lower (or true) vacuum state and vice versa.

Outline of the problem

It is well known[2,3] that a non-zero vacuum energy density E_v corresponds to a non-zero value of the cosmological constant $\Lambda = 8\pi G E_v/c^2$, whose effects on the dynamics of the universe can be taken into account by redefinition of energy density and pressure as $E = E_s + E_v$, $P = P_s + P_v = P_s - E_v$, where E_s and P_s are the energy density and pressure of substance (matter and radiation[4,5]). As proposed by Einstein, the cosmological term, or E_v, cannot be diverged. Variation in this term can be generated by a scalar field[6]. The possibility of a phase transition allows variation in the value of Λ or E_v. Then the conservation equations must be generalized to allow for the conversion of vacuum energy density into energy density of substance and vice versa[7]: $a(\mathrm{d}E_s + \mathrm{d}E_v) = -3(E_s + P_s)\mathrm{d}a$. Here a is the expansion parameter. We are interested in the early phase of the universe where E_s is dominated by radiation and relativistic pairs in thermal equilibrium. Then $P_s = E_s/3$ and $E_s = (1+g)E_r$ where g (which can vary across a phase transition) is the contribution of fermion and boson pairs, and $E_r \propto T^4$ is the energy density of radiation at temperature T.

In what follows, modified Planck units $8\pi G/3 = \hbar = c = 1$ are used. Normally $S^{4/3}E_s$ is a constant and in thermal equilibrium, $S = (1+g)^{3/4}0.15N_r$ (N_r is the total number of photons in the closed universe of volume $2\pi^2 a^3$), which is proportional to the total number of free particles in the universe, is also a constant or varies due to the changes in g. During a phase transition, however, because of presence of the $\mathrm{d}E_v$ term in the above conservation equation, this is no longer true and the differential equations governing the expansion parameter can be written as (overdot stands for derivative with respect to time t)

$$\begin{aligned}(\dot{a}a)^2 &= E_v a^4 - a^2 + S^{4/3} \\ \ddot{a}a^3 &= E_v a^4 - S^{4/3}\end{aligned} \qquad (1a)$$

from which (or from the conservation equations directly) we obtain a modified form for the conservation laws.

$$\mathrm{d}S^{4/3}/\mathrm{d}t = -a^4\dot{E}_v \qquad (1b)$$

0028-0836/82/340805—04$01.00

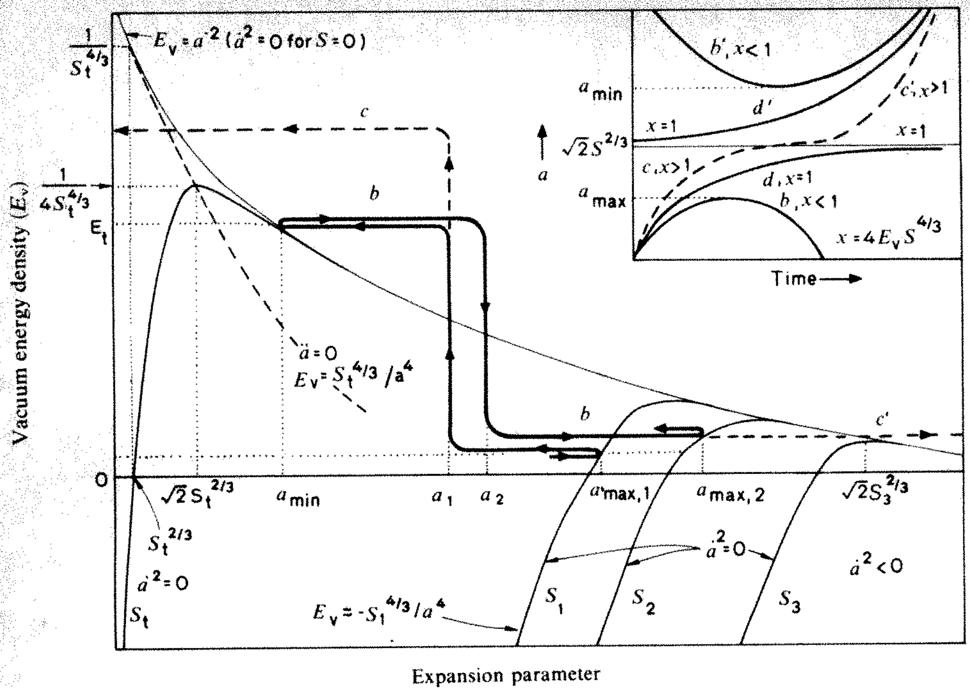

Fig. 1 Schematic variation of vacuum energy density with the expansion parameter for a radiation-dominated universe. Above the thin dashed line marked $\ddot a = 0$ expansion is accelerated. Thin solid lines represent $\dot a^2 = 0$. For higher values of S these curves shift to the right and decrease in amplitude. For each S the region below this line ($\dot a^2 < 0$) is forbidden. The heavy solid and dashed lines show various paths of evolution with phase transitions at a_1 during the contraction and at a_2 during the expansion. The letters b, b', c, c' refer to the type of models described in the inset, where $x = 1$ corresponds to the Einstein static model.

Conventional models

Let us first review briefly the relevant aspects of the usual closed models[8] with $\dot E_v = 0$. Figure 1 shows curves of E_v against a for $\ddot a = 0$ (thin dashed lines) and $\dot a = 0$ (thin solid lines) at various values of S. The schematic variation of the expansion parameter a with time is shown in the inset of Fig. 1 for $x = 4S^{4/3}E_v > 1$ (models c, c'), $0 < x < 1$ (models b, b') and $x < 1$ (models d, d' and the Einstein static model). Of particular interest are the models with $0 < x < 1$ where the universe has either a maximum or a minimum size:

$$\begin{aligned} a_{\max} &= (2E_v)^{-1}[1-(1-x)^{1/2}] \\ a_{\min} &= (2E_v)^{-1}[1+(1-x)^{1/2}] \end{aligned} \tag{2}$$

For a constant E_v (therefore a constant S) the expansion or contraction of the universe follows a horizontal path until it reaches an $\dot a = 0$ curve (for the appropriate value of S) after which it reverses its motion contracting to a singularity or expanding to infinity (see models b and b' in the inset to Fig. 1). For large values of $E_v (x > 1)$ $\dot a$ never becomes zero and expansion continues forever.

Models with variable cosmological terms

If $\dot E_v \neq 0$, then the evolution of the universe will not be constrained along a horizontal line and at different stages will be limited by the $\dot a = 0$ curves of different values of S. It is therefore clear that arbitrary variation of E_v (and the corresponding variation in S) could result in a complicated evolution of the universe. Here we examine the simple variation of E_v from a small value to a large value comparable with the energy density of substance at the time of the variation.

Let us assume that the universe is closed, $S = S_1$, and that the vacuum energy density $E_v = E_1 < (4S_1)^{-4/3}$ ($\sim 10^{-120}$ for our present universe[5,9]). The universe then will evolve as in model b (see inset to Fig. 1), expanding to a maximum size, $a_{\max}$, after which it begins to collapse, as shown by the heavy line directed to the left in Fig. 1. (Our present universe is matter dominated; therefore, it will reach a maximum value if $E_1 < M^{-2} \sim 10^{-122}$ where $M = 2\pi^2 a^3 \rho$ is the total mass of the non-relativistic particles in the universe. However, when it collapses to a size smaller than its present size by a factor of -10^3, it will become a radiation dominated universe and revert back to our idealized model. Note that the present observational limits on E_0 do not rule out ever-expanding models such as model c'.) As the universe collapses it will follow an E_v = constant track of a radiation dominated universe and the temperature will rise as

$$T = 1.11/(1+g)^{1/4} S^{1/3}/a \tag{3}$$

until it reaches the critical temperature T_0 of the phase transition above which the vacuum energy density will increase by $E_0 \sim T_0^4$ ($\sim 10^{-20}$ for grand unification phase transition = GUT). After the phase transition is completed the vacuum energy density is $E_v = E_t = E_1 + E_0$ and, according to equation (1b), the number of photons and pairs changes to S_t given by

$$S_t^{4/3} - S_1^{4/3} = -\int_{E_1}^{E_t} a^4 \, \mathrm{d}E_v \approx -a_1^4 E_0 \tag{4}$$

The last equality will be valid if the transition occurs at a_1 instantaneously, or on a time scale short compared with the Hubble time at that epoch which is about $E_v^{-1/2}$ ($\sim 10^{-10}$ for GUT). Otherwise, a_1^4 can be taken to be an average value of a^4 during the transition period. The fate of the universe after the transition depends on the value of S_t and E_t. Note that right after the transition the universe is still contracting

$$\dot a = -(E_t a^2 - 1 + S_t^{4/3}/a^2)^{1/2}, \qquad \ddot a = aE_t - S_t^{4/3}/a^3 > 0 \tag{5}$$

Initially the first terms in these equations are dominant and the contraction will be exponential; $a \propto \exp(-E_t t)$. However, as a decreases the other terms (due to curvature and substance) in these expressions become more important. Whether the universe will bounce or continue to contract will depend on which of these two terms in the expression for $\dot a$ becomes important first. If S_t is large, so that $x_t = 4S_t^{4/3}E_t > 1$, then the radiation term ($S_t^{4/3}/a^4$) will become important before the curvature term ($1/a^2$) and the universe will contract to a singularity as shown by the heavy dashed line (c) in Fig. 1. On the other hand, if S_t is small so that $x_t < 1$, then the curvature term becomes dominant first, and the universe will reach the minimum value of the expansion parameter given in equation (2) and then will expand with acceleration as in model b' of the inset and as shown by the heavy solid line directed to the right in Fig. 1. During this adiabatic contraction and expansion phase S_t remains constant and the energy density of the substance increases but never exceeds E_t. The evolution during the expansion phase may follow an inflationary scenario similar to Guth's and others[10–12] where the symmetry breaking is delayed, the universe supercools, but finally it undergoes the phase transition releasing the vacuum energy density which heats the universe back up to a temperature of the order of T_0. However, in the model proposed here the expansion does not begin with a high entropy state but instead is dominated by the curvature and vacuum energy density similar to the scenario proposed by Bludmann[13].

Suppose this transition occurs at $a = a_2$, then the final value of S is given by

$$S_2^{4/3} = S_t^{4/3} + a_2^4 E_0 = S_1^{4/3} + (a_2^4 - a_1^4)E_0 \qquad (6)$$

After the phase transition is completed the universe evolves as a radiation-dominated universe ($E_v = E_1 \ll E_s$, see model b in Fig. 1) and if $4E_1 S_2^{4/3} < 1$ it reaches a maximum expansion with $a_{\max,2} = S_2^{2/3}$. This cycle is then repeated if $4E_1 S_2^{4/3} < 1$ and $4E_t S_t^{4/3} < 1$. These results are summarized in Fig. 2 where we plot schematic variations of a, E_v, $S^{4/3}$ and the three terms in the expression for $(\dot{a}/a)^2$ versus time for a bounce.

Note that there may be more than one spontaneous symmetry breaking and corresponding numbers of phase transitions, so that S_1 and S_2 are not necessarily the final numbers of photons in the universe. Furthermore, the bounce would occur only for grand unification (or for a higher temperature) phase transition when the net baryon to photon number ratio $N_B/N_r \ll 1$. Otherwise, between t_1 and t_2 the universe never becomes curvature dominated and the net baryon term, N_B/a^3 (which, of course, cannot be eliminated during any phase transitions occurring at temperatures less than the grand unification temperature), remains more important than the curvature term, $1/a^2$. If N_B is not zero, then it can be shown that a bounce becomes possible if both $S_t < E_0^{-3/4}(\sim 10^{15}$ for GUT) and $N_B < E_0^{-1/2}/m_B(\sim 10^9$ for GUT). Here $m_B \sim 10^{-19}$ is the rest mass of the baryons. Similarly, our scenario requires that near the bounce the curvature term must also dominate terms due to anisotropies[14] or other sources.

Finally, if the process of symmetry restoration and breaking is not reversible, the two transitions may occur at different values of the expansion parameter. In particular, if $a_2 > a_1$, then $S_2 > S_1$ and entropy is generated during a bounce. This suggests that the 10^{90} photons we observe today may have been produced through many successive bounces of the universe (see Fig. 3). After each bounce the number of photons increases as $S_{i+1}^{4/3} = S_i^{4/3} + E_0(a_{2,i}^4 - a_{1,i}^4)$, and the $\dot{a}^2 = 0$ curve in Fig. 1 moves to the right and decreases in amplitude. If the residual vacuum energy density $E_{v,i+1}$ is not zero, eventually as S increases, one may reach the condition $S_i > (4E_{v,i})^{-3/4}$ which will give rise to an ever-expanding Lemaitre type model as shown by model c' and by the heavy dashed line directed to the right in Fig. 1. However, note that as the symmetry is restored before each bounce, there must be a fine tuning of the exact epoch of the transition a_1 so that S_t, the equivalent number of photons and pairs during the transition period, is not too large; $S_t^{4/3} < 1/(4E_0)$. Otherwise, as discussed above, a bounce will not occur.

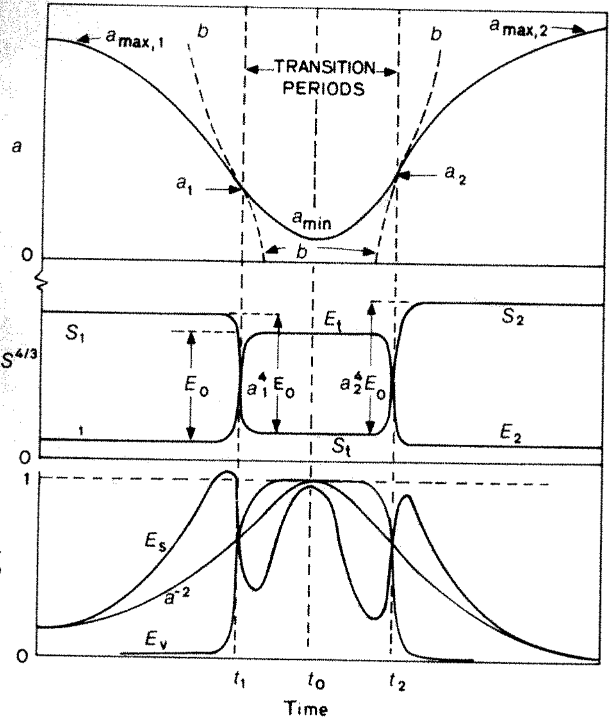

Fig. 2 Schematic variation with time of the expansion parameter (a), vacuum energy density (E_v), photon number (S), substance energy density (E_s), and the curvature term (a^{-2}), during a bounce. At t_1 and t_2 models b and b' (shown in Fig. 1) with two different values of S and with $a_{\min} < a_{\max}$ are joined smoothly. The minimum value of E_s at t_1 depends on the rate of the transition. The slower this rate the smaller the depth of the minimum. The minimum near t_2 depends on the degree of supercooling. Note that at $a_{\max}$, $E_s \approx a^{-2}$ and at $a_{\min}$, $E_v \approx a^{-2}$.

Discussion

Whether the above scenario will work in our Universe depends on the validity of the many assumptions involved. I now comment on these assumptions.

(1) The existence of the bounce requires an extremely small value for the total substance energy of the universe (more exactly the quantity $S_t^{4/3} = E_s a^4$) during the transition phase. We need $S_t < E_0^{-3/4}(\sim 10^{15}$ for GUT) as compared with $S_1 \sim 10^{90}$ for our Universe. This requires that, at the transition, E_s is very nearly equal to E_0 and that the transition occurs quickly so that the $P\mathrm{d}V$ work done by gravity during the transition is negligible. Such an extreme draining of energy from the substance clearly indicates that the two phases are not in thermal equilibrium or pressure balance. If equilibrium were maintained (say through a slow transition), then the substance energy would remain dominant (A. Guth, personal communication) and the entropy would be conserved, which, as shown by Sher[15], precludes any possibility of bounce.

(2) We have also assumed that the total energy density and pressure of the universe can be separated into two constituent parts, one for the radiation with $P_s = 1/3E_s$ and one for vacuum with $P_v = -E_v$. This clearly is true during times sufficiently far removed from the transition. Such a separation is also possible during the transition since, in general, given the total energy density E and pressure P with an arbitrary equation of state, we can always define $E_s = 3P_s = 3(E+P)/4$ and $E_v = -P_v = (E-3P)/4$, so that $E = E_s + E_v$ and $P = P_s + P_v$. However, the important requirement of the bounce is that during the transition E_v must increase monotonically from its initial value E_1 to the final value $E_1 + E_0$. If this variation is not monotonic, that is, if during some part of the transition $\dot{E}_v < 0$, then, according to equation (4), S_t will not be as small as required and it may even exceed S_1. Whether $\dot{E}_v$ remains positive throughout the transition depends on the details of the microphysics which determine the equation of state $P = P(E)$. We have shown that for the most commonly used (see, for example refs 1, 15) effective potential (or free energy) forms the vacuum part of the equation of state does, in fact, increase slowly and monotonically up to the temperature where the non-zero minimum of the potential disappears. As the temperature exceeds this value, the transition will probably occur very quickly. This will raise the vacuum energy density to its final value and, as demanded by energy conservation, will drain the substance of its energy.

Such a transition will destroy the thermal equilibrium of the substance and the normal relationship between entropy and energy density will no longer be valid. Thus, a decrease in the energy density E_s does not necessarily mean a decrease in entropy. The details of the variation of E_v and E_s and entropy will be discussed elsewhere.

(3) The most attractive feature of this scenario is that it allows for creation of substance through repeated bounces. This energy comes from the vacuum which, because of the nature of its equation state ($P_v = -E_v$), can be the source for creation of an unlimited amount of energy as the universe expands: $\mathrm{d}E = P_v\,\mathrm{d}V > 0$. However, our scenario cannot be extended to very small values of a number of particles. It will work as long as S·

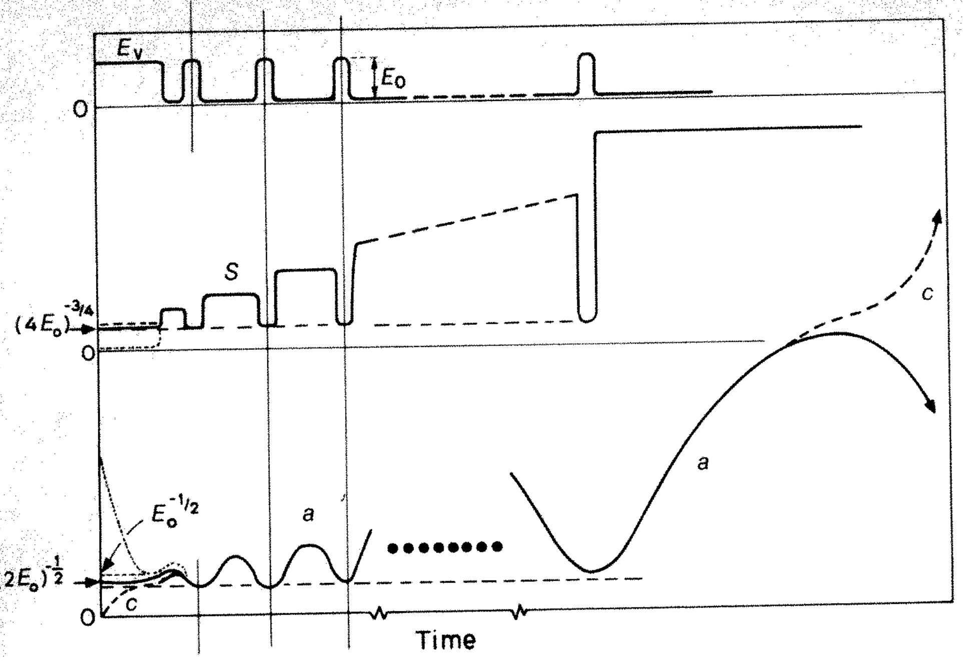

Fig. 3 Schematic variation of vacuum energy density (E_v), photon number (S) and expansion parameter (a) with time for repeated bounces. The oscillations stop if during the normal phase $4S_0^{4/3}E_0 < 1$); solid line for $x_0 = 1$ also Fig. 1.) Three possible initial conditions are shown. Dotted line is for initial $S_0 = 0$ (or $x_0 = 4S_0^{4/3}E_0 < 1$); solid line for $x_0 = 1$ has a static Einstein beginning; and the dashed line marked c (see also Fig. 1), with $x_0 > 1$, starts from a Planck era and undergoes a Lemaitre phase before the first phase transition.

in the symmetry broken (that is, normal) phase exceeds $(4E_0)^{-3/4}$ ($\sim 10^{15}$ for GUT). If S is less than this value, then $a_{\max} \sim S^{2/3}$ becomes less than $a_{\min} \sim E_0^{-1/2}$, indicating the breakdown of our analysis.

(4) There are various possible ways out of this dilemma with regard to the initial conditions. The universe may have started as a closed, vacuum-dominated deSitter universe, contracting from infinity to $a_{\min} = E_0^{-1/2}$ and then expanding with $a = +(E_0 a^2 - 1)^{1/2}$, as shown by the dotted lines in Fig. 3. If at $a = a_0$ the vacuum breaks down[1], then substance energy, with $S^{4/3} = E_0 a_0^4 > E_0^{-1}$ will be created. The expansion will continue at a new rate, $a = +(E_0 a_0^4/a^2 - 1)^{1/2}$, reaching a maximum expansion $a_{\max} = a_0^2/a_{\min}$. After this our previous scenario applies, the universe contracts, undergoes the usual symmetry restoring transition, rebounds at a new $a_{\min} > E_0^{-1/2}$, breaks the symmetry at a_2 and emerges with a higher value of S and so on. Another possibility is that the universe starts with $E_v = E_0$ and with some finite initial S_0. If $S_0 < (4E_0)^{-3/4}$, then the universe starts as described above with $a_{\min} < (E_0)^{-1/2}$ [or as an Einstein static universe with $a_{\min} = (2E_0)^{-1/2}$ if $S_0 = (4E_0)^{-3/4}$, solid line beginning in Fig. 3]. The result here will not be much different from that of the deSitter beginning described above. However, if $S_0 > (4E_0)^{-3/4}$ then the universe must begin from a Planck stage and undergo the first phase transition after it has cooled down below T_0 (dashed line marked c in Fig. 3).

Therefore, if the vacuum does not spontaneously break down to create $S_0 > E_0^{-3/4}$ pairs at once, then we must postulate a universe starting not only with $E_v = E_0$ but also containing $S_0 > (4E_0)^{-3/4}$ photons and pairs. We can relax this assumption if there exist other phase transitions at higher temperatures, with higher values of E_0 and, therefore, requiring lower values of S_0. In particular, phase transition near the Planck era ($E_0 = 1$ and $S_0 = 1$) will allow the universe to start with very little substance and create most of it through successive bounces.

(5) Finally let us consider the so-called monopole, horizon and flatness difficulties[16,17]. If the supercooling is extreme, the expected density of monopole would be acceptable as in Guth's[10] inflationary scenario. Furthermore, according to our scenario during the inflationary phase ($t_0 < t_2$) there are only S_1($\sim 10^{15}$ for GUT) photons and particles in the whole universe. Thus some of the restrictions imposed on the conventional models by the monopole problem will be alleviated. For example, if one bubble is nucleated per particle, then the total number of monopoles in the present universe would be $< 10^{15}$ and therefore insignificant.

It can also be shown that during the transition phase of each bounce ($t_1 < t < t_2$) signals moving with speed of light can circumnavigate the whole universe eliminating the horizon problem. The flatness problem is no longer a difficulty because during both reversals of each cycle the curvature term is important. During the in-between intervals ($t < t_1$ or $t > t_2$) the time duration for near flatness becomes longer and longer as the entropy increases through repeated bounces.

(6) A bounce will occur if the symmetry restoration process induces an increase in the vacuum energy density and a corresponding decrease in the energy of substance. These changes do not have to be equal to those expected from the reverse transition. However, if the two processes are not nearly symmetric, the occurrence of repeated bounces could not take place as simply as described here and the fine tuning process needed for continuation of the bounces would break down. This would cause the universe to expand indefinitely (or collapse and reach temperatures above the critical temperature T_0 of the phase transition) prematurely; that is before it has built up 10^{90} photons (and 10^{80} baryons). Such a model will not resemble our Universe and can be disregarded by appeal to the anthropic principle[18].

I thank Drs Lawrence Caroff and Robert Wagoner for critical readings of this manuscript and for valuable comments, also Drs Alan Guth, Marc Sher, Gary Steigman, Leonard Susskind and Michael Turner for interesting discussions. This work was supported in part by NASA–Ames Research Center grant NCA2-OR745-008.

Trace elements in orogenic lherzolites reveal the complex history of the upper mantle

Michel Loubet & Claude J. Allègre

Laboratoire de Géochimie-Cosmochimie, Institut de Physique du Globe et Département des Sciences de la Terre,
Université Pierre et Marie Curie, 4 Place Jussieu, 75230 Paris Cedex 05, France

Major and trace elements of several lherzolite-type bodies—at Lherz–Freychinède (French Pyrénées), Beni-Bouchera (Morocco), Lanzo (Italian Alps)—have been investigated. Quantitative model analysis of the element distributions shows that these bodies have undergone a rather complex series of events including successive partial meltings and subsequent differentiation of the melts produced. These events are related to the geodynamic evolution of these bodies within the upper mantle, and thus illustrate the multi-stage history of mantle material.

THE orogenic lherzolite type massifs[1], also called high-temperature peridotites[2] are thought to represent pieces of upper mantle material which were mechanically emplaced into the continental crust through large tectonic movements[3–5]. These massifs typically outcrop along major fault systems within chains where interactions between oceanic and crustal materials have occurred (for example, the Insubric line for the Alps massifs such as Lanzo and Baldissero and the North Pyrenean fault for the Pyrenean massifs such as Lherz and Freychinède).

These massifs are therefore unique and highly interesting because they occur as large bodies relative to the size of xenoliths embedded in highly reactive magmas, and are therefore exposed to possible contamination by their surroundings. Oxygen isotope studies show that the orogenic lherzolite type massifs are fresh representative samples of the upper mantle[6] and their analysis should provide important information on the composition, the structure and the evolution of the Earth's upper mantle.

Petrological and geochemical structure of the massifs

Many petrological and geochemical studies have already been performed on these massifs and, in particular, on Mt Albert (Canada)[7], Lizard (England)[8], Beni-Bouchera (Morocco)[9,10], Ronda (Spain)[10,11], Lherz (France)[12], Lanzo (Italian Alps)[13,14] and various Alps[15] massifs. Geochemical analyses were carried out at the Lizard (England)[16,17], Lherz and various Alps[18–24],

Beni-Bouchera (Morocco)[23-26], Ronda (Spain)[27,28], Liguria (Italy)[29] bodies.

We have studied in detail the following lherzolite type orogenic bodies: Lherz and Freychinède, French Pyrénées (see ref. 12 for petrographic descriptions); Beni-Bouchera, Morocco (see refs 9, 10 for petrographic descriptions); Lanzo, Italian Alps (see refs 13, 14 for petrographic and structural descriptions). In other massifs from the Alps—Locana, Rivara, Baldissero and Alpe Arami[15]—only the lherzolites were looked for. We report here our results from the trace-element viewpoint and also present our main data. Detailed studies will be published elsewhere.

Orogenic lherzolite-type massifs are mainly formed of apparently rather homogeneous lherzolite which constitutes around 90–95% of the whole bodies. The remaining part is formed by mafic layers of various sizes apparently more or less parallel to one another. These layers are chemically basaltic but mineralogically variable, their modal composition extending from that of olivine websterite to that of garnet clinopyroxenite (pyroxenite layers). In some of the massifs late amphibole-bearing-type or gabbroic-type dykes cut across the mafic layers. Our data, presented in Tables 1 and 2 with details on the experimental procedure, include major element, rare-earth elements (REE) and transition element contents. The REE data

Fig. 2 Summary of the REE content evolution which, according to our analysis, has affected the various products found in the lherzolite-type bodies—in particular, the pyroxenite layers—during the various episodes of their history. The REE patterns are represented by the classical chondrite normalized diagram. Step 1: the pyroxenite layers are created through partial melting of a peridotitic upper mantle (CO), either undepleted (as in this figure) or depleted. This partial melting yields (one stage) residual peridotites (R) and melts (M) which can differentiate (two stages) through fractional crystallization into different cumulate types: websterites (types W_2 or W_1) or garnet pyroxenites (GC) and residual melts (RM). Step 2: a more recent partial melting event affects these pyroxenite layers. The effect of this last event may be rather small, affecting the pyroxenite layers only selectively—(thus we explain the Lherz–Freychinède and Beni-Bouchera features) or stronger and, then, affecting also the peridotites. In the latter case, a general reequilibration of the pyroxenite layers with the peridotites will occur (the Lanzo features are thus explained).

are shown in Fig. 1 according to the classical chondritic normalized diagram.

For data analysis we will consider in turn the common lherzolites, the pyroxenite layers and the late dykes. We have used quantitative models based on the concept of partition coefficient and on the formulation of partial melting and fractional crystallization processes for trace elements. For each case experimental data are compared with the results of computed models.

Lherzolites

Although apparently homogeneous, those peridotites that constitute the major part of the bodies exhibit significant variations in composition which can even exist in a single massif within several hundreds of metres of each other.

Major elements—some correlations are observed between CaO, Al_2O_3, Na_2O and TiO_2 as well as between MgO, NiO, Cr_2O_3 contents and the MgO/FeO ratio[9,10,18].

Trace elements—the distribution observed can be summarized as follows[20–27]: as far as we know, the elements characterized by high partition coefficients (highly compatible elements (Ni, Co and to a lesser extent Cr)) have a remarkably homogeneous content. Elements with intermediate partition coefficients such as Yb and Ti have content variations which do correlate with the CaO variations. Large variations are observed for the incompatible trace elements. In particular, the REE patterns of the lherzolites show remarkably similar characteristics. They are all light REE depeleted, the light REE contents varying within a rather wide range and the heavy REE contents in a rather narrow one[18–20]. Early results confirmed the preliminary study by Haskin *et al.*[30] and Frey[16,17] and were later supported by further data[27–29].

In agreement with Frey[16], we interpreted[18] these characteristics as those of a residual material which originated through partial melting of a rather homogeneous primitive peridotitic mantle. This primitive upper mantle may have been characterized by a REE chondrite normalized pattern parallel to the chondritic line of reference but with about double the chondritic value[18]. The most important conclusions reached from the quantitative models developed[18,19,26,27,28] are that the residual peridotites resulting from partial melting of an originally homogeneous lherzolitic upper mantle display a wide range of variations in light REE contents and a relatively small range of variations for the heavy REE—a feature effectively observed in the orogenic lherzolites.

The degree of partial melting which gave rise to these residual peridotites can be estimated from REE analysis to vary between 1 and 5% (ref. 18). The state of equilibrium of these peridotites during their partial melting is unclear due to uncertainty over the REE partition coefficients for clinopyroxene. This residual character also explains the small variation of Ni, Co, Cr and the covariation of CaO, Al_2O_3, Na_2O, TiO_2. Nd and Sr isotopic data corroborate the residual nature of this peridotitic upper mantle material[22–24]. Their Nd isotopic composition moves along the same Nd–Sr anticorrelation line as the one characteristic of the oceanic basalts, especially in the zone corresponding to high Nd isotopic values[24]. At the same time Nd isotopic data exclude alteration as a possible process for light REE depletion of these peridotites—as proposed elsewhere[29].

Thus, major elements, trace elements and isotope data agree with the idea that orogenic lherzolites are residues after extraction of a small amount of basaltic melt. This interpretation is supported by most authors who have studied these massifs[24,25,27–29], and agrees with the general idea, based on oceanic basalt trace elements[31–33] and isotope analysis[34–36], that the 'oceanic' upper mantle should be residual (extraction of small basaltic amount). At the same time this agreement suggests that the orogenic lherzolite massifs could effectively represent oceanic upper mantle material.

Pyroxenite layers

The chemical composition of these layers as a whole is basaltic. Thus, one could think of these layers as representing the peridotite complement, that is the part which was extracted during the partial melting of these rocks. However, the detailed mineralogical and chemical analysis of these layers implies that the process cannot be so simple. In particular it looks as though some differentiation processes should have occurred, as indicated by the symmetrical structure displayed by some complex pyroxenite layers formed by the superposition of several sublayers[9–12]. The models proposed for the origin of these layers should thus take this complexity into account.

REE contents of the pyroxenite layers

The REE patterns of the large set of pyroxenite layers is illustrated in Fig. 1 through the classical chondrite normalized representation. For the various lherzolite type bodies we studied, the main characteristics of these patterns are:

(1) In general the pyroxenite layers look more REE-enriched

Major elements were analysed by X-ray fluorescence, transition elements by atomic absorption, rare earths by isotope dilution mass spectrometry with an accuracy of better than 2.5%. The experimental techniques have been described elsewhere[20].

than common peridotites. In particular the heavy REE content of some pyroxenite layers appears very high, for example, that of garnet clinopyroxenite layers (M5-367, M6-79 complex layers).

(2) They display a large variety of REE patterns characterized by a wide range of light REE fractionations relative to the heavy REE, some being light-REE enriched (74–57 in Freychinède, M5-103 in Beni-Bouchera), others light-REE depeleted.

(3) The light REE depleted pyroxenites are the most common with a tendency to be more light-REE depleted relative to the heavy REE than are the common lherzolites.

(4) No distinct Eu anomaly is observed in these patterns (with the exception of the websterite 73-78W from Lherz).

Quantitative models for estimating the REE contents that should represent the products resulting from partial melting of a lherzolitic upper mantle have been developed. The basic hypothesis is that the primitive upper mantle affected has a homogeneous and uniform composition.

In the single stage model we try to compute the composition of the various types of melts that are generated through a single partial melting. More complex models are needed to describe the composition of the various cumulates which may crystallize from these melts and the corresponding residual liquids after an evolution to these melts through fractional crystallization (two stage process). The most important conclusions of this quantitative modelling are: (1) the melts produced have a large diversity in their REE patterns, characterized by a wide range of fractionation of the light REE relative to the heavy REE. Taking into account the fractionated type partial melting process, these melts may indeed be light REE enriched or depleted relative to the heavy REE; (2) the cumulates which crystallize from these melts thus exhibit, as well as the melts, a wide range of REE patterns also characterized by a large variety of fractionations of the light REE relative to the heavy REE. This diversity in the REE patterns will be accentuated in the cumulates, given the variety of mineralogical assemblages which may crystallize; for example, the crystallization of garnet in the cumulates will yield a strong enrichment of such cumulates in heavy REE.

The large diversity of the REE patterns displayed by the pyroxenite layers conforms with what would be expected for products derived through partial melting of a peridotitic upper mantle, according to the models developed. However, we cannot decide from these REE data, whether most of the layers are cumulates or melts, because of the large range of contents these two types of products can display in such a model. To solve this problem, the use of elements with high partition coefficients appears adequate. Cumulates and melts should have very different properties for this kind of element.

Trace elements with high partition coefficients

Large variations are found in the literature for the partition coefficients of this kind of element so that the models obtained may be rather imprecise. A correct estimate may, however, be realized in a special case, that is for the cumulates supposed to correspond to the first per cent of crystallization of the primary melts. The phases of these first cumulates should have the same trace-element content as the phases of the common peridotites. So, taking values for peridotite phases from the literature, we estimated the content of several types of cumulates presenting different modal compositions, all supposed to have crystallized during the first per cent of crystallization of primary melts. This gives us some kind of upper limit for the content of the cumulates[26].

The pyroxenite layers seem to contain a rather large amount of such elements (Ni, Co, Cr), compared with our estimates. This convinces us that most of the pyroxenite layers should be cumulates representatives. Possible exceptions to this rule include some complex layers, the contents of which are close to melt estimates[26].

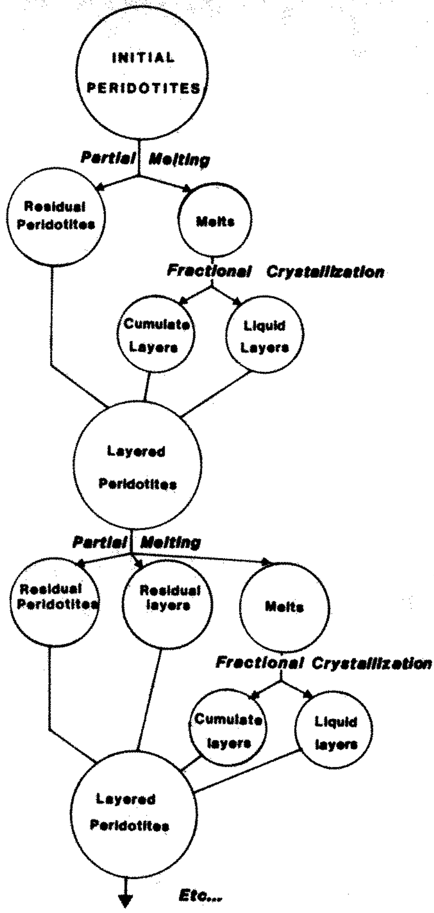

Fig. 3 Deduced model of evolution of the lherzolite type bodies. These peridotite bodies have been the object of successive melting events, each one producing melts possibly mobile and which differentiate through fractional crystallization. These derived products yield the pyroxenite layers. A later partial melting of this layered peridotite affects the various materials with variable intensities. Other types of products and layers will be generated through this new partial melting event.

Evidence for remelting

However, several observations suggest that most of the pyroxenite layers do not present primary structures and have been modified through a further process. More precisely we suspect that these pyroxenite layers have been affected after their formation by a further selective late partial melting event[19–22].

The main points supporting this hypothesis are first, in several bodies the rocks which have the lowest content of highly incompatible elements are the garnet clinopyroxenite layers. Such are the garnet clinopyroxenites 70-291 from Lherz, and M6-79 from Beni-Bouchera which have the lowest light REE content, even lower than the common lherzolites from these bodies. Such a low light REE content is surprising in these clinopyroxene-rich rocks which represent the latest stage of differentiation of the melts yielding the pyroxenite layers.

Second, in some peridotite bodies a peculiar evolution is observed[37]: a depletion in the content of the highly incompatible trace elements characterized by low partition coefficients when going from the slightly differentiated to the highly differentiated layers (from the olivine websterites to the garnet clinopyroxenites).

Third, some of the lherzolite type bodies that we studied effectively bear the mark of such a late partial melting event in the form of late dykes cutting the websteritic layering—in particular the amphibole bearing dykes—as in Lherz and Freychinède (French Pyrénées). The geochemical analysis of these dykes shows[20,37] that they may effectively represent products derived from the melts resulting from partial melting of these pyroxenite layers.

Sr isotope studies performed on these same rocks support this interpretation of a complex history of these layers[23] and were the basis for the Rb–Sr systematics given by Polve and Allègre[23].

The occurrence of such a late partial melting event has a direct consequence. As the primary trace element distribution of the pyroxenite layers has changed, a precise interpretation of the characteristics of the melts at the origin of these layers becomes difficult.

In the framework of our model for the origin of the pyroxenite layers from melts resulting from partial melting of the peridotitic mantle we would have liked to define precisely the nature of these melts. In Fig. 2, we retrace in the chondrite normalized representation, the various steps which according to our interpretation explain the actual REE content of these layers. They correspond to the different partial melting events suffered by these bodies.

Late dykes

In the Lherz massif late amphibole-bearing dykes do exist which cut across the pyroxenite layering[38]. The REE patterns of these dykes are characteristic—all being enriched in light REE relative to the heavy REE. From their trace-element distributions we interpret these dykes as representative of cumulates crystallized from melts highly enriched and fractionated in light REE relative to the heavy REE. We have already supported the idea that these melts may have been issued from the partial melting of the pyroxenite layers[20–37].

In the Lanzo body, the REE patterns displayed by the gabbroic-type dykes is characteristic of plagioclase bearing cumulates. In this massif there are some indications that the last partial melting event at the origin of these dykes also affected the peridotites[13,14].

Conclusions

The analysis of these orogenic lherzolites yields strong evidence that several magmatic events affected these bodies. One was at the origin of the formation of the pyroxenite layers. The last one affected the pyroxenite layers in a selective way in some massifs (Lherz and Freychinède–Beni-Bouchera) but also reached the peridotites in others (Lanzo). Other partial melting events may have previously affected these lherzolite bodies thereby giving their residual character to the peridotites. Each magmatic event is characterized by the formation of various melt types through partial melting, a possible mobility of the melts produced and further fractional crystallization of the melts.

Thus, the final image which emerges is that the actual state of the orogenic lherzolite bodies can be understood through a model in which these peridotite bodies suffered a complex history involving successive partial meltings and further differentiation of the melts so generated, the partial melting events giving rise each time to a diversity of products. The ^{87}Rb–^{87}Sr isotope systematics has also been interpreted in the light of a complex process[23]. Dickey *et al.*[28], through the study of the Ronda massif (Spain), also support a similar complex evolution for this body but without clear evidence for pyroxenite-layer remelting. Wilshire and Shervais[39] inferred that the upper mantle parts should have suffered a rather complex evolution through a petrological and structural analysis of ultramafic xenoliths from the western United States.

Such a complex history can be understood geodynamically as resulting from an evolution of these bodies in an upper mantle affected by convection processes and uprising movements to the surface through tectonic events. The partial melting events thus appear during the decompression stages[22,23,26].

Several characters displayed by these Alpine-type peridotite bodies can be explained in the light of such an evolution. First, the relatively uniform lherzolites characteristics found throughout these bodies would result from an evolution of these upper mantle bodies in active convection processes, implying large mixing and chemical reequilibration—favoured by the presence of melts and fluids generated through the partial melting events. Second, the specific characteristics of the pyroxenite layers in each body may be explained by the relative intensity of the last partial melting event (the one which selectively affected these layers) (Fig. 3). In some bodies (Lherz, Freychinède, Beni-Bouchera) this last event was of low intensity. It affected only the pyroxenite layers in a selective way. In others, such as Lanzo, this last event was more intense, also affecting the peridotites[13,14]. In this body the pyroxenite layers look perfectly equilibrated relative to the lherzolites.

This reequilibration should be a general phenomenon in the mantle—the temperatures being rather high, recrystallization occurring rather easily, the presence of melts or fluids permitting an efficient equilibration[40].

The apparent equilibrium of many websteritic layers with the surrounding peridotites in these bodies may result from such a further reequilibration process of ancient pyroxenite layers. In this case, these websteritic layers may be indicative of past partial melting events.

The oceanic mantle is composed of a mechanical mixture of an old subducted, elongated, sheared oceanic crust with a residual peridotite. Through several cycles of convection, including rising and melting at ridge crests, subduction with some rare melting events, origin of calcalkaline suites, and so on, we certainly have a quite complex petrological assemblage. Such a sequence of events, is in full agreement with petrological and isotopic data on orogenic lherzolite massifs[23,24]. If this were verified, the pyroxenite would represent the old oceanic crust, sometimes recycled, or melted in subduction zones and the peridotites, the residual mantle.

Reversion of a promoter deletion in yeast

Stewart Scherer*, Carl Mann & Ronald W. Davis

Department of Biochemistry, Stanford University School of Medicine, Stanford, California 94305, USA

Promoter function in yeast has been examined by obtaining revertants of a his3 *promoter deletion* in vivo. *Events which provide a new promoter for the* his3 *gene include insertion of the transposable element Ty*1, *rearrangements of the plasmid vector, and chromosomal mutations. A role for dicentric chromosomes as a source of the plasmid rearrangements is discussed.*

PROMOTER function was originally defined by mutations which reduced the fully induced level of expression of the lactose operon of *Escherichia coli*[1]. Since then, various selective methods have been developed to identify different types of altered promoter sequence. These include the isolation of mutations that increase gene expression and mutations which alter the regulation of specific genes[2]. Additional information about promoter function in prokaryotes has come from studies of the *in vitro* interactions of purified RNA polymerase with promoter sequences[3].

As most mutations that decrease gene expression, isolated *in vivo*, reside in coding sequences, genetic analysis of promoter function in eukaryotes has centred on systems where one can select for overproduction or altered regulation. An alternative approach to the study of promoter function is through the reversion of existing promoter mutations. Two eukaryotic promoter mutations have been examined in detail by this method: the *his4*-912 and *his4*-917 mutations of yeast[4]. In both cases, the pattern of revertants obtained by selection for restoration of *HIS4* function was influenced by the fact that the original mutations were due to the insertion of transposable elements.

Recombinant DNA techniques have made it possible to produce a series of deletions or base changes that modify promoter sequences. These altered promoters can then be returned to an appropriate host in order to examine their function *in vivo*[5–7].

Here we have studied the reversion of a promoter deletion of the yeast *HIS3* gene. The deletion was first constructed in *E. coli* and then introduced into yeast as a new chromosome: a plasmid containing a functional centromere, an *ARS* sequence, and additional selectable markers (see Figs 1, 3). The promoter mutant chosen, *his3*-Δ4, deletes to within a few nucleotides of the start point of *HIS3* transcription (41 ± 1 nucleotides from the start of translation) in wild-type strains and produces no detectable *HIS3* mRNA[7]. The deleted sequences are replaced with λ DNA (see Fig. 3) rightward from the *att* site to the *Bam*HI site at 0.577.

Revertants of this *his3* promoter deletion are extremely rare, less than 1 in 10^9 viable cells, but arise by a variety of mechanisms. Yeast cells require only low levels of *HIS3* transcription for growth; this provides for a wide range in the level of expression that can be detected in revertants. In this report we describe several types of revertants. Potential sources for certain classes of the revertants and mechanisms for the restoration of *HIS3* function are discussed.

Blocking recombination between a plasmid-encoded gene and a chromosomal copy

Previous attempts to examine the reversion of *his3* mutant genes introduced into yeast by DNA transformation have been hampered by recombination with the *his3* allele present at the normal location on chromosome 15 (ref. 8). One solution to this problem is to delete the homologous sequences at the normal *HIS3* locus. This approach has been used in the isolation of some of the revertants described below. In general, the removal of entire genes in yeast has been difficult. The intercistronic regions are frequently small and suspected silent regions may encode essential functions for which transcripts are not readily detected.

Another solution to the recombination problem is to block all homologous recombination. However, in yeast, one does not have a single mutation, analogous to the *rec*A mutants of *E. coli*, which effectively blocks most homologous recombination. The yeast *rad52* mutation[9] will block gene conversion but reciprocal recombination remains unaffected. This latter form of recombination was effectively blocked in the *rad52* strains used here by incorporation of a yeast centromere[10,11] into the plasmid. Cells containing the dicentric chromosomes which arise from reciprocal recombination of a centromere-containing plasmid into a normal yeast chromosome are not recovered in these strains.

The experiments which led to the above conclusion are summarized in Table 1. In each experiment, the host strain contained a *his3* gene with a small internal deletion and the plasmid contained the *his3*-Δ4 promoter deletion. In the situation where the host strain was $RAD52^+$ and the plasmid cen^-, both gene convertants and reciprocal recombinants were recovered. The cen^-, plasmids were unstable and in some cases where gene conversion events occurred, the other plasmid marker (and presumably the entire plasmid) had been lost. Cells that had integrated the plasmid by reciprocal recombination are at a selective advantage during the growth of the culture required to measure the recombination frequency. One would normally expect a rather higher ratio of gene conversion to reciprocal recombination than was observed[12]. When the *rad52* mutation was incorporated into strains containing the cen^- plasmids, only the reciprocal events were recovered (Table 1). In addition, a high background of apparent suppressors of *his3*-Δ4 was observed when using cen^- plasmids. This may be related to the poor control of copy number of the *his3* gene with these plasmids.

Table 1 Reversion to His^+ of strains carrying the *his3* promoter deletion on a plasmid

Strain	Plasmid	Reversion frequency	Fraction Ura^+
$RAD52^+$	cen^-	$\sim10^{-6}$	~40%
$RAD52^+$	CEN^+	$\sim10^{-7}$	~50%
$rad52^-$	cen^-	$\sim10^{-6}$	100%
$rad52^-$	CEN^+	$<10^{-9}$	100%

The background of apparent suppressors, which generally show poor growth in selective conditions, has been excluded (see text). The $RAD52^+$ strain was strain YNN36 (α *trp1*-289 *his3*-Δ1 *ura3*-52). The $rad52^-$ strain was YNN209 (α *trp1*-289 *his3*-Δ1 *ura3*-52 *ade2 rad52*). The cen^- plasmid was 2944 (YRp12 with the *Bam*HI fragment containing *his3*-Δ4) and the CEN^+ plasmid was 2961 (see Fig. 1) which contains a slightly smaller *his3*-Δ4 fragment. Reversion to His^+ of *his3*-Δ1 strains containing no plasmid was $<10^{-11}$.

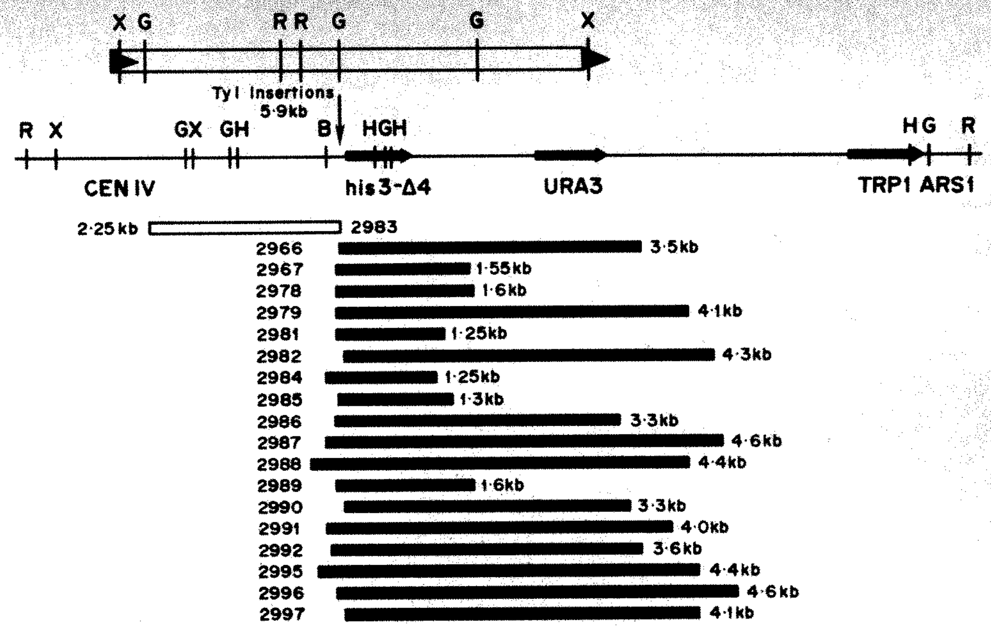

Fig. 1 Plasmid rearrangements associated with reversion of the *his3* promoter deletion. A linearized map of plasmid 2961 with the positions of certain restriction endonuclease cleavage sites is shown. The total length of the plasmid is 11.1 kb. The ColE1 origin and ampicillin resistance gene are located between the *URA3* and *TRP1* genes. R, *Eco*RI; B, *Bam*HI; H, *Hin*dIII; G, *Bgl*II; and X, *Xho*I. Above the map of the plasmid is a map of the prototype Ty*1* element[14]. The terminal repeats of Ty*1*, the δ sequences, are indicated as filled triangles. One of the Ty*1* elements which inserted into 2961 lacked the *Xho*I sites in the δ sequences. The Ty*1* elements all inserted into the vector in the orientation shown. Transcription of Ty*1* is from right to left as drawn. The single open box represents the deletion contained in one of the revertants. The solid bars indicate the regions duplicated in the other revertants. The sizes of the deletion and the tandem duplications are shown. The sizes are ±50 bp for the smaller rearrangements and ±100 bp for the largest ones.

CEN$^+$ plasmids in the *RAD52*$^+$ strain will also convert *his3* mutations on chromosome 15 to His$^+$. We did not determine whether plasmid integration by reciprocal recombination also occurred in this strain. Some of the His$^+$ recombinants no longer contained the plasmid as judged by the loss of the other plasmid markers, which may be due to the imperfect stability of the centromere plasmids. It has also been noted that gene conversion events near centromeres are frequently associated with chromosome loss[13]. Finally, when the *CEN*$^+$ plasmids were introduced into *rad52*$^-$ strains, the frequency of His$^+$ colonies fell dramatically. Among the His$^+$ revertants, no His$^+$ recombinants were detected (see below). In previous work[12], the block to gene conversion produced by *rad52* was not as complete as that observed here. However, in the experiments described here the regions of homology were quite small and one of the alleles contained an internal deletion. The frequency of viable recombinants in this situation is less than 1 in 10^{10} cells.

Revertants of the *his3-Δ4* promoter deletion

All the revertants obtained in our study were derived using the same plasmid vector, 2961 (Fig. 1). Two host strains were used: a *rad52* strain, YNN209, which contains the *his3-Δ1* allele[8] and strain YNN211, which contains a total deletion of the *his3* gene, *his3-Δ200* (M. Fasullo, unpublished strain). In both strains, the frequency of spontaneous His$^+$ revertants was <1 in 10^9 viable cells.

Spontaneous *His*$^+$ revertants of yeast strains YNN209 and YNN211 containing plasmid 2961 fall into three broad classes: insertions of the transposable element Ty*1*, rearrangements of the plasmid DNA, and apparent chromosomal mutations. The revertants were first characterized by isolation of the plasmid DNA from the revertant cells by transformation of *E. coli*. Certain revertants yielded plasmids that appeared identical to the starting plasmid. All of these yeast strains grew poorly on selective media and the plasmids obtained from them would not transform yeast *his3* mutants to His$^+$. These apparent chromosomal mutants have not been characterized further. The plasmid-encoded mutations are described below.

Reversion by insertion of the transposable element *Ty1*

Of 14 revertants isolated using the *rad52*/centromere-plasmid system described above, 6 were insertions of the transposable element Ty*1*, as determined by comparison with restriction site maps of other cloned Ty*1* elements[14] and confirmed by hybridization of ^{32}P-labelled Ty*1* sequences with the plasmid DNA recovered from the revertants (not shown). Restriction site mapping placed the insertion of the element near the 5′ end of the *his3* coding sequences. The orientation of the element, as shown in Fig. 1, was the same relative to the gene as observed at the cytochrome *c*[15] and alcohol dehydrogenase[16] loci. The Ty*1* elements inserted into at least four distinguishable sites. This was determined by digestion of heteroduplexes of revertant DNA and end-labelled parental DNA with S_1 nuclease and measurement of the distance from the labelled end to the novel joint in the revertant DNA (Fig. 2*a*). These results are summarized in Fig. 3.

All six plasmids containing Ty*1* insertions transformed *his3* mutants to His$^+$. The insertions which were closer to the start of the *HIS3* coding sequences expressed *HIS3* at a rather higher level as judged by growth in the presence of 10 mM 3-amino-1, 2, 4-triazole, an inhibitor of the *HIS3* gene product, imidazole glycerol phosphate dehydratase. Attempts to correlate the level of *HIS3* expression with insertion site were complicated by the fact that the Ty*1* elements that had inserted were not identical. Digestion with two restriction endonucleases, *Sal*I and *Xho*I, revealed that the presence of at least three different Ty*1* elements. Many polymorphisms of Ty*1* have been characterized[14,17] and it is possible that the six insertions were six different Ty*1* elements. These studies have demonstrated that Ty*1* elements can transpose to a non-promoter sequence (λ DNA) near a gene and activate that gene. Also, Ty*1* transposition can occur in a *rad52* strain.

Of 21 revertants of *his3-Δ4* obtained in a strain containing a total deletion of the chromosomal *his3* gene (YNN211); none were due to the insertion of Ty*1* elements. Thus, the frequency of transposition relative to the efficiency of other mechanisms available for reversion of the promoter deletion seems to be different for different strains. The source of the difference between these two strains is unknown.

Reversion by tandem duplication

Plasmids recovered from 15 revertants contained tandem duplications of a portion of the starting plasmid. Plasmids were screened for duplications by cleavage of the plasmid DNA with *Bgl*II endonuclease, which cleaves once in the *HIS3* gene and has no sites for ~6 kilobases (kb) downstream from this gene

(Fig. 1). As described below, all the duplications had one breakpoint near the 5′ end of *HIS3* and one well beyond 3′ of the gene in the vector sequences. These breakpoints produced a single novel junction near the 5′ end of the *HIS3* gene for each new plasmid.

Cleavage of the revertant DNA with *Bgl*II produced a pattern of fragments that contained all the fragments of the vector with an additional fragment, which corresponds to the size of the duplicated region. Several examples of this are shown in Fig. 4. Cleavage of the plasmid DNA from a revertant with any other enzyme which cleaves once in the duplicated segment will produce all the vector fragments normally observed for that enzyme and an additional fragment whose size is the same for all enzymes of this type.

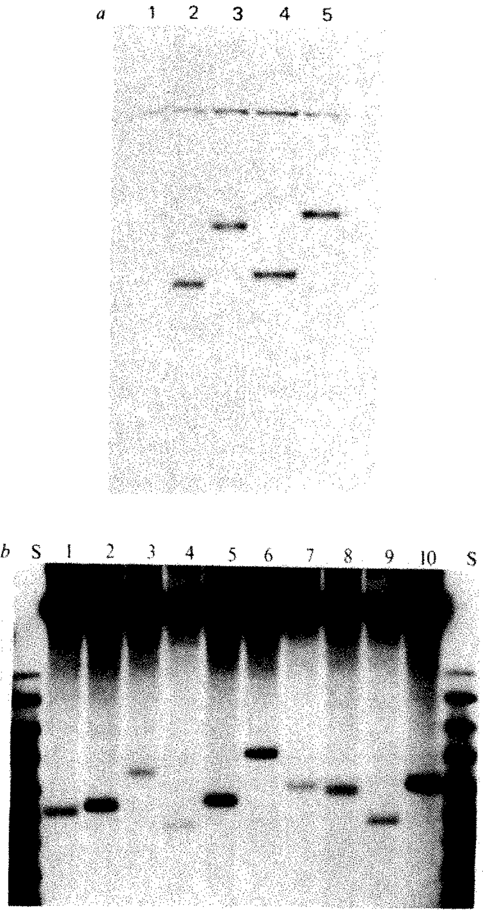

Fig. 2 Mapping of rearrangement breakpoints near *HIS3* with S_1 nuclease. ^{32}P-end-labelled DNA was prepared by treatment of *Hin*dIII-cleaved 2961 with calf intestine alkaline phosphatase followed by incubation with polynucleotide kinase and $[\gamma\text{-}^{32}\text{P}]$-ATP. In *b*, the fragment of interest was purified by gel electrophoresis; in *a* it was cleaved also with *Bam*HI endonuclease before separation. For each sample, the DNA was cleaved with *Bgl*II endonuclease in 20 µl of 10 mM Tris-HCl *p*H 7.5, 10 mM magnesium chloride, 1 mM dithiothreitol. In *a*, purified plasmid DNA was used; in *b*, DNA from rapid plasmid isolations was used. 3 µl of 0.1 M Na_3EDTA, 1 M NaOH and $\sim 10^4$ d.p.m. of probe fragment were added to each sample and incubated at room temperature for 15 min. The DNA was renatured by adding 3 µl of 2 M Tris-HCl and incubating at 65 °C for 3–5 min. The samples were diluted with 300 µl of 50 mM sodium acetate *p*H 4.4, 280 mM NaCl, 2 mM $ZnAc_2$ and digested with 1,000 units of S_1 nuclease at 37 °C for 30 min. After ethanol-precipitation, the samples were electrophoresed on a 5% polyacrylamide Tris–borate–7 M urea denaturing gel (*a*) or on a 2% agarose Tris–acetate–EDTA native gel (*b*). After electrophoresis, the gels were dried for autoradiography and exposed at −70 °C with an intensifying screen. The samples in *a* were: 1, no DNA; 2, 2970; 3, 2971; 4, 2973; and 5, 2976. The fragments were measured as 340–400 bp (standards not shown); the probe measures 575 bp. The samples in *b* were: 1, 2997; 2, 2996; 3, 2992; 4, 2990; 5, 2989; 6, 2987; 7, 2986; 8, 2985; 9, 2982; and 10, 2981. Standards, S, were *Bst*NI fragments of SV40 DNA.

The end point of the duplicated segment near the 5′ end of the *HIS3* gene was localized by an S_1 nuclease mapping procedure similar to that used for the Ty*1* insertions (see Fig. 2*b*); the results are shown in Fig. 3. The rearrangement breakpoints were spread over a wide region beginning near the start of the wild-type *HIS3* mRNA and extending back as far as 500 base pairs (bp) from that point.

Given the size of the duplication and one of its end points, the other end point was determined. The regions that were duplicated in each revertant are shown in Fig. 1. There are no obvious hotspots for the duplication breakpoints, nor is there any obvious correlation between the duplications that break in a given region of the vector DNA and a particular distance from the 5′ end of the *HIS3* gene for the other breakpoint. It is interesting that no duplications were found which fuse the *his3* gene to *URA3* sequences. The *URA3* gene is constitutively expressed and transcribed in the appropriate direction. About half of the revertants were selected in conditions where the *URA3* gene on the vector was also being selected. In these conditions, *URA3* is transcribed at a higher level[18].

Eight of the duplication-containing plasmids, including those with the closest and the two most distant breakpoints relative to the *HIS3* gene, were tested for the ability of the plasmid DNA to transform *his3* mutant strains to His$^+$. All transformants tested were His$^+$. All except those generated using 2988 DNA were resistant to 10 mM 2-amino-1, 2, 4-triazole and therefore must express *HIS3* at near wild-type levels. The duplications were responsible for the *HIS3* expression as removal of the duplication from two different plasmids by homologous recombination resulted in reversion of the His$^+$ phenotype to His$^-$.

Miscellaneous revertants

One revertant was a simple deletion of the starting plasmid; one breakpoint of the deletion was near the 5′ end of the *HIS3* gene (Fig. 3). The size of the deletion was ~2.25 kb, which placed the other breakpoint in a region of yeast DNA normally transcribed into poly(A)-containing RNA[11]. The deletion-containing plasmid retained at least partial *CEN4* function during mitotic growth.

Several revertants seemed to be duplications of most of the starting plasmid, excluding the *CEN4* region (not shown). The size of these duplications resulted in the production of a large number of coincidentally sized restriction fragments and made their characterization less certain.

Two plasmids were found to contain multiple rearrangements of the starting plasmid DNA. One was a triplication or two similar duplications; the other appeared to contain two different duplications (not shown).

Plasmids isolated from the revertants described in this section transformed *his3* mutants to His$^+$ and presumably represent the event in those cells that restored *HIS3* function.

Possible source of the plasmid rearrangements

Mutations associated with tandem duplications have been found in many systems. Some arise through recombination of repetitious DNA sequences and are generally sensitive to mutations affecting the general recombination systems of the organism. The large duplications of portions of the *Salmonella* chromosome are thought to arise by this type of mechanism[19]. In contrast, the frequency of spontaneous duplications of the phage λ chromosome is insensitive to such mutations[20].

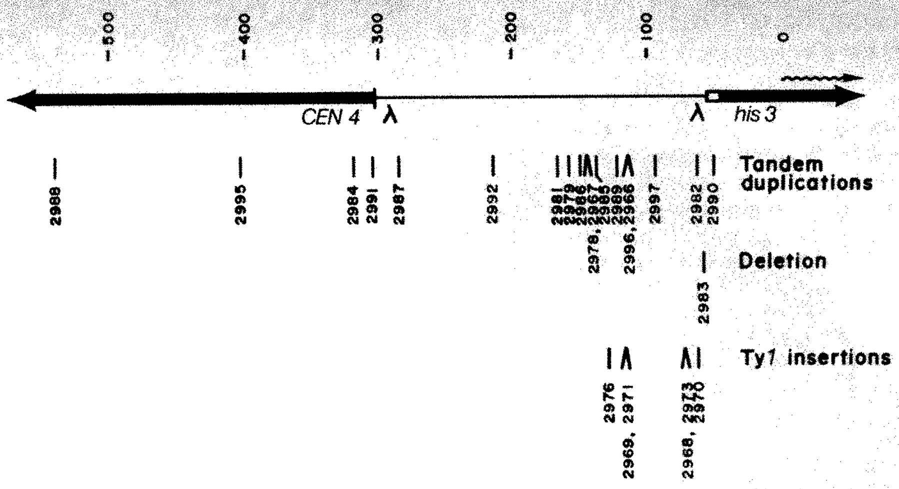

Fig. 3 Rearrangement breakpoints near *HIS3*. The position of the breakpoint for the tandem duplications, deletion, and Ty*1* insertions (mapped as described in Fig. 2 legend) are shown. The positions are ±10 bp for the closest breakpoints and ±20 bp for the more distant ones. Distances from the start of the *HIS3* coding sequences (ATG) are given in base pairs at the top. The yeast DNA sequences in 2961 (*his3*-Δ4 and *CEN4*) are indicated as thick lines. The *CEN4* function is associated with sequences 2 kb to the left of the λ DNA (see Fig. 1). The *HIS3* structural gene sequences are indicated by the wavy line. The small region of λ DNA, to the right of the *att* site, attached to *his3*-Δ4 is shown as a thin line. The λ *att* site, which has partial homology to the yeast DNA that it replaced, is represented by an open box. All revertants shown were independently isolated, except 2966, 2967, 2968 and 2969, which form one group. The strains containing the rearranged plasmids are: pNN163 (2966), pNN164 (2967), pNN165 (2967), pNN166 (2969), pNN167 (2970), pNN168 (2971), pNN169 (2973), pNN170 (2976), pNN171 (2978), pNN172 (2979), pNN173 (2981), pNN174 (2982), pNN175 (2983), pNN176 (2984), pNN177 (2985), pNN178 (2986), pNN179 (2987), pNN180 (2988), pNN181 (2989), pNN182 (2990), pNN183 (2991), pNN184 (2992), pNN186 (2995), pNN187 (2996), pNN207 (2997). pNN163 to pNN172 were selected in YNN209, and pNN173 to pNN207 were selected in YNN211.

DNA rearrangements are normally quite rare in yeast. Some are due to recombination of repeated DNA sequences: rearrangements of chromosome 3 through the mating type loci[21], recombination of Ty*1* sequences[8] and recombination of the partially homologous cytochrome coding sequences[22]. Duplications have been detected in several cases. The *SAD1* mutation[23] duplicates a portion of the right arm of chromosome 3; it appears to be an unequal cross-over between *MAT* and *HMR*[24]. Copper resistance is associated with tandemly repeated sequences (S. Fogel, personal communication). The results described here are unusual for yeast in that duplications seem to be the most abundant class of mutations.

We suggest that the formation of dimeric, dicentric plasmids may be an intermediate in the formation of the rearranged molecules found in the revertants described above. Asymmetric breakage of the dimer plasmids will be a source of deletions and tandem duplications (Fig. 5). The relative frequencies at which the revertants are recovered may reflect both the position of *his3* relative to the centromere in the starting plasmid and the locations of DNA sequences that can restore *HIS3* function.

With the isolation of centromeric DNA, it has become possible to construct dicentric chromosomes *in vitro*. In yeast, these molecules are rapidly rearranged, usually by deletion of one of the centromeres (C. M., unpublished results). Plasmids that do not contain centromeres will freely form multimeric molecules in yeast[25]; however, multimers of centromere plasmids are not readily detected[11].

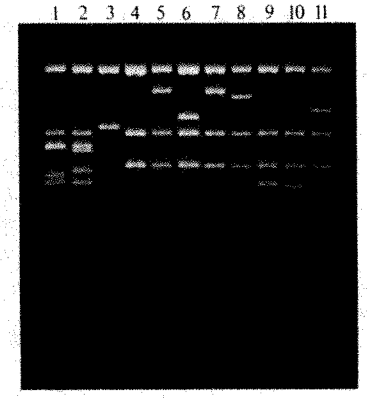

Fig. 4 Plasmid DNA from revertants. The samples were cleaved with *Bgl*II endonuclease and electrophoresed on a 0.8% agarose Tris–borate–EDTA gel. The samples in lanes 1 and 2 are 2976 and 2970, both Ty*1* insertions; lane 3, 2983, a deletion; lane 4, 2961, the parent plasmid; lanes 5–11, 2995, 2990, 2988, 2979, 2978, 2967, 2966 (all duplications). The sizes of the fragments of 2961 (lane 4) are: 6.15, 2.55, 1.90 and 0.55 kb (going from top to bottom).

Cyclization of the broken dimer plasmids leads directly to circular molecules containing simple duplications. Transformation of yeast with linear DNA molecules prepared from cloned circular DNA molecules has shown that these ends can be rapidly joined *in vivo* and that they appear to stimulate recombinational events involving the transforming DNA[26]. One would expect that the molecules containing linear duplications produced by the mechanism outlined above would rapidly convert to circular molecules and possibly catalyse more complicated rearrangements. Broken dicentric chromosomes in maize are known to precede multiple rearrangements that can be observed cytologically[27]. Consistent with this model is the observation that transformation of yeast with a dimer of plasmid 2961 yields >100 times the frequency of His$^+$ colonies as that for the monomer. We chose to isolate the His$^+$ revertants with the *HIS3* gene on a plasmid to facilitate rapid recovery of the functional *HIS3* DNA sequences. A different distribution of revertants would be predicted from the above model if the promoterless *HIS3* gene was located in a linear chromosome.

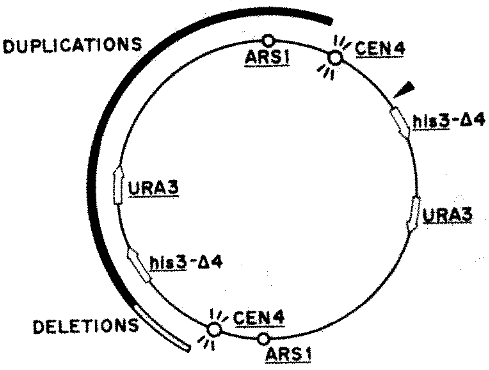

Fig. 5 A model for the origin of the duplications. A dimer of plasmid 2961 is shown. The various structural features of the plasmid are indicated. An arbitrary breakpoint near *his3* is marked by an arrowhead. The regions of the plasmid where a second break would yield a duplication (solid line) or a deletion (double line) are shown outside the plasmid.

Creation of promoters by genomic rearrangement

In almost all the *HIS3* revertants described above, a new promoter was created by a genomic rearrangement near the 5′ end of the gene. As can be seen with the tandem duplications, the distance from the start of the *HIS3* protein to the rearrangement breakpoint can be quite large, up to 500 bp.

The Ty*1* insertions are clustered more tightly than the duplications; however, the events that have been detected may reflect both the target specificity of the transposon, and the spectrum of sites from which it can activate a gene.

Activation of cryptic genes, or enhanced expression of wild-type functions by insertion of transposable elements, is found in many systems: for example, in *E. coli*, the major mechanism for activation of the genes for the metabolism of β-glucosides is the insertion of IS*1* and IS*5* (ref. 28). Similarly, the c-*myc* gene, the cellular homologue of the oncogene contained in the transforming virus MC29, is overproduced after nearby integration of a retrovirus[29].

Clearly, the orientation of the Ty*1* insertions is significant as all the insertions found here and all the insertions seen at cytochrome *c* (selecting for overproduction) and at alcohol dehydrogenase (selecting for altered regulation) are the same relative to the gene. This orientation is the reverse of that of transcription of the Ty*1* element itself[30]. One might imagine bidirectional positive control (promoter) sequences at one end of the element. Some portion of this information must reside outside the identical end repeat sequences of Ty*1*[8].

The duplications, which represent changes only in the arrangement of the plasmid DNA sequences, are more difficult to interpret. Most of the rearrangements involve only bacterial DNA sequences (λ and pBR322). Presumably several sequences which will pass for all or part of a promoter are to be found in the vector DNA; however, they do not function in their present positions. The one known functional promoter, *URA3*, has not been fused to *his3* in any of the duplications examined. This may indicate some specificity in the rearrangement breakpoints or an incompatability in the regulation of *URA3* with *HIS3* expression.

Duplication is an important mechanism in the evolution of chromosomes. It allows for new regulation of genes without loss of either the original copy of the gene or the source of the new regulation. One well-characterized example of this process is found in the mammalian globin genes. A series of related structural genes has evolved with different regulation for the various members of the family. Interspersed among these are several non-functional copies[31]. The new regulation developed after duplication need not be at the level of transcription. In the case of the immunoglobulin heavy chain constant region genes it appears to reside in additional genomic rearrangements[32].

Although the mechanism suggested above as the source of the duplications applies to circular chromosomes, duplications clearly occur in linear chromosomes. The ability to insert the promoterless *his3* derivative at almost any point in the yeast genome allows one to examine the mechanisms which may produce duplications or other rearrangements in the chromosomes.

The experiments described here indicate that genomic rearrangements can create new promoters at low but detectable frequencies. As studies on the various aspects of gene expression proceed it will become increasingly important to understand the mechanics of the chromosomes on which they reside.

We thank Robert Malone for providing strains containing the *rad*52 mutation. S.S. and C.M. were supported by NIH training grant funds. This work was supported by ACS grant no. NP-268B and NIH grant no. 21891.

Chemical evidence for the capsomeric structure of phage Qβ

Hisao Takamatsu & Koujiro Iso

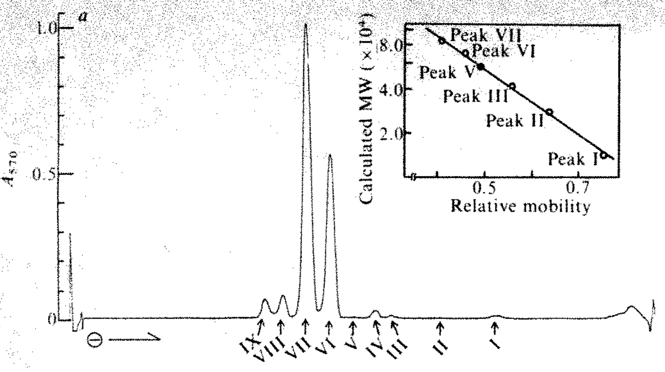
Department of Chemistry, College of General Education, University of Tokyo, Komaba, Meguro, Tokyo 153, Japan

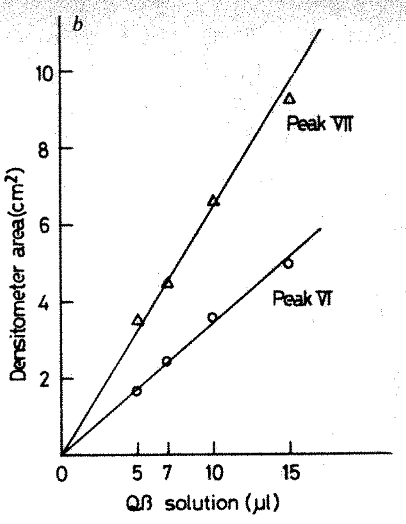
Novel capsomeric complexes, pentamers and hexamers were detected as chemical entities in phage Qβ. Both were composed of identical protein subunits and stabilized by intermolecular disulphide bonds. Their numbers per particle were about 12 for pentamers and about 20 for hexamers—consistent with theoretical expectation from the quasi-equivalent packing of 180 identical subunits in a coat protein shell.

SINCE Loeb and Zinder discovered RNA bacteriophages[1], several spherical RNA-containing coliphages have been isolated and classified into four groups according to serological and physicochemical properties[2,3]. Among them, groups I (for example, R17, f2 and MS2) and III (phage Qβ) have been extensively studied and have provided important insight into genetics and molecular biology.

A virus has a clearly defined and highly organized structure outside a cell, in contrast to the complexity of its form inside a cell. It was theoretically proposed that the protein

0028–0836/82/340819—06$01.00





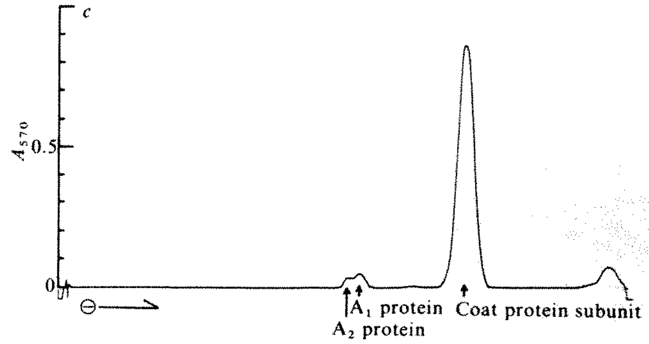


Fig. 1 SDS–polyacrylamide gel electrophoresis of phage Qβ protein. Purified phage Qβ were obtained by a published procedure[21]. Phage solution (0.05% in 0.01 M sodium phosphate, *p*H 7.2) was incubated with SDS (finally 3% w/v) at 90 °C for 30 min. Ten μl of solution were analysed by SDS–5% acrylamide gel electrophoresis according to the method of Weiner *et al.*[10]. For the first 30 min, electrophoresis was done at a constant current (2 mA per tube); it was then stopped to flush out the top of the gels with the tray buffer to remove RNA. The electrophoresis was re-started at 7 mA per tube until the marker dye had migrated 9 cm. Using this method, there was no need to separate protein and RNA before electrophoresis, and so we were able to analyse the entire protein. Gels were stained with Coomassie brilliant blue (0.25% w/v in 45% ethanol, 7% acetic acid) for 40 min and then were destained with 7% acetic acid. Gels were scanned at 570 nm with an Ozumor 82 microdensitometer. *a*, Protein peaks were designated I–IX from the peak having the highest mobility. Although peaks I–III and V were very small, they were observed when the gels were overloaded. Inset: peaks I–III, V–VII were tentatively assigned to be those of monomer, dimer, trimer, tetramer, pentamer and hexamer of coat protein subunits, as no other peaks except peak IV were observed in this region. Peak IV was later shown to be composed of A_2 protein. When their relative mobilities compared with the marker dye were plotted against their calculated MWs ($14{,}050 \times n$: n is an integer), a linear line was obtained. *b*, Various amounts (5–15 μl) of phage solution (0.05%) were electrophoresed. Each peak area of the traced patterns was measured with a planimeter. The measured areas were plotted against the applied quantities. Linearity was observed and the slope for peak VII was twice as steep as the slope for peak VI. Provided both peaks were composed of the same proteins, the weight ratio of peak VII to peak VI was 2.0. The same value was obtained after the gels were stained with Fast green which is also recommended for quantitative densitometry[22]. *c*, Phage solution was incubated with 2-ME (3% v/v) in the presence of SDS for 5 min at 90 °C. The reaction mixture was electrophoresed. The apparent MW was determined based on mobility relative to the marker proteins: ovalbumin (45,000), bovine serum albumin (67,000), chymotrypsinogen A (25,000) and myoglobin (17,800).

arrangement on the outer shell (capsid) of a virus could be predicted from a knowledge of the number of its constituent protein molecules[4]. For example, group I phage particles were estimated to contain about 180 molecules of coat protein, 1 molecule of maturation protein and 1 single-stranded RNA molecule[5]. The capsid structures were therefore considered to have a $T=3$ icosahedral symmetry[4], and, indeed, electron microscopic analysis has shown that the coat protein subunits of phages R17 and f2 are in dimer clusters based on the $T=3$ structure[6]. Phage Qβ is also predicted to have a $T=3$ icosahedral structure, as its protein composition is similar to that of group I phages, except for the presence of a few molecules of a third protein component[7] (discussed below).

Here we have approached the determination of the protein arrangement (including minor protein components) in phage Qβ, in two ways. First, by using a biochemical method, we have sought to characterize the constitutive intermediates during the assembly of protein subunits into the capsid. After the controlled dissociation of Qβ particle, we have found pentamer and hexamer complexes, presumably true constituents of a $T=3$ capsid, which are stabilized through intermolecular disulphide linkages. The capsid is estimated to consist of ~12 pentamers and ~20 hexamers. Second, using electron microscopy, we show that the Qβ capsid is composed of 32 morphological units (capsomeres) which we interpret to consist of 12 pentamers and 20 hexamers based on the quasi-equivalence theory[4]. The two approaches give consistent results.

This is the first report to describe the detection of a discrete substructure of a capsid, corresponding to a capsomere, as a chemical entity in a small spherical virus, and the verification of the quasi-equivalence theory by a chemical method. Detection of a substructure of a capsid may provide an important clue to the assembly process of a viral particle.

Specific dissociation of the phage Qβ particle

The capsid is known to be stabilized in part by hydrophobic forces between coat proteins[8], and the amino acid composition of coat protein is rich in hydrophobic residues[9]. We therefore reasoned that detergents or denaturing reagents might be useful for the disassembly of the capsid and the dissolution of the resulting products.

Phage Qβ particles were treated with SDS and the reaction mixture was subjected immediately to SDS gel electrophoresis[10]. Nine protein peaks (I–IX, in order of decreasing mobility) could be observed reproducibly (Fig. 1*a*). About 90% of the total area is comprised of peaks VI and VII, which are estimated by comparison with several marker proteins to have apparent molecular weights (MWs) of 65,000 and 78,000 respectively. As a linear relationship exists between the applied quantity of protein and peak area (Fig. 1*b*), we can estimate the weight ratio of peak VI to peak VII; the ratio is 0.5. As the phage capsid is mainly composed of coat protein subunits[5], the major peaks VI and VII probably consist of complexes of coat protein subunits.

Peaks I–III and V–VII are tentatively proposed to be monomer, dimer, trimer, tetramer, pentamer and hexamer of coat protein subunits respectively (peak IV is composed of A_2 protein, as described below). When the mobility of each peak is plotted against its calculated MW using the chemically determined MW (14,050)[11], a straight line is obtained (Fig. 1*a* inset). The pentamer of coat protein subunits (peak VI) and the hexamer (peak VII) are stable in SDS solution, so specific bonding must exist to keep these complexes intact; we suggest that it is disulphide bonding between protein subunits.

In addition to peaks VI and VII, there are seven small peaks in Fig. 1*a*. Peaks VIII and IX are particularly prominent and together comprise ~8% of the total area. Their apparent MWs are 98,000 and 110,000 respectively. The other peaks amount to only ~2% of the total area. They can be distinguished when excess amounts of phage protein are separated by electrophoresis and their apparent MWs are 52,000 (peak V), 44,000 (peak IV), 39,000 (peak III), 28,000 (peak II) and 17,000 (peak I).

Reduction of the coat protein complexes

To confirm the disulphide bonding, phage $Q\beta$ was treated with SDS in the presence of 2-mercaptoethanol (2-ME). As shown in Fig. 1*c*, three peaks can be observed, with mobilities corresponding to those of peaks I, III and IV. For convenience, the peaks have been designated peaks I, III and IV.

Peak I comprises ~94% of the total area, and peaks III and IV ~4% and ~2% respectively. The amount and relative mobility of each peak are consistent with published data[7,12,13] and we conclude that peaks I, III and IV consist of coat protein subunit, A_1 (or IIb)[7] protein and A_2 (IIa)[7] protein respectively. The apparent MW of the coat protein subunit is estimated to be higher in our system than the chemically determined MW; similar values[14,15] have been obtained by SDS-gel electrophoresis. These results show that our sample of phage $Q\beta$ is of sufficient purity and further confirm that the components of low mobilities (as shown in Fig. 1*a*) are held by intermolecular disulphide bonds.

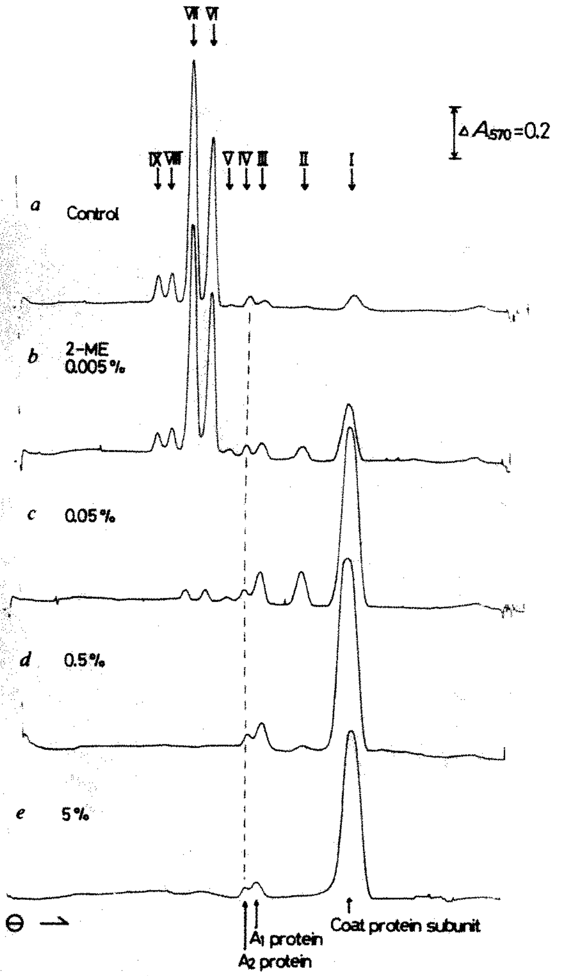

Fig. 2 Partial reduction of phage protein complexes. To the phage solution (0.05%, 10 μl) was added an equal amount of 0%, 0.01%, 0.1%, 1.0%, or 10% (v/v) 2-ME solution and the mixture was incubated for 20 min at room temperature. Immediately afterwards, reaction mixtures were electrophoresed. After treatment with 0.005% 2-ME, peaks I–III and V were increased compared with the non-treated sample. When the pattern of the 0.05% 2-ME treated sample was compared with that treated with 0.005% 2-ME it was clear that peaks VI–IX had decreased and peak I had increased. In the presence of 0.05–5% 2-ME, peak I still increased, while peaks II, V–IX disappeared. Peak III decreased, but remained as in Fig. 1*c*. Peak IV was not affected by these treatments.

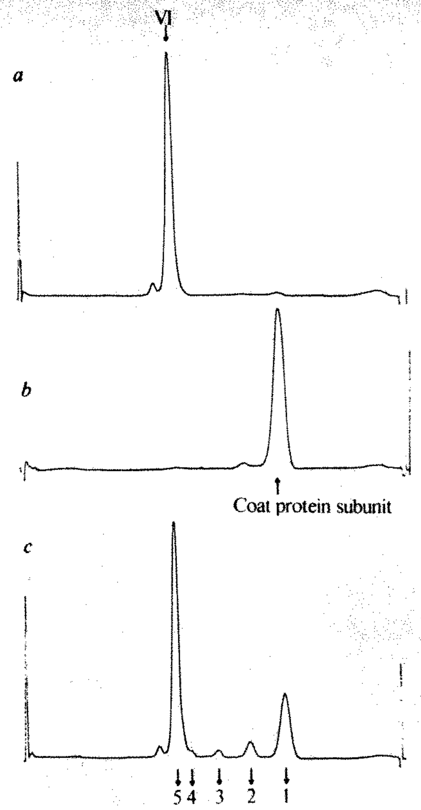

Fig. 3 Analysis of peak VI composition. Phage proteins were electrophoresed without treatment with 2-ME, as described in Fig. 1*a* legend. After electrophoresis, gels were frozen and sliced in 1-mm sections. Protein was then eluted from each slice into 0.2 ml of 0.1% SDS overnight at 37 °C with agitation. The protein solutions were divided into three parts: *a*, no further treatment and electrophoresed; *b*, treated with 5% 2-ME for 20 min at room temperature and then electrophoresed; *c*, treated with 0.005% 2-ME and immediately electrophoresed. As shown in *a*, the protein from peak VI was obtained. After treatment with 5% 2-ME, the peak of coat protein subunit was observed. In *c*, four new peaks can be seen, which have the same mobilities as peaks I–III and V in Fig. 1*a*. When the peaks were numbered as indicated by the arabic figures in *c*, peak VI was the fifth peak. No other peaks were detected in any other conditions. Peaks 1–5 had the same mobilities as peaks I–III, V and VI in Fig. 1*a* respectively.

We next tried to obtain an intermediate pattern between those of Fig. 1*a* and *c*. Phage $Q\beta$ was treated with various concentrations of 2-ME in the presence of SDS. Significant changes could be seen (Fig. 2): further reduction decreased peaks VI and VII, and increased peak I. Peaks VIII and IX decreased in the same manner as peaks VI and VII. At the intermediate degree of reduction, peaks II, III and V increased slightly, in a reproducible fashion. These peaks were further diminished at greater concentrations of 2-ME. After complete reduction, only three constituent proteins of phage $Q\beta$ could be observed. These results show that the complexes disassemble via intermediate products to the constituent protein subunits. These intermediates proved helpful in determining the structure of the complexes (see the following).

Structure of the specific complex

To determine the constitution of each peak, the gel was cut into slices and the protein eluted from each slice. The protein of peak VI was isolated, as shown in Fig. 3*a*. Reduction with 2-ME shifted the mobility of the protein peak to that corresponding to coat protein subunit (Fig. 3*b*). Thus peak VI was composed solely of coat protein subunits. The next question was how many coat protein subunits make up the complex of peak VI? As partial reduction of the complex led to the production of intermediates, in this case oligomers of coat protein subunits, it was possible to determine the polymerizing number of the original complex from the order of the intermediate oligomers. After mild reduction of the complex, four new peaks

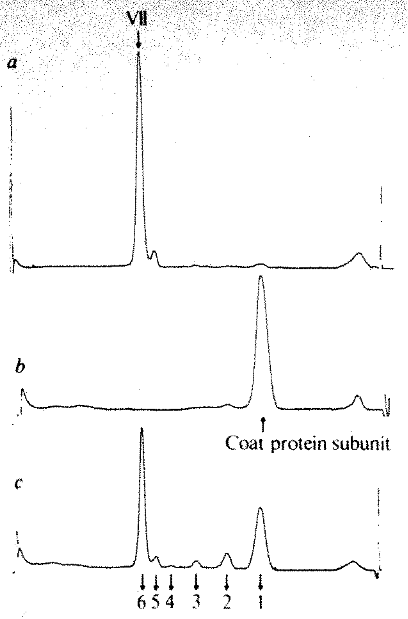

Fig. 4 Analysis of peak VII. The protein of peak VII was eluted from the sliced gel as described in Fig. 3 legend. The protein solution was treated with 0% (*a*), 5% (*b*) and 0.005% (*c*) 2-ME and then electrophoresed. After treatment with 5% 2-ME, only the peak corresponding to coat protein subunit was observed. Thus, peak VII was shown to consist of coat protein subunits. In *c*, six peaks were observed and no other peak could be detected in any other conditions. When the peaks were numbered as indicated by the arabic figures in *c*, peak VII was the sixth peak. Peaks 1–5 showed the same mobilities as corresponding peaks in Fig. 3*c*.

could be observed (Fig. 3*c*). No other peaks could be detected using different conditions, although greater reduction led to conversion of high molecular weight complexes to low molecular weight ones. Thus the four peaks are successive oligomers of coat proteins—monomer to tetramer. Therefore, the original complex (peak VI) must be a pentamer of coat protein subunits.

Peak VII (Fig. 4*a*) was analysed in the same way. Complete reduction leading to its full dissociation yielded only coat protein subunits, showing that peak VII consists of only coat protein subunits (Fig. 4*b*). With intermediate reduction, six peaks could be observed (Fig. 4*c*). No other peaks could be observed in different conditions, and the mobilities of the six peaks were the same as those of peaks I–III, V–VII in Fig. 1*a*. Thus peak VII consists of hexamers of coat protein subunits.

Next, peaks VIII and IX were examined. Because of their low mobilities, the separation distance between these peaks was relatively short compared with that between high-mobility peaks. Protein fractions eluted from the sliced gels therefore contained components of both peaks, in various ratios, depending on the position of the slices (peaks IX : VIII 10.1, 8.5, 3.0 and 0.7 in Fig. 5*a–d*). After treating each fraction with 2-ME, two peaks could be observed (Fig. 5*a–d*, lower patterns). The low-mobility peak corresponds to A_1 protein and the other to coat protein subunits. The molar ratios of coat protein subunit to A_1 protein are 4.6, 4.3, 4.1 and 4.9 in Fig. 5*a–d* respectively, assuming MWs of 39,000 for A_1 protein (electrophoretically determined) and 14,050 for coat protein subunit (ref. 11), and that the peak area is proportional to the applied quantity of protein, as shown in Fig. 1*c*. The high molar ratio for Fig. 5*d* is thought to be due to the contamination of peak VII (15%) which consists of coat protein subunits. On the basis of the molar ratios of A_1 protein to coat protein subunit, as well as the MWs of peaks VIII and IX, it is concluded that peak VIII consists of one A_1 protein molecule and four coat protein subunits, and peak IX consists of one A_1 protein molecule and five coat protein subunits. As the difference of the apparent MWs between peaks VIII and IX (12,000) equals that between peaks VI and VII (13,000), it is reasonable to conclude that the complex of peak IX is larger by one coat protein subunit than that of peak VIII.

Minor peaks I–III and V show the same mobilities as monomer, dimer, trimer and tetramer of coat protein subunits. It was observed, however, that the size of peak III increased with intermediate reduction and after full reduction it remained as an A_1 protein (Fig. 2). This suggested that peak III is a mixture of coat protein trimer and A_1 protein; this has been confirmed by a reduction experiment of the isolated components (not shown). Peak IV was not changed by treatment with various concentrations of 2-ME (Fig. 2), and after isolation, peak IV was shown to be composed of A_2 protein.

These results show that ~90% of the total phage protein is in the form of pentamers and hexamers, both of which are composed of only coat protein subunits. Accordingly, about 95% of all the coat protein subunits is calculated to be in the form of pentamers and hexamers since the fraction of the coat protein subunits in the whole phage protein is ~94%. The remaining coat protein subunits mostly form pentamers and hexamers with the A_1 protein molecules (peaks VIII and IX). Since the amount of A_1 protein is ~4% of the total phage protein and ~40% of peaks VIII and IX consists of A_1 protein, most of the A_1 protein molecules are in the form of pentamers and hexamers with coat protein subunits. A_2 protein does not form such a complex.

Capsid structure model

To formulate a model of the phage Qβ capsid, we had to determine the contribution from each component. The total weight of protein per particle is 2.7×10^6 daltons, using the reported MW of 4.2×10^6 for the the phage particle[16] and 1.5×10^6 for its RNA[17]. About 90% of all the protein is in the form of pentamers and hexamers which are made up of the

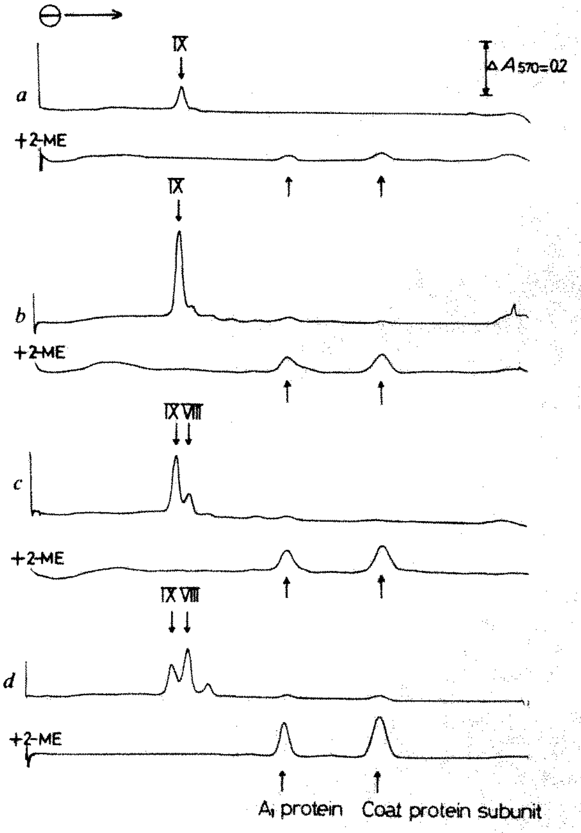

Fig. 5 Analysis of peaks VIII and IX. Protein was eluted from each sliced gel which contained the components of peaks VIII and IX. The ratio of components of peak IX to peak VIII were different in each slice: 10.1 (*a*), 8.5 (*b*), 3.0 (*c*) and 0.7 (*d*). There was a significant amount of peak VII (15%) (shown in *d*). The protein solutions were electrophoresed after treatment with 5% 2-ME (lower) or without treatment (upper). After treatment, two peaks were observed: the high-mobility one corresponds to coat protein subunit and the other to A_1 protein. The area ratios of coat protein subunit to A_1 protein were 1.64 (*a*), 1.54 (*b*), 1.49 (*c*) and 1.78 (*d*). The value for *d* was high due to the contamination of peak VII.

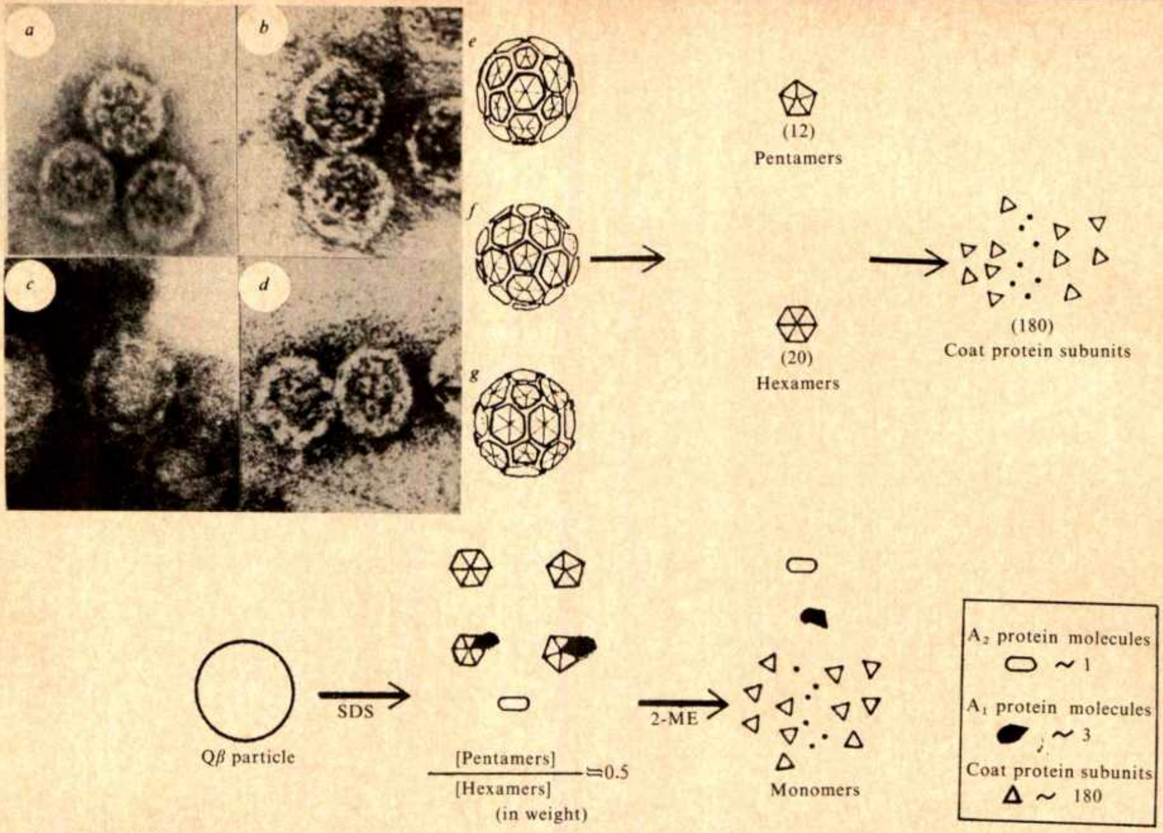

Fig. 6 Summary of electron microscopic (upper half) and chemical (lower half) observations. Phage Qβ particles were observed by electron microscopy as described previously[23] although they were stained with phosphotungstate. The phage Qβ was a spherical particle (mean diameter ~250 Å). On the particle surfaces, morphological units (capsomeres) were observed, which appeared as a hollow cylinder (~30 Å high and ~60 Å diameter with a ~25 Å diameter hole). Capsomeres were regularly arrayed on the particle in four ways: *a*, one capsomere surrounded by six capsomeres; *b*, one capsomere surrounded by five capsomeres; *c*, 10 capsomeres at the periphery of a partcle; *d*, four capsomeres arranged at the four corners of a lozenge respectively. Based on the electron microscopy observations, the particle model was constructed, in which capsomeres were located at each apex (12) and on each facet (20) of a icosahedral structure. The capsomeres at 3-fold axes were drawn as hexagons and those at 5-fold axes as pentagons. The model is illustrated, viewed along the 3-fold axes (*e*), along the 5-fold axes (*f*) and along the 2-fold axes (*g*). According to the quasi-equivalence theory[4], the capsomeres located at the 3-fold axes are hexamers and those at the 5-fold axes are pentamers. Then, the total number of subunits can be estimated to be $5\times12+6\times20=180$. Lower half: schematic drawings summarizing the chemical study. After phage Qβ particles were treated with SDS, pentamers and hexamers of coat protein subunits were produced in a weight ratio of 0.5:1. In addition, A_1 protein-containing pentamers and hexamers were detected as minor products. These pentamers and hexamers were dissociated to subunits after reduction with 2-ME. It was calculated that one particle contained as protein components ~180 coat protein subunits, ~3 A_1 protein molecules and ~1 A_2 protein molecule.

coat protein subunits, and the weight ratio of pentamer to hexamer is 0.5. The number of these complexes per particle, therefore, is calculated to be 11.5 for the pentamers and 19.2 for the hexamers, based on the chemically determined MW of the coat protein subunit (14,050). On the other hand, A_1 protein-containing pentamers and hexamers comprise ~8% of the total amount of protein and are present in an equal amount per particle. There are thought to be about one of each per particle, based on their MWs ($95{,}000=39{,}000+14{,}000\times4$ for the pentamer; $109{,}000=39{,}000+14{,}000\times5$ for the hexamer). Therefore, it is estimated that, on the average, one particle contains ~12 pentamers and ~20 hexamers. In addition, the particle contains A_2 protein as a minor component (~2% of total protein). As the MW of A_2 protein is 44,000, we estimate there is about one A_2 protein per particle; this is in good agreement with published data[9].

The presence of 12 pentamers and 20 hexamers is consistent with a structure based on the $T=3$ icosahedral surface lattice[4], but the symmetry cannot be exact since only some of the pentamers and hexamers contain A_1 protein, and we do not know the location of the one copy of A_2 protein per particle.

Electron microscopy

The relationship between the chemically obtained complexes and the morphologically expected units on the capsid was investigated by observing Qβ particles by electron microscopy. The Qβ particle appeared as a regular, spherical particle (~250 Å in diameter) with surface morphological units (capsomeres) consisting of hollow cylinders (~30 Å high and ~60 Å in diameter with a ~25 Å diameter hole) (Fig. 6). Capsomeres were regularly arrayed on the surface in one of four patterns: (1) one capsomere surrounded by the six nearest capsomeres (Fig. 6*a*); (2) one capsomere surrounded by the five nearest capsomeres (Fig. 6*b*); (3) ten capsomeres radially arranged at the periphery of a particle (Fig. 6*c*); (4) four capsomeres arranged at four corners of a lozenge respectively (Fig. 6*d*). These patterns would correspond to views of different sides of an icosahedral structure model as illustrated in Fig. 6, in which six capsomeres were arrayed around 3-fold axes (*e*), five capsomeres arrayed around 5-fold axes (*f*), 10 capsomeres located at the periphery (*f*) and four capsomeres arrayed in the 2-fold symmetrical position (*g*). From such consistency, it is concluded that the Qβ capsid is composed of 32 capsomeres, arranged in an icosahedral symmetry (details will be published elsewhere by H. T., H. Funakoshi and K. I.). These morphological observations are consistent with the chemical estimation of the number of pentamers and hexamers per particle.

Protein subunits and icosahedral capsid structure

We have demonstrated that the pentamers and hexamers are stabilized by intermolecular disulphide linkage. As the coat protein subunit (131 residues) has two cysteine residues at positions 73 and 79 (ref. 11), pentamers and hexamers of coat protein subunits can be held by successive disulphide bonds between subunits. Although we have no direct evidence of disulphide bonds in the particle, we believe this to be the case; even when Qβ particles were disassembled at the low pH (pH<4) or in the presence of an excess amount of iodoacetic acid[18] most of the coat protein subunits were in the form of pentamers and hexamers, in the ratio of 0.5 pentamers to 1.0 hexamer. Furthermore, spectrophotometric studies using 5, 5′-dithiobis(2-nitrobenzoic acid) in the presence of guanidine hydrochloride or SDS[19] showed most of SH groups were blocked (not shown). Pentamers and hexamers were clearly detected as chemical entities, although it remains to be determined whether the disulphide bonds are formed before or after virus assembly.

A_1 protein is known to be synthesized by the failure of termination of translation of coat protein cistron[12,13], but its role is unknown, though the protein was reported to be essential for the formation of infectious particles[20]. We have shown here that an A_1 protein molecule is substituted for a coat protein subunit in a pentamer and a hexamer. A_1 protein may bind coat protein subunits through the same contact between coat protein subunits since the N-terminus of A_1 protein molecule is identical to the entire stretch of coat protein subunit. A_1 protein may thus serve to modify the surface structure rather than to introduce a different intermolecular contact.

We particularly thank Professor Itaru Watanabe for giving us the opportunity to investigate phage Qβ and for stimulating advice, also Drs K. Furuse, T. Shiba, H. Akanuma, H. Funakoshi, M. Moroi and S. M. Jung for helpful suggestions and Professor M. Yamasaki for encouragement. This study is supported in part by Scientific Grants from the Ministry of Education, Science and Culture of Japan.

Is there a local source of magnetic monopoles?

Cabrera[1] has reported the possible detection of a magnetic monopole in flight with magnetic charge g given by the Dirac condition[2] $2eg = \hbar c$. Here, we accept the Cabrera candidate as a t'Hooft–Polyakov[3,4] monopole of mass $M \sim 10^{16}$ GeV as expected[5] in SU(5) or other grand unified theories. The monopole flux on Earth, on the basis of the single candidate, is $f \sim (0.1)$ cm^{-2} yr^{-1} $(2\pi$sr$)^{-1}$, presumably consisting of roughly equal numbers of north and south monopoles. Galactic or intergalactic monopoles will have typical velocities of ~ 300 km s^{-1}. The Cabrera flux would correspond to a mass density $fM/v \sim 1$ GeV cm^{-3}. Because the mean mass density of the Universe cannot exceed 10^{-5} GeV cm^{-3}, the mean flux of monopoles in the Universe must be at least five orders of magnitude smaller than f (refs 6,7). This would not be a problem if the monopoles were concentrated in the Galaxy. However, Parker has shown[8] that the existence of galactic magnetic fields is inconsistent with a mean galactic monopole flux of 10^{-7} cm^{-2} yr^{-1}. It follows that f must be a local flux resulting from the special nature of the observation site. Three possibilities come to mind: the local monopole flux may be associated with the Earth, the Sun, or with the Solar System as a whole.

If the monopoles observed at the Earth's surface originate from the core, as does the local magnetic field, and if the flux is not time dependent, the Earth has emitted more than 10^{27} monopoles since its birth, implying an initial (or present) monopole density $n \sim 1$ cm^{-3}. However, the density of monopoles in the Earth's core is bounded by[8]

$$n < B/8\pi g v \tau \qquad (1)$$

where $\tau = 10^4$ yr is the characteristic growth time of the geomagnetic field, v is the monopole velocity within the core, and B is the magnetic field within the core. With a core field ~ 100 G, we expect $v \sim 3$ km s^{-1} on the basis of either magnetic or gravitational force arguments. This gives a limit $n < 10^{-9}$ cm^{-3}. Thus, the Cabrera flux cannot originate from the Earth.

Can the monopole flux seen on Earth originate from the Sun, in the fashion of radiant energy or solar wind? If so, the Sun has emitted (and presumably still contains) some 10^{36} monopoles. This implies a mean solar monopole density $n \sim 10^3$ monopoles cm^{-3}, with 10^{-5} of the solar mass made up of monopoles. If the monopoles are gravitationally bound to the Sun, they must have velocities ~ 400 km s^{-1} and kinetic energies $\sim 10^{10}$ GeV. They will lose energy in nuclear collisions, and by inducing currents in the highly conductive solar medium. The energy they dissipate by these losses must be compensated by magnetic acceleration. Thus, there must be a mean interior magnetic field in the Sun of $\sim 10^3$ G so that

$$g\langle B \rangle \sim \mathrm{d}E/\mathrm{d}x \sim 10 \text{ MeV cm}^{-1} \qquad (2)$$

The characteristic time of the solar interior field is assumed to be ~ 20 yr, the period of the sunspot cycle. With these values of B and τ, equation (1) yields an upper bound on the density of monopoles in the Sun, $n < 10^{-7}$ cm^{-3}. Moreover, the ohmic loss due to 10^{36} orbiting monopoles is $\sim 10^5 L_\odot$. For both these reasons, it is difficult to explain the observed monopole flux in terms of a direct solar flux. Of course, it could be that most of the solar monopoles are concentrated in the centre of the Sun, and are only rarely extricated by transient magnetic fields. Escape velocity for these monopoles is $\sim 1{,}400$ km s^{-1}, which would require magnetic fields $\sim 10^5$ G over distances $\sim R_\odot$.

Can the local monopole flux result from a diffuse cloud of monopoles which are in newtonian orbits about the Sun, rather

---

0028-0836/82/340824-02$01.00

like meteorites and meteoritic dust? Their velocities about the Sun will then be $\sim 30\ \mathrm{km\ s^{-1}}$, while their arrival velocities at Earth will vary from 10 to $70\ \mathrm{km\ s^{-1}}$ as do the arrival velocities of meteorites. Their density must be $\sim 10^{-15}\ \mathrm{cm^{-3}}$ to explain the observed flux, corresponding to $\sim 10^{24}$ monopoles within the Earth's orbit. These monopoles are subject to a solar magnetic field $\sim 3\times 10^{-5}$ G, and a consequent magnetic force which is $\sim 10^{-4}$ of the solar gravitational force. Following Parker[9], we have estimated the time over which the magnetic perturbation significantly alters the energy of a monopole in solar orbit. We assume that the distant solar magnetic field fluctuates over a time scale of half a solar rotation period, $T = 10^6$s, and that its magnitude at 1 AU is 3×10^{-5} G. The residence time of a monopole in solar orbit is given by[9]

$$t = (v/c)^2 T^{-1} \omega^{-2} \tag{3}$$

where $\omega = gB/Mc \sim 2\times 10^{-15}$ Hz. We find $t \sim 100$ Myr. The eventual fate of the orbiting monopoles will be to fall into the Sun, or to escape the Solar System. In any case, to maintain the local monopole flux, a source of $\sim 10^9$ monopoles per second is required.

We must verify that the monopole flux on the Earth does not generate too great a monopole density within the Earth. The incident monopoles have kinetic energy $\sim 10^8$ GeV and lose $\sim 1\ \mathrm{MeV\ cm^{-3}}$ (hence $\leq 10^6$ GeV) as they traverse Earth. They pass through the Earth without stopping. Their density, $n \sim 10^{-15}\ \mathrm{cm^{-3}}$, is well within the bound set by equation (1).

The monopole cloud of the Solar System is maintained either by an external (cosmic) or internal (solar) flux. Cosmic monopoles traversing the Sun may lose enough energy by ohmic losses or magnetic deceleration to be captured into solar orbit. Indeed, $\sim 10^9$ monopoles per second pass through a hypothetical sphere of solar radius if the Parker bound on the flux of galactic monopoles is saturated. The actual number impacting the Sun is larger by the factor $[(1+(v_E/v)^2]$ where v is the monopole velocity and $v_E \sim 600\ \mathrm{km\ s^{-1}}$ is the escape velocity from the Sun. As $\langle v\rangle \sim 300\ \mathrm{km\ s^{-1}}$, the enhancement is considerable, particularly for slower monopoles. The Sun may well capture enough monopoles to sustain its cloud.

On the other hand, the cloud may be fed internally by a flux of $\sim 10^9$ monopoles per second which is extracted from the Sun by solar flares. Either mechanism implies a solar monopole number of $\sim 10^{26}$ and a density of $n \sim 10^{-7}\ \mathrm{cm^{-3}}$, corresponding to an acceptable ohmic dissipation of $10^{-5} L_\odot$. With kilogauss mean fields, equation (2) is satisfied. The limit on monopole density given by equation (1) is just saturated, a result whose significance we discuss below.

Simple considerations of magnetic diffusivity yield the expression $\tilde{T} = (4\pi\sigma/c^2)R^2$ for the characteristic time of the solar magnetic field. This is known to overestimate $\tilde{T}$ by six orders of magnitude[8]. In the presence of monopoles, $\tilde{T}$ is correctly determined to be ~ 20 yr by the magnetic dissipation time given in equation (1).

Monopoles within the Sun can have other significant effects. They can lead to a lower central temperature by promoting heat transfer from the solar interior, or by catalysing nuclear fusion or nucleon decay. This could ameliorate the solar neutrino problem.

It is suggested that magnetic monopoles may have a substantial cross-section σ to induce nucleon-number violating processes such as

$$\text{Monopole} + p \rightarrow \text{Monopole} + (e^+ \text{ or } \pi^+\bar{\nu}). \tag{4}$$

This process can be observed directly as monopoles pass through material on Earth; it can contribute to energy production in the Sun; and it can act as a source of high-energy solar antineutrinos which can be detected on Earth. Monopole-induced nucleon decay, seen in the laboratory, will not seem to conserve momentum because the recoiling monopole is not detected. A limit can be placed on σ from known limits on the nucleon lifetime: $f\sigma < \tau_p^{-1}$ where τ_p is the lower limit on the proton lifetime in experiments where momentum conservation is not imposed. Taking $\tau_p > 10^{29}$ yr, we obtain $\sigma < 10^{-28}\ \mathrm{cm^2}$. With this cross-section, catalytic nucleon decay within the Sun can account for no more than $10^{-6} L_\odot$. However, this process can also yield GeV electron antineutrinos, with a flux on Earth as high as $10^3\ \mathrm{cm^{-2}\ s^{-1}}$. A search for this kind of solar emanation is called for.

The net flux of monopoles from all stars in the Galaxy would amount to 10^{28} monopoles per year. These will be accelerated by galactic magnetic fields to an escape energy of 10^{10} GeV, requiring an energy source of $10^{38}\ \mathrm{GeV\ yr^{-1}}$. This is easily compatible with the estimated energy content of the galactic magnetic field $(B^2/8\pi)V \approx 10^{57}$ GeV and a restoration time of one galactic period, or 10^8 yr.

We conclude that the Cabrera flux of magnetic monopoles can be understood in terms of an orbiting cloud of monopoles in the Solar System, which is replenished by a small 'monopole wind' from the Sun or from the Galaxy. Monopoles may have an important role in solar energetics. Our hypothesis can be established if the monopole flux on Earth is shown to be similar (in velocity distribution, angular distribution, and its seasonal and diurnal variations) to the observed flux of meteorites, except for the fact that monopoles (but not meteorites) pass freely through the Earth.

Interstellar scintillation and pulsar velocities

A. G. Lyne & F. G. Smith

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Macclesfield, Cheshire SK11 9DL, UK

Interstellar scintillation of the intensity of pulsar radio signals is known to be the effect of diffraction in random irregularities in electron density, with typical scales of 10^{13} cm and density fluctuations of typically $3\times 10^{-4}\ \mathrm{cm^{-3}}$. The observed fading pattern is believed to be due to the combined motion of the pulsar and the observer relative to an effectively stationary and quasi-static interstellar medium; this has, however, not been clearly demonstrated so far, and the possibility has remained open that the fluctuations are due at least partly to streaming or wave motions in the medium. Recent measurements of the proper motion of pulsars by radio interferometry[1] now allow a direct test. We present here new observations which show that the scintillation characteristics of pulsars are closely related to their velocities, as measured by their proper motions.

The basic theory of scintillation was presented by Scheuer[2], who analysed the effect of a thin screen of irregularities. An analytical solution for irregularities filling the whole path, and with a gaussian distribution of sizes, is due to Lerche[3], who extended previous work by Lee and Jokipii[4]. (For a review of theory and observations see ref. 5.)

$V_s = 4.36\times10^4\,(BD)^{1/2}\tau^{-1}$ V_t is the transverse velocity from ref. 1.
* Pulsars for which a separate series of observations was made at 930 MHz.
† Scintillation patterns exhibiting frequency drifting.

The velocity V of the pattern past the observer can be obtained from the characteristic time of fading τ provided that the scale S is known. Spaced receiver observations are of little use in determining S, as it is typically larger than the Earth's diameter. It is, however, closely related to the frequency structure of the pattern observed at a single site. This arises from the relation between multi-path propagation and θ, the angular spread of waves constituting the diffraction pattern. Lee and Jokipii[4] show that the scale S is related to θ by

$$S = V\tau = 0.113\,\lambda/\theta \tag{1}$$

and the correlation bandwidth Δf is related to θ by

$$\Delta f = \frac{c}{\pi D \theta^2} \tag{2}$$

where D is the distance of the pulsar. Hence at 408 MHz

$$V = 4.80\times10^4\,(D\Delta f)^{1/2}\tau^{-1}\ \mathrm{km\ s^{-1}} \tag{3}$$

where the units of D, Δf and τ are kpc, MHz and s.

In equation (1) we have chosen the relation for a Kolmogorov power law distribution of irregularities, in contrast to a gaussian distribution: the coefficient differs only by ~10%, but there is some evidence in favour of the power law even though there is as yet no complete analytical solution for diffraction in that case[6]. The bandwidth Δf in equation (2) is the frequency separation at which the correlation falls to 0.5.

We measured the characteristic fading time and correlation bandwidth at 408 MHz for 20 pulsars whose proper motions are known[1]. Observations were made with the Mark 1A radio telescope, with an integration time of 1 min and frequency resolutions of 0.5 MHz and 0.125 MHz, using eight adjacent frequency bands. A typical observation on one pulsar lasted 3 hours. The bandwidth and time scales were found by fitting gaussian autocorrelation functions: this is formally correct only for the time scales as the autocorrelation function in frequency, although not precisely known, probably resembles the more complex function given by Lerche for the restricted case of a gaussian distribution of irregularities. We tabulate vaues of τ and of bandwidth B both as values where the autocorrelation falls to $1/e$ and assumed that $B \approx 1.2\,\Delta f$.

In fitting gaussian functions we allowed both the height of the function and its zero level as degrees of freedom; this allows for broadband intrinsic variations in the pulsar signal both on short and long time scales, as discussed by Roberts and Ables[6].

For some pulsars for which the frequency structure was not resolved with these bandwidths, a separate series of observations was made at 930 MHz using a frequency resolution of 0.5 MHz in eight adjacent bands; the time scales and bandwidths were scaled to 408 MHz assuming that $\tau \propto \nu$ and $B \propto \nu^4$. These pulsars are indicated in Table 1.

The scintillation pattern for some pulsars shows organized frequency drifting. For these, marked in Table 1, we have taken the bandwidth as the maximum, following the slope of the frequency drift. We find that values of τ and B generally repeat within ~20–30% from day to day. Some doubtful values are enclosed in parentheses in Table 1.

Figure 1 shows the relation between the observed transverse speed of the pulsar (from proper motion) and the quantity $4.36\times10^4\,(DB)^{1/2}\tau^{-1}$ where D is the distance of the pulsar as used by Lyne *et al.*[1] in obtaining the proper motion. The theoretical relation is a line of slope unity through the origin.

Part of the correlation in Fig. 1 might arise artificially as a result of errors in the estimates of the distance D, as the ordinate contains a factor of D and the abcissa contains $D^{1/2}$. We therefore show in Fig. 2 the same results as an angular measure, that is as measured and expected proper motions. These quantities are entirely independent, and the correlation is seen to be at least as good as in Fig. 1.

The fact that there are roughly equal numbers of pulsars above and below the theoretical line in Fig. 2 is indicative of the success of the theory described earlier and of the model of the electron density distribution used to derive the distances[7]. The scatter in Fig. 2 is attributable to measurement errors of the proper motion, scintillation time scales and bandwidths as well as errors in the assumed distances. The small amount of scatter indicates that even in individual cases the distance estimates cannot be very much in error.

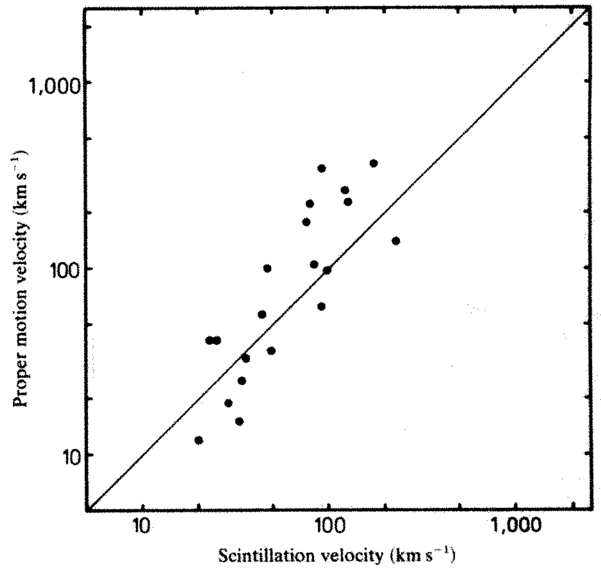

Fig. 1 The transverse speeds of 20 pulsars measured by their proper motions and compared with the speeds deduced from their scintillation characteristics.

We note that there is a good relation in Fig. 1 between observed and calculated speeds. The lower speeds obviously can be affected by the Earth's orbital velocity of 30 km s^{-1}: we suggest that this accounts for the larger than expected scintillation speeds for those pulsars having proper motions less than about 30 km s^{-1}. In contrast we note that most of the derived

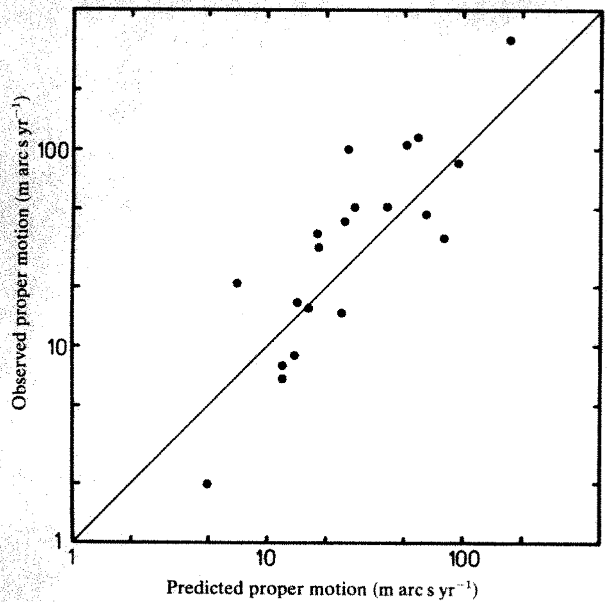

Fig. 2 The data of Fig. 1 expressed as angular motions: that is, a comparison between measured proper motions and angular speeds deduced from scintillation characteristics.

speeds of the faster moving pulsars are underestimates of the true values by a factor of about 2.

The agreement between theory and observation suggests that the irregularities are fairly evenly distributed between the pulsar and the observer. Most of the faster moving pulsars, for which the diffraction pattern is moving at about half the speed of the pulsar itself, are at large distances from the galactic plane: for these it is reasonable to suggest that the irregularities are concentrated within the half of the path closest to the observer. The main effect of such a concentration is a leverage which reduces the speed of the pattern by a factor of the order of 2.

These observations show that scintillation fading rates are directly related to the transverse velocities of the pulsars, with no appreciable contribution from velocities within the interstellar medium. This is in accordance with observations by Galt and Lyne[8] who used simultaneous reception at widely spaced sites to obtain correct values for the magnitude and direction of the velocity of PSR0329+54. Some other observations, by Rickett and Lang[9] and by Slee *et al.*[10], also using spaced receivers, gave a contrary indication, and found apparent reversals of velocity in the diffraction pattern: however, as Hewish[11] pointed out, these may have been the effect of frequency drifts in the pattern combined with small differences in receiver frequency.

We now suggest that the apparent speeds deduced from scintillation measurements alone may provide a useful indication of the magnitudes of the actual speeds of the pulsars, even at distances so large that proper motion itself cannot be directly observed.

Inclinations of the uranian rings

R. G. French*†, J. L. Elliot*‡ & D. A. Allen§

Rings formed with the birth of a planet are thought to arise after planetary condensation, from material remaining within the outer accretion limit—which has a radius of approximately two planetary radii, depending on the density of the material and the relative size of the particles[1,2]. Although the initial distribution of particles would be spherical, collisions would cause rapid evolution of the particle orbits into circular orbits in the equatorial plane of the planet[3]. Also, gaps might form at the position of strong resonances with the planet's satellites, in an otherwise broad ring. Observations of planetary rings at high spatial resolution have revealed a more complex situation. The nine confirmed uranian rings are narrow, not broad, and most have elliptical orbits, not circular. Furthermore, the Voyager observations have shown that Saturn's rings consist of a multitude of narrow ringlets, at least some of which have elliptical orbits. Here we report an additional feature that we have found for the uranian ring orbits, not predicted by current theoretical models: at least seven of the nine rings have orbits inclined to the equatorial plane of Uranus.

The kinematic models for the uranian ring orbits have become increasingly sophisticated as more occultation timings have expanded the data base over the past 5 yr. The first kinematic model[4] included only the α, β, γ and δ rings. It assumed their orbits to be circular, in a common plane that is coincident with the mean orbit plane of the five known uranian satellites. This would presumably be the equatorial plane of Uranus. The first improvement to the original model was made by Nicholson *et al.*[5], who demonstrated that the ϵ ring is elliptical and precesses under the influence of the first spherical harmonic in the uranian potential field. Following this, elliptical models were formulated for all the known rings, and six of the nine were found to have measurable ellipticities[6–9]. The most complete model[9] treats all nine rings as co-planar ellipses, precessing under the influence of the first two even harmonics of the uranian gravity potential; this model also includes the coordinates of the common orbit pole as free parameters. This model included 43 free parameters and was fitted by least squares to 105 occultation timings. The r.m.s. post-fit residual from this model is 0.31 s per degree of freedom, somewhat larger than the error of an occultation timing, which is <0.1 s in most cases. Hence, Elliot *et al.*[9] concluded that this discrepancy implied that modelling the ring orbits as co-planar ellipses is not adequate and the situation must be more complex.

Although not expected on the basis of traditional models of ring formation[3], the next step in a more complete kinematic model would include inclinations of the individual ring orbits to the equatorial plane of Uranus. For each of the nine rings we added two free parameters to our model: i, the inclination of the ring with respect to the uranian equatorial plane, and Ω_0, the angle between the line of nodes of the ring orbit and a common reference line in the equatorial plane.

An inclined, elliptical ring undergoes both precession in its orbit plane and regression of its orbital nodes. The rate of

0028-0836/82/340827—03$01.00

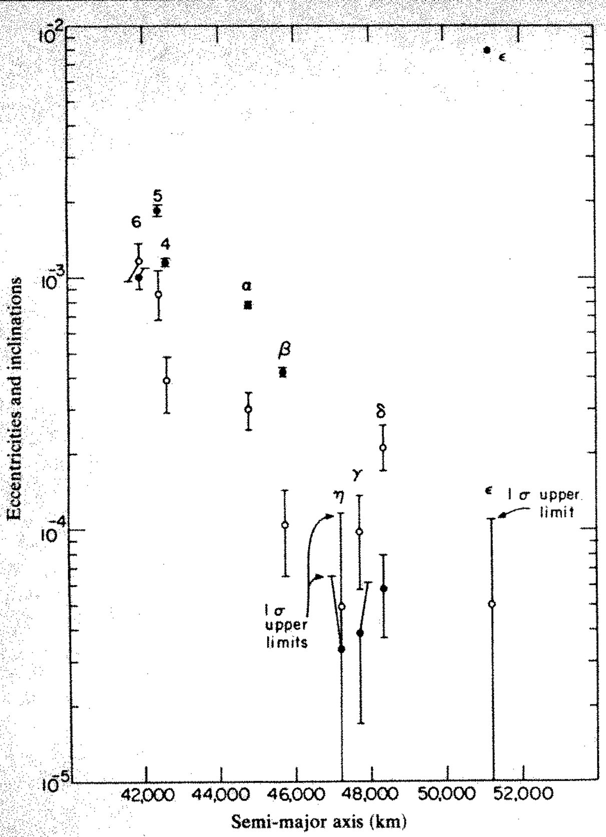

Fig. 1 Eccentricities (●) and inclinations (○) of the uranian rings. The eccentricity and inclination (in rad) for each of the nine presently known rings is plotted against the semi-major axis. Except for the eccentricity of the ε ring, the *e*s and *i*s show a decreasing trend with increasing semi-major axis. The eccentricities of the η and γ rings, as well as the inclinations of the η and ε rings, are not large enough to be statistically significant.

precession, $\dot{\varpi}$, is given to second order in i, e and J_2 by the expression

$$\dot{\varpi}=\left(\frac{GM}{a^3}\right)^{1/2}\left\{\frac{3}{2}J_2\left(\frac{R}{a}\right)^2(1+2e^2-2i^2)-\frac{15}{4}J_4\left(\frac{R}{a}\right)^4\right\} \quad (1)$$

where the terms have their usual definitions[9]. Similarly, the rate of nodal regression, $\dot{\Omega}$, is

$$\dot{\Omega}=-\left(\frac{GM}{a^3}\right)^{1/2}\left\{\frac{3}{2}J_2\left(\frac{R}{a}\right)^2(1+2e^2-i^2/2)-\frac{1}{4}\left(\frac{R}{a}\right)^4(15J_4+9J_2^2)\right\} \quad (2)$$

We fitted our expanded model to the available set of occultation timings, which included those used previously and a new set of 18 timings (see Table 1) from observation of the 26 April 1981 occultation by Uranus and its rings with the 3.9 m AAT[10]. The midtimes of the ring occultations were determined by methods used previously[6]. The results of the fit showed no substantial changes of the other parameters of the model[9], but seven of the nine rings showed statistically significant inclinations—the largest being $(1.15\pm0.21)\times10^{-3}$ rad for ring 6. The inclinations and eccentricities of the rings are plotted in Fig. 1. We note that the results for rings η and ε show no inclinations to the limit of our sensitivity. The r.m.s. post-fit residual per degree of freedom dropped from 0.31 to 0.14 s with inclinations included.

As a check on the consistency of our results, we also fitted the timing data with the precession and regression rates ($\dot{\varpi}$ and $\dot{\Omega}$) of the elliptical and inclined rings as free parameters (not calculated from J_2 and J_4 as given by equations (1) and (2)). The values for $\dot{\varpi}$ and $\dot{\Omega}$ obtained from this fit are plotted in Fig. 2, and can be compared with the solid line plot of the rates calculated from J_2 and J_4. The agreement is excellent.

Figure 1 shows that the inclinations generally decrease with increasing semi-major axis—a pattern noted earlier[9] for the eccentricities, which remains in our present model. The ε ring has an exceptionally large eccentricity compared with the other rings, but its inclination is consistent with zero. For all rings (except ε) the value of $ae\sim ai$ (within a factor of 4). Also, our results show that $e>i$ for rings 5, 4, α, β and ε. For rings 6, γ and δ we find $i<e$, but this result lies within the uncertainty imposed by statistical errors.

The widest eccentric rings—α, β and ε—have been shown to be in uniform precession[5,6], probably by the mechanism of self-gravity[11]. The uniform precession implies 'streamline' orbits, so that there is a gradient of *a*s and *e*s across the ring. Inclined rings in uniform precession would necessarily have inclination gradients within the ring. Such gradients would be more difficult to extract from the data than the eccentricity gradients, but we shall attempt to do so soon.

So far there has been little theoretical discussion about the significance of inclined rings. One way to form an inclined ring would be through the capture and tidal breakup of an incident, small body, which would almost certainly have an orbit inclined to the equatorial plane of Uranus[12,13]. This explanation is highly unlikely for the inclined uranian rings, because the inclinations are so small. The shepherd satellite model for narrow rings[14] can apparently account for orbital eccentricities[15], and according to Goldreich and Tremaine (personal communication), orbital inclinations could be produced if the shepherd satellites have inclined orbits. However, the ability of this model to account for orbital inclinations has not been examined in detail.

Even after inclinations have been included in our orbit model, we note that the r.m.s. residual per degree of freedom (0.14 s)

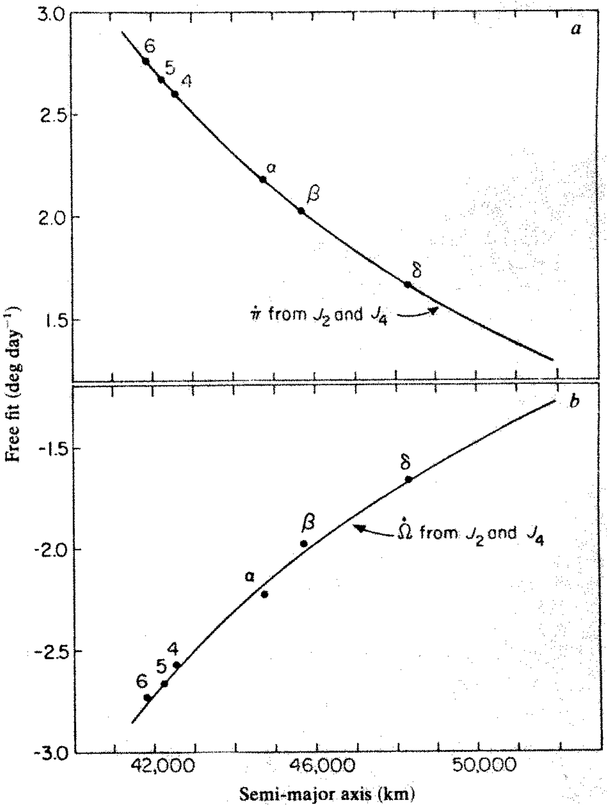

Fig. 2 Precession rates (*a*) and regression rates (*b*). The precession and regression rates for all rings having both a statistically significant inclination and eccentricity were fitted (not calculated from J_2 and J_4), simultaneously with all model parameters (except J_2 and J_4) allowed to vary in our previous fit (see Fig. 1). The results agree well with the rates calculated from equations (1) and (2), with fitted values for J_2 and J_4 (solid lines).

Table 1 Midtimes* of uranian ring occultations

† The occultation times for the η ring refer to the narrow core at its inner edge[9].

of our model is still significantly larger than the error in determining a ring occultation time. Hence, further improvements to our model should result in even more information about the Uranus system.

An example of induced centrifugal force in general relativity

Jeffrey M. Cohen*, William J. Sarill† & C. V. Vishveshwara‡

Thirring's solution[1] for a rotating spherical mass is cited often as an example which exhibits induced Coriolis and centrifugal forces in general relativity[2,3]. Previously, it was pointed out[4] that the 'centrifugal terms' proportional to the square of the angular velocity actually represented quadrupole effects. These effects arose as a consequence of the latitude-dependent velocity distribution which generated an axially symmetric (non-spherical) mass distribution. This raises the question: Are there solutions to Einstein's equations which exhibit induced centrifugal force? If no such solutions exist, then the concept of induced rotation of inertial frames breaks down. Such a lack of connection between rotating masses and induced inertial frame rotation would in turn imply a breakdown of the Machian[5,6] idea that an inertial frame is a system of reference in which the stress-energy of the universe is at rest on the average[7]. Here we demonstrate that there are solutions to Einstein's equations which exhibit induced centrifugal force (other solutions may also be of interest in this connection[8]).

As pointed out elsewhere[2], velocity-dependent density distributions can give terms easily misinterpretable as centrifugal force—a difficulty which can be circumvented by treating a body for which the symmetry of the density distribution is velocity-independent; such a body is a rotating cylindrical shell. Other important advantages of this choice of source geometry are that it generates a simple geometry within the shell, that is, the flat space-time (ref. 9 and W.J.S., unpublished thesis), and the solution is exact. When written in the appropriate coordinates, flat space is well understood and easily interpreted. Furthermore, as the solution is exact, no ambiguities arise due to approximations.

A rotating cylindrical shell can be treated using a generalization of the Weyl–Levi-Civita[10,11] metric

$$ds^2 = -e^{+2\psi}\,dt^2 + e^{2(\gamma-\psi)}(dr^2 + dz^2) + r^2\,e^{-2\psi}(d\phi - \Omega\,dt)^2 \tag{1}$$

and the corresponding vacuum field equations

$$\begin{gathered}\nabla^2\psi = \tfrac{1}{2}r^2\,e^{-4\psi}\nabla\Omega\cdot\nabla\Omega\\ \nabla\cdot(r^2\,e^{-4\psi}\nabla\Omega) = 0\end{gathered} \tag{2}$$

derived by Ehlers[12] and later independently by the authors (ref. 13 and J.M.C. and W.J.S., unpublished). Here ∇ and ∇^2 are the usual flat space operators. The function γ is determined by quadrature from the equation

$$\gamma_r = r\psi_r^2 - \tfrac{1}{4}r^3\,e^{-4\psi}\Omega_r^2 \tag{3}$$

where the subscript denotes differentiation with respect to r and cylindrical symmetry has been assumed so that the derivatives with respect to z vanish. Inside the shell of uniform density, the only non-singular stationary exact solution is the flat space metric in rotating coordinates

$$ds^2 = -dt^2 + dr^2 + dz^2 + r^2(d\phi - \Omega dt)^2 \tag{4}$$

where Ω is a constant. This rotating form of the flat space-time is used to obtain an explicitly smooth match across the rotating shell; this form also facilitates an unambiguous identification of the Coriolis and centrifugal terms. The metric outside the shell can be obtained from the Weyl–Levi-Civita metric via the multivalued transformation $dt' = dt + K\,d\phi$ where K is a constant. The matching across the shell relates the constants Ω and K to the mass per unit length and angular velocity ω of the shell.

It is generally known that the geodesic equations corresponding to the flat space-time metric (3) contain Coriolis terms proportional to Ω and centrifugal terms proportional to Ω^2. The frame in which all these terms vanish simultaneously is defined as the inertial frame. When the angular velocity ω of the shell vanishes, Ω also vanishes. Thus, Ω can be interpreted as the induced angular velocity associated with the dragging of inertial frames. We conclude, therefore, that there are solutions of Einstein's equations which exhibit induced centrifugal as well as Coriolis forces in accordance with Machian ideas.

Space shuttle ice nuclei

R. P. Turco*, O. B. Toon†, R. C. Whitten†

With the advent of the space shuttle era, increasing rocket activity is expected in the Earth's upper atmosphere. The space shuttle solid-fuelled booster rockets emit ~150 tonnes of alumina (Al_2O_3) particles per launch, much of which spreads throughout the upper troposphere and stratosphere[1]. Such particles can seed aerosols and clouds, and might therefore cause changes in the terrestrial radiation balance and climate[2]. Estimates are made here showing that average ice nuclei concentrations in the upper troposphere could increase by a factor of 2, and that an aluminium dust layer weighing up to 1,000 tonnes might eventually form in the lower stratosphere.

The morphology of alumina particles collected in high-altitude Titan exhaust trails may be summarized as follows[1,3]: typically smooth and spherical with occasional deeply-grooved surface structures; hexagonal α-Al_2O_3 or cubic γ-Al_2O_3 crystallography; heavy-element composition dominated by Al with smaller amounts of K, Na, Ti, Fe and Si; trace quantities of chlorine adsorbed on surfaces; and densities in the range of ~1.5 to ~3.5 g cm^{-3}, suggesting individual particles with a porous or hollow construction.

Previous theoretical investigations[4–6] focused on the role of Al_2O_3 particles as stratospheric condensation nuclei (CN, considered here as particles capable of nucleating supersaturated sulphuric acid vapour). However, space shuttle Al_2O_3 particles emitted in the stratosphere eventually filter downwards into the troposphere, after being widely dispersed over the hemisphere of injection. Inasmuch as alumina provides an excellent ice-forming epitaxy[7], they might contribute significantly to the population of background ice deposition nuclei (IN) at high altitude. IN produce ice crystals directly from the vapour phase at low temperatures (−5° to −25 °C) and supersaturations ($\geq$10%, or equivalently, relative humidities over ice ~100–110%). Cloud condensation nuclei (CCN), which can nucleate liquid water droplets at supersaturations $\leq$1%, are not subject to great influence by space shuttle emissions on a global scale.

Parungo and Allee[8,9] and Hindman and co-workers[10–13] studied IN concentrations in the stabilized ground clouds of solid-fuelled Titan rockets, which emit copious quantities of Al_2O_3 dust. They also discuss related laboratory data. Recognizing that the conditions in ground clouds are quite different from the conditions in high-altitude launch plumes, a consensus of the ground-cloud research nevertheless points to copious production of IN by rocket engines, perhaps as many as 10^{10} IN per gramme of fuel burned (active at −16° to −20 °C and 101% relative humidity over ice).

To estimate the accumulation of space shuttle IN (or SSIN) in the upper troposphere and lower stratosphere, a comprehensive one-dimensional model of multicomponent atmospheric aerosols was used[14,15]. The model segregates sulphate aerosols and unnucleated CN particles, and keeps track of the amounts of different CN materials incorporated into the aerosols by nucleation and coagulation. In this manner, the Al_2O_3 component of aerosols in the size range from 0.001 to 10 μm radius (subdivided into 40 distinct size bins) was calculated for the size- and height-dependent Al_2O_3 particle deposition rate associated with the space shuttle. The aerosol physics and chemistry treated in the model are discussed elsewhere[14]. In the present simulations, micrometeorites, which are the dominant natural stratospheric particles above ~1 μm radius, are neglected; their presence does not materially alter the results.

The adopted Al_2O_3 mass deposition profile corresponds to 52 space shuttle launches per year, with emissions averaged over the Northern Hemisphere and smoothed in time to yield a continuous injection rate[4]. All of the aluminium burned was assumed to condense as dust. Particle interactions in the rocket wake were ignored, as these interactions act mainly to reduce the particle population below ~0.01 μm radius (see below). Al_2O_3 particle injection above 8 km was included in the calculations, the total mass deposition amounting to ~5,000 tonnes yr^{-1}. The size distribution of the injected particles (the number injected per cm^3 of air per μm radius) was taken to be constant below 0.01 μm radius, and to vary as $r^{-\alpha}$ above 0.01 μm. The latter dependence, with α in the range 3.5–4.5, is suggested by direct sampling in Titan exhaust plumes[1,8,9]. The average particle density was assumed to be 1.7 g cm^{-3}, which emphasizes the number deposited.

The Al_2O_3 particle nucleation time in the stratosphere, τ_n, and the aerosol 'rainout and washout' lifetime in the troposphere, τ_r, were parameterized in a simple manner. For aluminium oxide dust, a fixed, relatively short nucleation time of 100 s was assumed as a base case[16]. Longer nucleation times up to 10^6 s were also tested. The simulated rainout loss rate decreases linearly from the ground-level value τ_r^{-1} to zero at the tropopause[14]. The baseline rainout rate of 10^{-6} s^{-1} at the ground translates into a rainout rate of ~10^{-7} s^{-1} near 10 km; ground-level rates as small as 10^{-7} s^{-1} were also considered.

To estimate the concentrations of SSIN in the upper troposphere and lower stratosphere using model predictions, three factors were taken into account: the composition of the particles, the extent of surface poisoning, and the size of the particles. The average composition of the sulphate aerosols in a given model size bin, i, is specified by the material volume fractions, $f_i(j)$, where j is a material index. Similarly, the volume fraction of material j in CN of size i is $f_i^{CN}(j)$. In the present work, the aerosol materials consist of three types: sulphuric acid aqueous solution, 'tropospheric' particulates, and aluminium oxide dust. The CN are composed of only the last

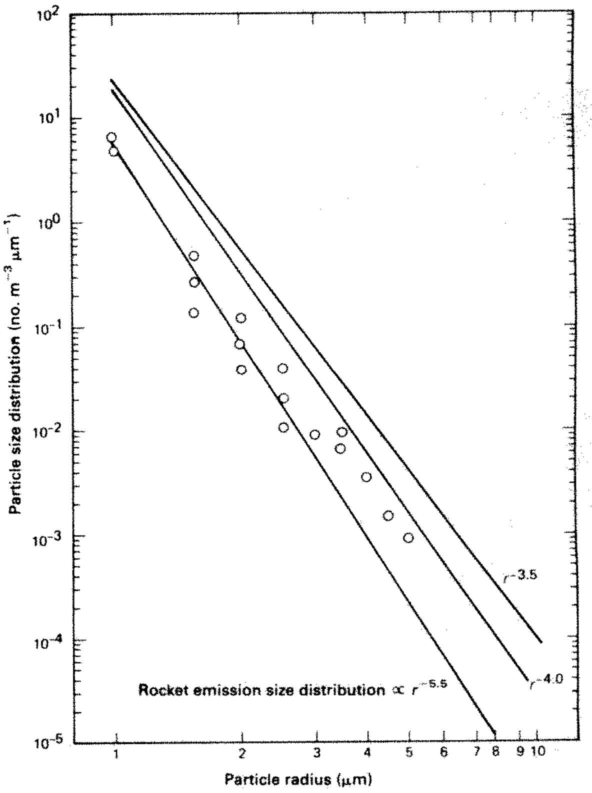

Fig. 1 Calculated stratospheric aerosol size distributions at 20 km with space shuttle particulate injection. 52 shuttle launches yr^{-1}, with emissions averaged over the Northern Hemisphere, were assumed. In each calculation, a nucleation time of 100 s was used (see text). Observations are compared: ○, data from ref. 3 for Al_2O_3 at 20 km, multiplied by 10.

0028–0836/82/340830—03$01.00

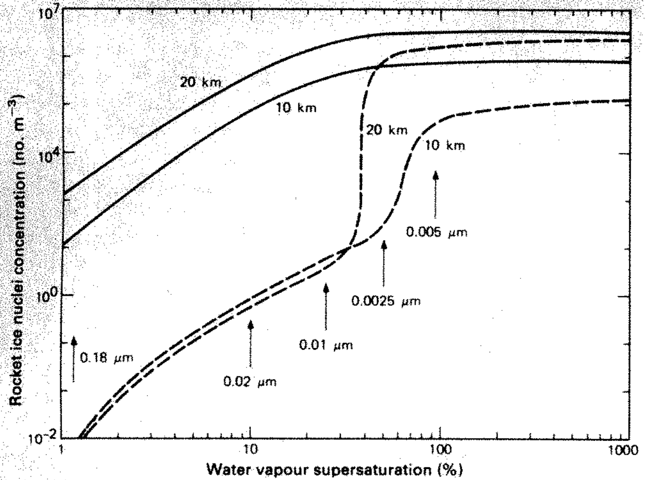

Fig. 2 Calculated space shuttle ice nuclei concentrations at 10 and 20 km altitude corresponding to different water vapour/ice supersaturations. The results were obtained for 52 shuttle launches per year with emissions averaged over the Northern Hemisphere, a dust emission size distribution of $r^{-4.5}$, and a nucleation time constant (τ_n) of 100 s. Estimates of the maximum (solid line) and average (dashed line) IN concentrations are given (see text). Also indicated are the minimum radii of spherical ice nuclei for several water vapour supersaturations at −30 °C.

two materials. The maximum number of CN identified as active SSIN in each model size bin was taken as the fraction, $f_i^{\mathrm{CN}}(\mathrm{Al})$, of the total number of CN in that size bin. Nucleated CN are classified as acid aerosols in the model, and are discussed below. Possible deactivation of Al_2O_3 CN by coagulation with background 'tropospheric' CN was neglected in the stratosphere, as the background CN concentrations are so low ($<10\ \mathrm{cm}^{-3}$).

For H_2SO_4 aerosols, two estimates of the SSIN concentration were made (and added to the CN SSIN concentrations derived above). They are a 'maximum' number and an 'average' number. Such an approach was called for because the precise extent of the poisoning of individual alumina particles cannot be predicted with the model. Rather, the average sulphate and Al_2O_3 composition fractions of all the aerosols in a given model size bin are predicted.

The maximum concentration of (nearly) pure Al_2O_3 particles identifiable among the total population of aerosols in size bin i was first estimated as

$$n_i(\mathrm{Al})_\mathrm{m} = n_i f_i(\mathrm{Al}) \qquad (1)$$

where n_i is the concentration of aerosols of size i (number cm^{-3}, excluding CN), and $f_i(\mathrm{Al})$ is the volume fraction of Al_2O_3 in aerosols of size i. However, the present model also provides information on the aerosol core size distribution in terms of the core volume moment fraction, h_i, which is a measure of the size dispersion of the cores in aerosols of size i, independent of core composition[14]. It can be shown that using h_i and f_i [where $f_i = \sum_j f_i(j)$], the maximum number of essentially-pure core aerosols may also be approximated as

$$n_i(\mathrm{core})_\mathrm{m} \doteq n_i[h_i^2 - f_i^2]/[1 + h_i^2 - 2f_i] \qquad (2)$$

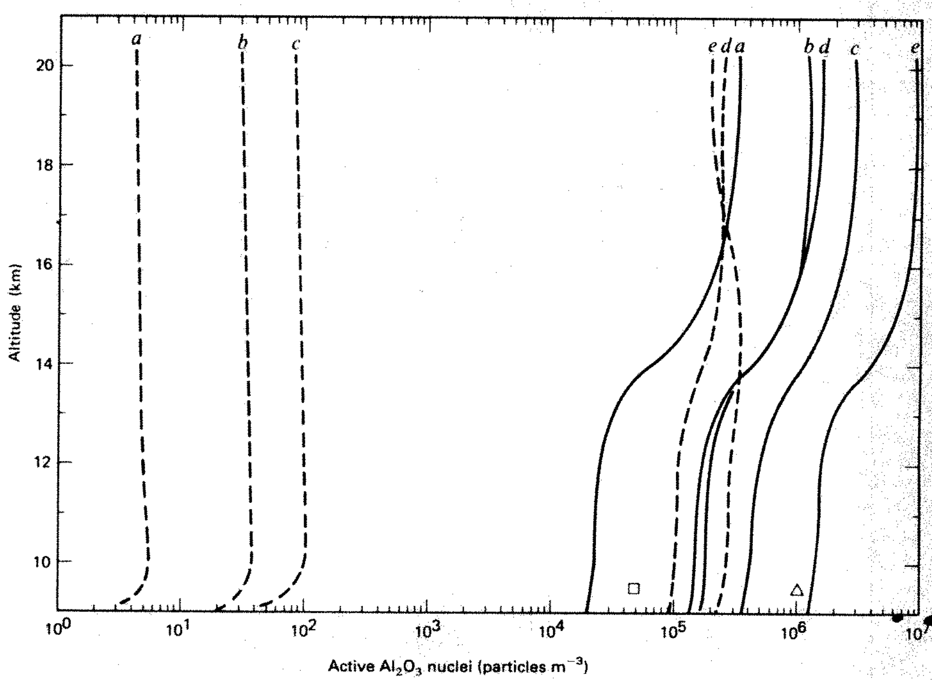
Accordingly, the maximum concentration of aerosol SSIN of size i was taken as the lesser of $n_i(\mathrm{Al})_\mathrm{m}$ and $n_i(\mathrm{core})_\mathrm{m}$.

The 'average' number of aerosol SSIN was calculated by assuming that all of the aerosols of size i have an average coating, or film, of contaminating material (mainly liquid sulphuric acid). If, in any size bin, the contamination amounted to more than a uniform monolayer coating ≃4Å thick, all of the aerosols in that bin were considered to be poisoned.

The effect of particle size on the activity of rocket nuclei was estimated in two ways. In one case, the SSIN concentrations deduced above (including the contributions of CN and droplets) were truncated to exclude particles <0.01 μm radius; such particles generally require supersaturations exceeding ~10% to cause nucleation at ~−20° to −30 °C (refs 16, 17). In the second approach, the effect of particle size on the water vapour pressures of small ice spheres was calculated using the Kelvin relation[17]. At a temperature of −30 °C (adopted to estimate the critical size at each altitude) the minimum nuclei dimensions corresponding to water vapor supersaturations of 1, 10, 50, 100 and 900% are 0.19, 0.020, 0.0046, 0.0027 and 0.0008-μm radius, respectively.

Figure 1 shows projected aerosol size distributions at 20 km for several different Al_2O_3 emission size spectra, $r^{-\alpha}$. In the size range 1–10 μm, the aerosols are essentially pure alumina (>95% pure). The data of Brownlee *et al.*[3] are plotted for comparison. The close agreement between the observed size distribution and the computational results suggests that the present shuttle simulations are physically reasonable. Brownlee *et al.*[3] estimated the global stratospheric burden of Al_2O_3 in 1974–5 as ~100 tonnes. The stratospheric lifetime of particles in the size range 1–5 μm is ~1 month, implying an Al_2O_3 mass input rate of ~1,000 tonnes yr^{-1} worldwide. The space shuttle calculations in Fig. 1 yield ~10 times as many rocket alumina particles for a hemispherical input rate of ~5,000 tonnes yr^{-1}, in clear accord with the Brownlee *et al.* observations. The

Fig. 3 Predicted space shuttle ice nuclei (SSIN) concentrations in the lower stratosphere and upper troposphere. The cases shown are: *a*, $r^{-3.5}$, $\tau_n = 100$ s, $\tau_r = 10^6$ s; *b*, r^{-4}, $\tau_n = 100$ s, $\tau_r = 10^6$ s; *c*, $r^{-4.5}$, $\tau_n = 100$ s, $\tau_r = 10^6$ s; *d*, r^{-4}, $\tau_n = 10^6$ s, $\tau_r = 10^7$ s; *e*, r^{-4}, $\tau_n = 10^5$ s, $\tau_r = 10^6$ s (see the text for an explanation of these parameters). In cases *a*–*d*, 52 shuttle launches per year were assumed, with the effluent spread uniformly over the Northern Hemisphere. In case *e*, a 10-fold increase in the numbers of launches was assumed. A minimum nuclei radius of 0.01 μm was used to estimate the SSIN abundances. Maximum (solid line) and average (dashed line) numbers of Al_2O_3 nuclei are shown. △, Observed ice nuclei concentration in cirrus clouds at −30 °C. □, Maximum ice crystal concentration in cirrus clouds.



corresponding predicted global mass of the stratospheric alumina layer is ~1,000 tonnes.

The computed size distributions in Fig. 1 have a relatively simple explanation. If rocket particles are injected at all altitudes with the same size distribution ($r^{-\alpha}$), and if particle growth by condensation and coagulation can be neglected, then the resultant atmospheric aerosol size distribution depends on radius roughly as $r^{-\alpha-\beta}$, where β is the exponent of the radius dependence of the particle fall velocity; that is, $v(r) \propto r^{\beta}$. In the lower stratosphere, $1 < \beta < 2$ for particles with radii in the size range 1–10 μm. Thus, for Al_2O_3 rocket particles one expects $5 \leq (\alpha + \beta) \leq 6$, as is found in Fig. 1.

Figure 2 illustrates the influence of water vapour supersaturation on apparent SSIN concentrations. As expected, higher supersaturations yield larger IN abundances. The abrupt increase in the 'average' IN curves at S values of 40–80% is due to a substantial number of nearly-pure rocket dust particles at sizes below ~0.01 μm. For meteorologically significant supersaturations (<10%), the average number of IN in Fig. 2 is nearly four orders of magnitude smaller than the maximum number of IN. The difference represents, in one sense, the uncertainty in predictions of rocket IN abundances.

Predicted SSIN concentrations in the upper troposphere and lower stratosphere, for various physical parameter values, are given in Fig. 3. Several trends in the data are noteworthy. As in Fig. 2, with fast Al_2O_3 nucleation ($\tau_n = 100$ s), there is a difference of a factor of 10^4 between the 'average' and 'maximum' numbers of SSIN. Obviously, there is ample sulphate material present in the atmosphere to contaminate most of the injected dust grains. The maximum SSIN concentrations would apply if Al_2O_3 particle surfaces were not efficently nucleated and poisoned by H_2SO_4 vapour (see, for example, cases d and e in Fig. 3). Comparison of cases b, d and e suggests that the average SSIN concentration is roughly proportional to τ_n^{-1}. In other words, once nucleated, most Al_2O_3 grains accumulate enough sulphur vapour to be poisoned (in the model). Rainout has a much smaller influence on SSIN concentrations; the residence time of injected particles in the upper troposphere is controlled primarily by vertical diffusion (for the cases studied).

One might expect a short nucleation time ($\tau_n \sim 100$ s) to apply to Al_2O_3 dust released in the upper atmosphere. For one thing, the H_2SO_4 supersaturation ratio between 10 and 20 km altitude is quite large, ~10^4–10^5 (ref. 16). Hence, adsorption of H_2SO_4 on alumina surfaces should commence immediately on injection. Continuing growth of the dust particles larger than the critical (Kelvin) size would also be guaranteed. However, a factor which causes the effective nucleation time to be much longer is the time required to deposit a monolayer of acid molecules on the dust grain surfaces. The ambient quantity of H_2SO_4 vapour available in the neighbourhood of the launch plume is insufficient to coat more than a few per cent of the rocket particles. Nevertheless, it may be demonstrated that, within a day or so, individual launch plumes are dispersed widely enough for extensive acid adsorption to occur. This does not take into consideration the HCl vapour in the early launch plume, which acts to poison the dust surfaces at high concentrations[9–11], but appears to activate the surfaces at low concentrations[13]. Accordingly, an effective dust nucleation time $\leq 10^5$ s appears to be most appropriate for stratospheric conditions.

Many of the SSIN residing in the upper troposphere are injected between 8 and 12 km. At these altitudes, the transient space shuttle launch clouds should be considered. Case e in Fig. 3, which corresponds to a 10-fold enhancement in the average shuttle particle deposition rate, might crudely forecast the elevated IN concentrations to be expected in isolated launch plumes.

The maximum number of rocket IN that could be generated from 1 g of fuel, based on an r^{-4} Al_2O_3 dust size distribution and a minimum activation radius of 0.01 μm, is ~10^{15} IN g^{-1}. This number corresponds closely to the maximum number predicted by the model. By contrast, Hindman *et al.*[12] measured ~10^{10} IN g^{-1} in small shuttle propellant burns, while the present calculations yield estimates of average long-term shuttle IN yields ~10^{11} IN g^{-1}. Hence, the maximum SSIN profiles in Fig. 3 are very likely to represent upper-limit global-scale concentrations of artificial ice nuclei produced by space shuttles.

Typical IN concentrations measured at cirrus cloud heights are indicated in Fig. 3 (ref. 17). Maximum concentrations of ice crystals observed in cirrus clouds are also shown. Based on a comparison of measured and predicted IN concentrations, and the previous discussion, we conclude that planned space shuttle activity probably will not increase the global abundance of ice nuclei at cirrus cloud levels by more than a factor of 2, although larger transient increases might occur locally. Injected space shuttle alumina particles, on the other hand, could enhance the concentrations of stratospheric aerosols in the size range 1–10 μm radius by a factor of 10 or more, creating in the stratosphere an aluminium oxide layer exceeding 1,000 tonnes in weight.

The Earth's early hydrosphere

A. Henderson-Sellers

J. Graham Cogley
Department of Geography, Trent University, Peterborough, Ontario, Canada K9J 7B8

The date at which the Earth's hydrosphere came into existence is unknown. Although all current geological models for the very early Precambrian predict or suppose a hydrosphere[1–4], there are difficulties in reconciling this with geological and astronomical theories of planetary formation. Furthermore the effect of a substantial hydrosphere on the Precambrian climatic environment is difficult to determine. Recent developments make it possible to synthesize a picture of this environment during the 700 Myr preceding the deposition of the oldest known sediments[5]. We attempt such a synthesis here, drawing together work on the dynamics of accretion from the protoplanetary nebula[6,7] and of planetary differentiation[7], on the role of volatiles in impact cratering[8–10], and on the composition[11–22], isotope systematics[23–25] and radiation climatology[26–29] of the early hydrosphere. We can reconcile these diverse contributions if the hydrosphere—the inventory of excess volatiles[1]— is allowed to differentiate during accretion, with most of the H_2O and CO_2 going rapidly into oceans and sediments. Both gradual outgassing[30] and a massive CO_2 atmosphere[2] are unlikely, and a reduced mantle beneath a neutral hydrosphere is not paradoxical[1,3,17]. Results from both a one-dimensional radiative–convective (1D RC) model and a general circulation model suggest that self-regulating mechanisms are important in the climate of this early hydrosphere.

0028-0836/82/340832—04$01.00

The idea of early degassing[31] now seems more probable than slower degassing. The possible histories which cannot yet be excluded are very diverse, but the Earth probably grew over 10^7 yr or more [6] from a population of planetesimals, the largest having a mass not less than 1/500 that of the total accreted mass[7]. Not all of the impact heat is radiated away. Some of it is buried, and it sets up convection in the outer accreting layer and triggers formation of the core, perhaps as early as accreted mass $\sim 0.1 \times$ final mass. The energy released by core formation[7], and by subsequent steady settling of dense phases, establishes convection throughout the growing mantle, and volatiles differentiate upwards as iron phases segregate downwards. A growing planet tends to 'reject' icy impactors[8,9]. That is , the ratio r (ejecta mass escaping the planet/impactor mass) is large when the impactor density is small, and metals and silicates accrete much more readily than do ices; r depends also on impact velocity, however, and during growth the velocity needed for net erosion ($r > 1$) increases. In the late stages of growth only the most energetic impactors actually sputter the surface, and because the planet has depleted its source of planetesimals the latest arrivals are previously-rejected, volatile-rich bodies. This inhomogeneous accretion[32] yields an outer layer of more or less volatile-charged silicates, which separates efficiently into veneer and substrate under the influence of repeated impacts. Vapour volumes exceeding impactor volume are produced in a large proportion of impacts[8,10]. Hydrous and carbonate vapours disperse more widely, and precipitate less completely, than silicate vapours[10].

The earliest mantle, with volatiles strongly concentrated upwards, was thus overlain by an impact-processed protocrust, hydrated and carbonated but of uncertain thickness. Two points deserve emphasis:

First, geothermal energy sources were much larger during accretion than at any later time; models with outgassing due to radioactive warmup[30], or similar gradual processes, now seem mechanically and thermally improbable, and it is safest to conclude that the excess volatiles had a mass comparable with that of the present by the time accretion was completed.

Second, enrichment in ^{129}Xe of Earth-interior gases with respect to the present-day atmosphere and to Archaean shales[23,24] requires outgassing of the atmosphere within a few half-lives (17 Myr) of ^{129}I, with negligible net additions since 3,300 Myr ago[25]. The history described above explains this important observation well.

It is important to consider the oxidation state of the early hydrosphere. It seems to be accepted that H_2O and CO_2 were significant components even of the earliest atmosphere[11], but questions persist over the reduced species H_2, NH_3 and CH_4 (refs 2, 3, 12).

Modern volcanic gases have elemental bulk ratios similar to those of the excess volatiles[13], and have high-temperature low-pressure equilibria[14,15]; they seem to sample the modern hydrosphere, but not necessarily the juvenile source during accretion. The lower continental crust seems to be anhydrous[16], its volatiles dominated by CO_2. This is consistent with empirical thermodynamics[17], as is the observation that the upper mantle is strongly reduced[3,18,19]. The modern mantle seems to be closer to equilibrium with the core than with the hydrosphere. This pattern would evolve from our picture of accretion if (1) some of the H_2 in a reduced proto-mantle went to the core[20] and/or (2) the primitive outgassed volatiles were reduced. In case (2) we must explain how and when the hydrosphere lost its evolved reduced gases.

The primary control of atmospheric H_2 is escape from the top of the atmosphere[21], which for exospheric temperatures $T_x > 600$ K is controlled by hydrogen diffusion into the upper atmosphere. Most OH and H radicals, from photolysis of H_2O for example, will recombine, and only a fraction of the hydrogen arriving from below actually escapes (as H). Likely values[22] of T_x exceed 1,300 K, a temperature at which, if diffusion into the upper atmosphere were not restricted, the early Earth could evaporate an excess of hydrogen rather efficiently. In an early atmosphere without ozone, a very cold and nearly isothermal stratosphere[33] might indeed allow more H_2O vapour to diffuse upwards as the temperature inversion at the tropopause would be absent. A great excess of hydrogen, if produced by a large-body impact, would blow away very rapidly, possibly in a few minutes[21].

Other reduced constituents are also unlikely to persist. Ammonia is highly soluble in water and would be removed rapidly by rainout and by solution at the ocean surface. It would also be destroyed by photolysis[26]. It has been calculated that a mixing ratio of $<10^{-4}$ of NH_3 will convert irreversibly to N_2 in <40 yr (ref. 27). Methane photolyses at wavelengths <160 nm, where the incident solar flux is two orders of magnitude less than in the region important for the destruction of NH_3 ($\lambda <$ 230 nm), and where atmospheric water vapour will provide a substantial shield[28]. CH_4 is rapidly destroyed above 100 km (ref. 29), but at the surface it appears much more stable. However, photolysis of H_2O vapour forms large quantities of OH, an important intermediary in the methane oxidation chain. At an OH concentration of 10^5 cm^{-3} in the early troposphere[28], the life time of CH_4 at the surface is <50 yr.

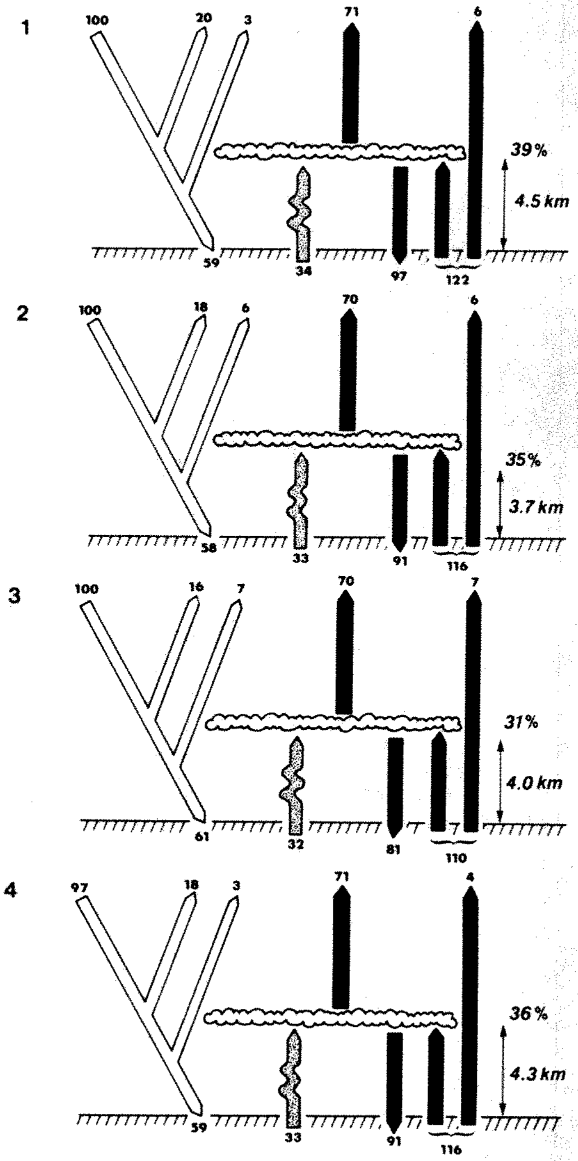

Fig. 1 Four likely configurations of the atmosphere/hydrosphere of the early Earth. The calculated fluxes have been normalized to the incident solar radiation of the standard case (1) (100 units $= \frac{1}{4}$ of 1,100 W m^{-2}). Solar fluxes (open arrows) are on the left of each sketch; upward arrows represent atmosphere (left) and surface (right) reflection. The wavy arrow represents convective heat flux from the surface, and infrared fluxes are on the right (solid arrows). Note the variations in mean cloud cover (per cent) and cloud height (km) at right.

Table 1 Radiative–convective model results

	Case 1	Case 2	Case 3	Case 4
Prescribed				
Incident solar radiation ($W m^{-2}$)	1,100	1,100	1,100	1,067
Surface albedo	0.05	0.10	0.10	0.05
CO_2 (p.p.m.v.)	1,650	1,650	330	1,650
Results				
T_s (K)	277.0	273.8	270.2	274.1
Cloud cover (%)	39.0	34.8	31.3	35.8
Mean cloud height (km)	4.48	3.71	3.99	4.32
Planetary albedo	0.23	0.24	0.23	0.22
Greenhouse ΔT (K)	29.7	27.7	22.9	28.3

The greenhouse temperature increment (present-day value ~33 K) is $T_s - [S(1-A)/4\sigma]^{1/4}$, where σ is the Stefan–Boltzmann constant, A is the planetary albedo and T_s is the mean surface temperature.

Hence in a water-vapour-dominated atmosphere neither NH_3 nor CH_4 can persist, H_2 escapes rapidly, and a reduced-gas greenhouse is at most transient, dissipating on time-scales shorter than that of accretion. Greenhouse warming was controlled by the amounts of CO_2 and H_2O vapour in the early atmosphere.

We assume that there is always enough greenhouse gas to avoid the very stable[34] 'deep freeze' predicted by some models of the present-day climate. Note, however, that little reliance can be placed on predictions made by EBMs[34] unless careful consideration is made of the changes in the horizontal advection term and the effect of clouds on the planetary albedo. We assume further that surface albedo was controlled by the presence of liquid water, as exposed land was probably less extensive (0–10% of total planetary surface) than during the Phanerozoic (20–30%)[35]. The earliest topography was probably unimodal, with a few kilometres of relief on a mechanically weak protocrust shaped by large impacts. The continental mass has increased in the course of time[36,37], and high-standing continents probably did not appear until after the end of accretion.

A massive CO_2 atmosphere, $P_{CO_2} \simeq 1,000$ mbar, is unlikely. It is not necessary in our model to invoke a passage of CO_2 from atmosphere to sediments on the long time scale of continental differentiation[5], because carbonates would form in the aftermath of large-body impacts. In any case, the P_{CO_2} of a surface mixed layer (say 50m deep and covering 70–100% of the planet) would equilibriate with the atmosphere in a few months or years. CO_2 downwelling, and reaction with the sea floor at geohydrological (a few times 10^4 yr)[38] and geological ($\simeq 10^6$–10^7 yr) rates, would increase with atmospheric CO_2. Massive quantities of both liquid water and gaseous CO_2 are thus not compatible for more than short times. We choose $CO_2 = 1,650$ p.p.m.v. ($5 \times$ PAL) in the work described below. Actual concentrations might have been much higher. However, our results (Table 1) suggest that if they were of the order of 300,000 p.p.m.v. (refs 2, 11) the Earth could have evolved into a runaway greenhouse. The hydrospheric feedbacks we describe give temperatures warmer than those of a non-interactive model both for reduced solar flux and for increased levels of greenhouse gases[33]. Some early, non-hydrothermal[39] sediments do suggest deposition from warm water[40], but there is no evidence for a runaway greenhouse in the geological or geochemical records.

Atmospheric water vapour concentration depends primarily on T_s. Cloud effects have generally been simulated crudely or neglected in studies of the early atmosphere[2,11,41] and this may[42] be a serious omission. We explore cloud effects with the GISS 1D RC model[43] due to Lacis, incorporating an interactive cloud prediction scheme[33] which makes the model much less sensitive: $\beta < \simeq 80$, down from $\beta \simeq 100$ as found in prescribed-cloud models[44]. ($\beta = S\Delta T/\Delta S$, where S is the present-day solar constant.) At each altitude, cloud cover depends on the water mixing ratio which is calculated from the mixing ratio at the previous time step by accounting for additions from condensation and removal by rainfall. In common with most 1D RC models a fixed lapse rate of 6.5 K km^{-1} and fixed relative humidity are assumed. Additionally the Bowen ratio linking latent heat flux to convective flux is a function of T_s but is assumed to be constant with height. When clouds are predicted at levels with $T < 246$ K they are assumed to be ice rather than water clouds and the effective particle radius and optical depth are adjusted accordingly. Since the cloud cover is predicted by the model, the feedbacks are internally consistent. In particular, an increase in high, optically-thin clouds tends to feed back positively on temperature[33].

Our standard state is shown as case (1) in Fig. 1 and Table 1. The solar flux is 1,100 W m^{-2} (80% of the present-day flux[45]), and the albedo and atmospheric CO_2 are consistent with our model for the close of accretion. T_s is 277 K, warm enough to support liquid water. The dark surface, and IR absorbers in the atmosphere, contribute to a greenhouse effect almost as large as it is at present. The albedo is rather low; if we increase it to represent a substantial emergence of land (case (2)), T_s drops to 274 K. If we next reduce CO_2 to its modern value (case (3)), perhaps representing consumption of CO_2 in silicate weathering, the greenhouse is weaker (23 K), although even now at $T_s = 270$ K the oceans will probably not freeze over. A largely ocean-covered Earth[36,37] is extremely difficult to glaciate. The pole–equator temperature gradient is likely to be smaller than today; but even with temperatures significantly <273 K at the poles, the absence of large land masses either to be the site of glaciers or to constrain oceanic circulation is likely to inhibit severely ice formation.

Note that the calculated temperatures (cases (1)–(3)) probably represent the lower limit to the evolutionary curve of T_s. This is because we have chosen to include the smallest likely CO_2 concentrations to focus attention on the feedback effects operating as a result of the existence of the hydrosphere. Despite this minimization of the CO_2 greenhouse effect, the lower limit temperature curve presented here is physically reasonable and is consistent with the geological data. This is because the sensitivity, β, of the interactive-cloud 1D RC model[33] is lower than that of any other climate model. If cases (1), (2) and (3) followed each other, as they well might have, then glaciation becomes more likely with time. More importantly, however, the interactive-cloud model continues to predict a stable climatic régime in the face of these radical climatic perturbations.

The most dramatic single perturbation of early climate is probably the large impact. Mass input rates were negligible in comparison, but such impacts certainly continued after the end of accretion; the lunar bombardment which formed Imbrium at 4,000–3,800 Myr may have obliterated evidence of still earlier bombardment[46]. The most significant atmospheric effects would probably be changes in the vertical distribution of water vapour and liquid water. The climatic perturbation due to a 10^{15} kg impactor depositing $\simeq 10^{16}$ kg of water in the upper atmosphere (only 0.2×10^{16} kg below 10 km) has recently been calculated using the GISS general circulation climate model[47,48]. Changes were transient (with a decay time <1 yr) and small (temperature increasing by a maximum of 0.5 K after 5 months). Long-term effects are seen only if perturbations to the lower atmosphere are strengthened by continual replenishment of species[49,50]; positive feedbacks internal to the climatic system do not seem likely.

Placement of the vapour and debris at a much higher level in the atmosphere, it has been suggested[51], may create a permanent near-worldwide layer of mesospheric ice clouds, cooling the surface through a reduction of planetary albedo by several per cent. We can simulate this albedo effect by reducing solar flux to 1,067 W m^{-2} (case (4) of Table 1 and Fig. 1). The result is a drop of only 3 K in T_s, to 274 K, within the range of cases (1)–(3) and unlikely to lead to a global freeze-over.

Comparable remarks hold for other perturbations. Even during accretion, interior convection can dissipate the input of impact and gravitational heat if lava lakes cover a fraction (10^{-3}–10^{-4}) of the surface[7]. Shallow heat radiates away rapidly from vapour clouds, ejecta and melt pools. Buried heat enhances[52] a geothermal flux due to radioactivity and energy of accretion, but even with extreme assumptions[53] this flux does not reach 1 W m^{-2}. Short-term changes with complex regional variability will follow large impacts, but we have no evidence that the climate cannot recover from these sporadic intervals of disturbance.

A substantial early hydrosphere, then, is both consistent with results from a variety of disciplines and, as our results show, powerful in solving the paradox of the faint young Sun[45]. The most plausible date for its origin is at the very beginning. Most of its properties, and especially its stability against large, irreversible changes of composition and climate, seem to follow if we identify the principal surface volatile as liquid water. There was thus a long expanse of pre-Isuan time during which the Earth could have sheltered and nurtured organisms or their precursors, and this expanse of time would surely repay closer attention.

We thank W. Rossow for helpful discussions in this work, which was begun while A. H.-S. was a NRC (US) visiting research fellow at the Goddard Institute for Space Studies. J. G. C. thanks NSERC (Canada) for support.

Optimized anomalous dispersion in crystallography: a synchrotron X-ray polychromatic simultaneous profile method

U. W. Arndt*, T. J. Greenhough†, J. R. Helliwell†‡, J. A. K. Howard§, S. A. Rule† & A. W. Thompson‡

In principle, it is possible to phase the X-ray reflections from a macromolecular crystal which contains one heavy atom per molecule, without having recourse to the conventional method of multiple isomorphous replacement, by making use of anomalous dispersion effects alone[1]. To do this, it is necessary to measure each reflection over a narrow range of wavelengths centred on an absorption edge of the heavy atom, where f' and f'', the real and imaginary anomalous components of the scattering factor, are varying rapidly. The availability of powerful synchrotron radiation sources with a continuous energy spectrum has stimulated interest in such phasing methods, but previously experiments[1] have been limited to making measurements on only one reflection at a time and/or to measuring at only a few discrete wavelengths near the absorption edge. We are developing a method at the Daresbury Synchrotron Radiation Source (SRS) which produces an energy profile along an axis of each and every diffraction spot in a screenless oscillation photograph. We show here that the approach is feasible using a single crystal of heptahydrido *bis*(diisopropylphenyl)phosphine rhenium using the L_{III} absorption edge of rhenium at a wavelength of 1.1772 Å.

The white synchrotron radiation beam from a storage ring diverges from a small region at the tangent point of the beam line. A narrow wavelength band can be selected from this beam by reflection from a crystal monochromator; a cylindrically curved monochromator produces a converging X-ray beam. At the SRS protein crystallography station[2] the monochromator is a perfect crystal of either Si or Ge with the (111) planes cut at an angle α to the surface. The triangular crystal is clamped at its base and deflected at its tip: in this way[2–5] an accurately cylindrical curvature is achieved.

There is one curvature of the monochromator for a given Bragg angle (θ), angle of cut (α), image (p') and object (p) distances where all rays which are brought to a focus have been reflected at an equal angle so that they are all of the same wavelength. This 'achromatic condition' is usually referred to as the 'Guinier position' of the monochromator. However, for monochromator curvatures, R, other than that for the 'Guinier position', rays from a point source make different angles of incidence along the length, L, of the monochromator, over a range $\delta\theta_{\mathrm{corr}}$ where[2,4–6]

$$\delta\theta_{\mathrm{corr}} = \frac{L}{2}\left\{\frac{\sin(\theta-\alpha)}{p'} - \frac{\sin(\theta+\alpha)}{p}\right\}$$

$$\left|\left(\frac{\delta E}{E}\right)\right|_{\mathrm{corr}} = \left(\frac{\delta\lambda}{\lambda}\right)_{\mathrm{corr}} \approx \delta\theta_{\mathrm{corr}} \cot\theta$$

and

$$\frac{2}{R} = \frac{\sin(\theta-\alpha)}{p'} + \frac{\sin(\theta+\alpha)}{p}$$

(At the Guinier position $(\delta\lambda/\lambda)_{\mathrm{corr}} = 0 = \delta\theta_{\mathrm{corr}}$ and

$$\frac{1}{R} = \sin\frac{(\theta-\alpha)}{p'} = \sin\frac{(\theta+\alpha)}{p}.)$$

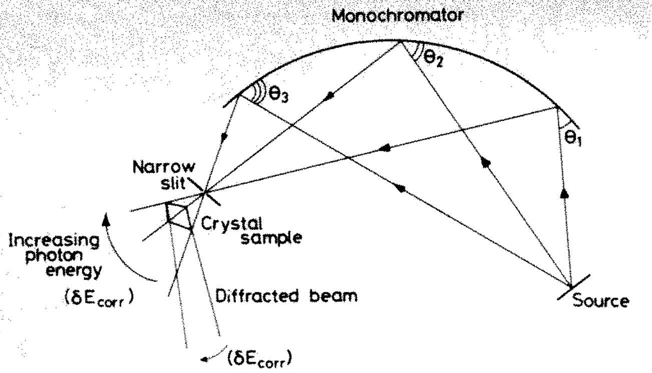

Fig. 1 When the monochromator curvature is not at the 'Guinier position' rays from a point on the source are incident at different angles to different points along the length of the monochromator and are reflected at different wavelengths (energies). At a point in the focus, defined by the narrow slit, the converging rays possess an exact correlation of photon energy with direction. The particular curvature of the monochromator that is needed is that for which $(\theta_3-\theta_1)=\delta\theta_{corr}$ gives a δE_{corr} adequate to straddle an absorption edge of interest (in this case rhenium L_{III}). We assume point-to-point focusing, $L \ll p, p'$.

The subscript 'corr' refers to the fact that there is a subsequent correlation of the direction of incidence of a ray towards the focus and its (photon) energy. Maier-Leibnitz[7] and later Thomas[8] first described the use of a focusing monochromator in this way in a 'modified Laue method' for neutrons.

By choosing appropriate angle of incidence and curvature of the monochromator the band-pass $(\delta\lambda/\lambda)_{corr}$ of the reflected X-rays can be made to straddle the absorption edge of a spectrum placed at or near the cross-over point. A cylindrical curvature does not exactly reproduce a point focus from a point source but instead a 'caustic'. However, for $L \ll p, p'$ this error is quite negligible[2]. Rays from different points of a finite source cross over at different points so that with such a source there is a finite focus width. However, an accurate correlation between direction and wavelength is maintained for all rays which pass through a sufficiently narrow slit placed at the foucs.

Matsushita[9] has used this property of the bent crystal monochromator for recording photographically the absorption spectrum of the K edge of a copper specimen placed at the cross-over point. The transmitted diverging X-beam produced a streak in which distance and wavelength were correlated.

We now suggest that, if a single crystal is placed near the cross-over point a diffraction pattern is produced in which each spot is drawn out into a streak in which the wavelength varies along the streak (Fig. 1). The theoretical basis for this has been established[10,11]. Every spot in the pattern then contains a complete energy profile across the absorption edge of one of the atoms in the specimen crystal. This method of producing the whole of all the streaks simultaneously makes much more efficient use of the synchrotron radiation spectrum than the rocking-monochromator streaks method proposed earlier[12] or the more usual appproach of measuring whole diffraction data sets at a few discrete wavelengths either with a double crystal monochromator[1] or the current monochromator at the 'Guinier position'[2].

In our preliminary experiments we used the SRS work-station with no modification other than that of placing a narrow adjustable slit at the 'front' end of a large diameter collimator (≈1 mm) mounted in the collimator bracket of an oscillation camera[13]. The X-ray beam was therefore effectively unrestricted in vertical height. In the horizontal plane the crystal sample was placed after the cross-over point so that the (now) diverging beam bathed most of the crystal, which also, therefore, accepted the full correlated energy bandwidth available (Fig. 1). The use of the narrow slit (Fig. 1) constrained the energy resolution within the diffraction spot profile to allow satisfactory sampling of the absorption edge fine structure[2,11].

We have tested our idea on a single crystal, in the form of a thin plate (0.1 × 1 mm approximately), of heptahydrido *bis*-diisopropylphenyl)phosphine rhenium, $(\mathrm{ReH_7(P^{i}_{r2}PhP)_2})$. This crystal structure has been solved[14] previously from low temperature X-ray data collected on a Nicolet P3/m 4-circle automated diffractometer with graphite monochromatized MoK_α X-ray irradiation.

The space group is $P2_1/n$ with refined cell parameters $a = 11.271$ Å, $b = 13.405$ Å, $c = 17.017$ Å, $\beta = 95.53°$. There is one rhenium aton , 2 phosphorus, 24 carbon and 45 hydrogen atoms in the asymmetric unit. Because the space group is

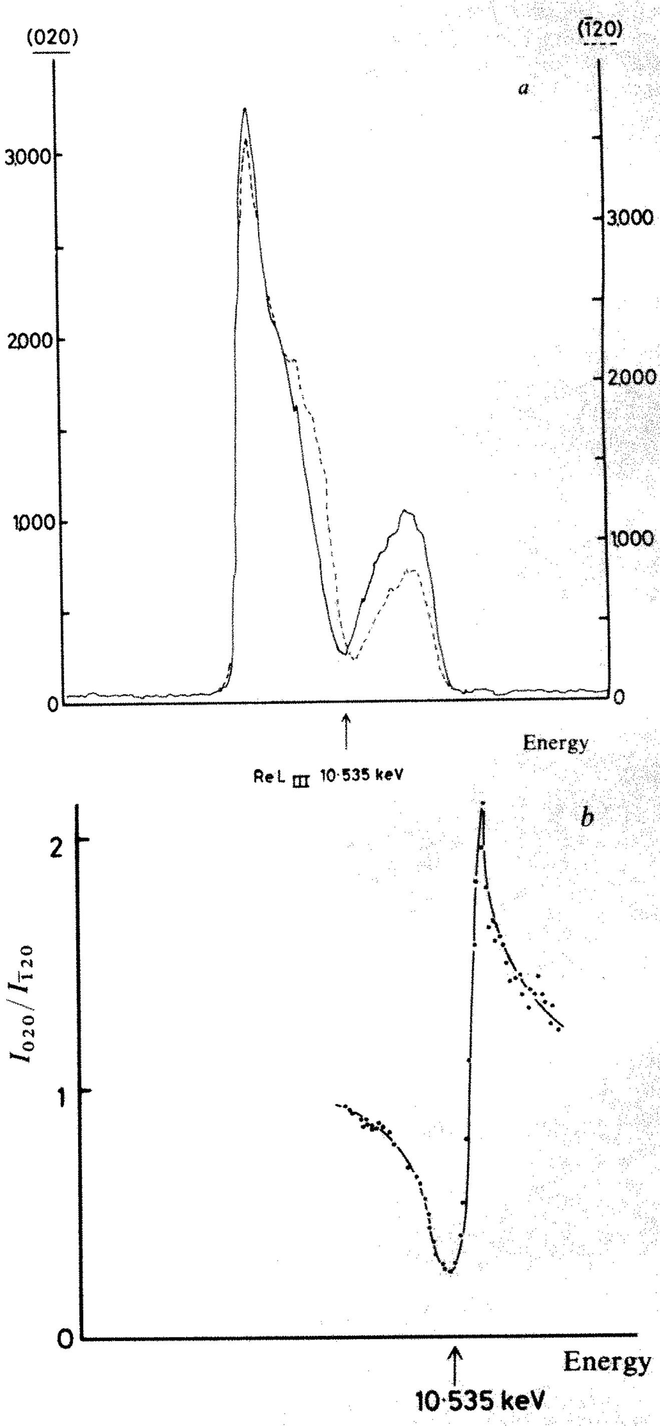

Fig. 2 *a*, Densitometer profiles of the two reflections with Miller indices $\bar{1}20$ and 020, for the 'on-edge' case. The ordinate scales have been selected to allow exact comparison of reflection widths and the position of the minima in the profiles. The 020 profile is shown as a solid line and $\bar{1}20$ as a broken line. *b*, The divided intensity profiles $(020/\bar{1}20)$, after removal of background, showing the effect of the expected dramatic variation due to f' 'on-edge'.

centrosymmetric, all phases are 0 or π and the variation in f'' has a negligible effect on the reflection intensity. At the SRS we aimed therefore to optimise the value of f' for the rhenium $L_{\rm III}$ edge ($\lambda = 1.772$ Å) across a diffraction spot energy profile with a total bandwidth of 67 eV. The monochromator was a triangular Si(111) monochromator 200 mm long (length in use 156 mm) with a measured oblique cut angle $\alpha = 6.73° \pm 0.05°$ (J.R.H., unpublished data) giving $\delta E_{\rm corr} = 67$ eV[10] for $p = 20.9$ m, $p' = 2.4$ m and $R = 45$ m. We recorded two oscillation photographs, one with the 67 eV centred on the point of inflection of the $L_{\rm III}$ absorption edge of the rhenium in the sample and the other with the 67 eV centred 200 eV below the edge. These two photographs can be compared in ref. 11. The wavelength was calibrated by step scanning the monochromator in 0.01° steps ($\delta E = 9$ eV) and measuring the intensity transmitted through a different but otherwise identical single crystal. At the two selected wavelengths about the rhenium edge the sequence of photographs produced was as follows; still 0°, still 85°, oscillation photograph 85–89.95, still 89.95. Exposure time for the 85–89.95° photographs was 5 seconds per degree with 10 oscillations. The crystal to film distance was 54.5 mm corresponding to an outer resolution limit on a flat plate cassette of 1.5 Å at this wavelength. The film used was low fog CEA Reflex 25 with three films in a data pack. The SRS was operating at 1.9 GeV with an injection current of ≈ 100 mA at the time of this experiment.

The diffraction patterns were indexed on the basis of a refined sample orientation (from the stills) taking account of the direction–energy correlation geometry[10] which introduces important changes compared with a conventional X-ray line source[15]. Because of the small unit cell, the same reflections are stimulated at both wavelengths though their positions on each film are slightly altered. In the on-edge photograph considerable fine structure is exhibited in the Bragg reflections. For a small heavy atom complex of this sort the absorption profile of the rhenium dominates the different intensities. This causes an apparent uniformity of fine structure between all reflections. The variations in spot-size and inclination for different reflections for this camera geometry is described elsewhere[10,11]. The on-edge photograph was recorded first; the fine structure recorded is not, therefore, due to a split crystal.

There is a considerable amount of information in these 'three-dimensional' rotation photographs (x, y, and energy). In this first report of the technique we have only analysed two reflections with the Miller indices 020 and $\bar{1}20$; both reflections are fully recorded. These reflections occur at a closely similar $\sin\theta$ value so that their absorption corrections as a function of λ across the edge are identical to within 1%, even at maximum absorption. However, in the $\bar{1}20$ reflection the rhenium atom happens not to dominate the structure amplitude. The reflection profile of the $\bar{1}20$ is therefore determined by the absorption profile. In the 020 reflection the rhenium does dominate the structure amplitude, hence the expected variation in f' across the edge (as well as absorption) will affect the 020 reflection intensity profile.

The reflections each at the two wavelengths were digitized using a Scandig flat bed densitometer with an aperture (raster) of 10 μm × 100 μm with a step size of 10 μm. The four central scans were averaged numerically making the sampling raster effectively 10 μm × 400 μm. The scan direction was along the variable energy direction which was here very close to horizontal[10,11] Figures 2*a* and 3*a* compare the profiles produced in each case. For the on-edge ($\bar{1}20$) profile the change in linear absorption coefficient is 28 mm^{-1}. Figures 2*b* and 3*b* show the reflection profile of the 020 divided by the $\bar{1}20$ profile at each wavelength; an average background was removed in each case. The relationship between wavelength and displacement along the streaks is linear within the 67 eV central position[10]. Neglecting the end effects the off-edge division shows a linear variation and the on-edge division does indeed reveal the expected dramatic variation of f' at the rhenium $L_{\rm III}$ edge.

Any estimate of f' from profile division should be based on a least squares refinement including many measured reflections, since small errors in alignment of the profiles may lead to large errors in f' estimates. This work is in progress, but the two reflections quoted here do provide useful evidence of the efficacy of the technique: they give f' estimates for Re which are in good agreement with those measured for Pr and Sm at SSRL[16]. From Fig. 2 we obtain estimates of $-27e^-$ at $f'_{\min}$ with an $f'_{\max}$ of $-1e^-$ and $-17e^-$ at the lower energy limit of our sampling. The energy width of the variation seen in f' from $f'_{\min}$ to $f'_{\max}$ is reasonable at 11 eV, although the position of the minimum f' value does not quite coincide with the point of

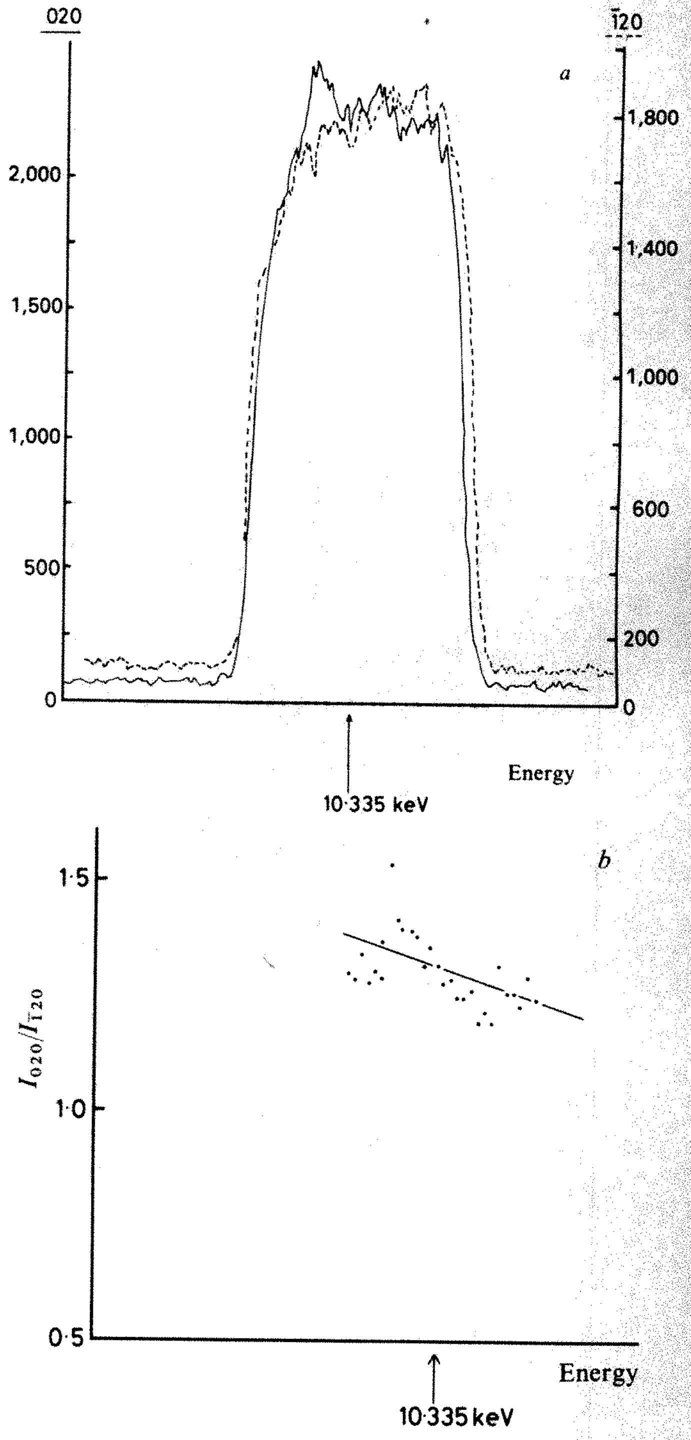

Fig. 3 *a*, Densitometered profiles of the two reflections $\bar{1}20$ and 020, for the 'off-edge' case. The 020 profile is shown as a solid line and the $\bar{1}20$ as a broken line. *b*, Divided intensity profiles (020/$\bar{1}20$), after removal of background, showing the effect of a slight linear variation due to f' 'off-edge'.

inflexion of the $\bar{1}20$ absorption profile which would have been expected. The energy resolution $\delta E/E$ at any point in the profiles, in this experiment, is of the order of 1×10^{-3}; this estimate makes allowance for monochromator rocking width, size of slit at focus, thickness of sample, sample mosaic spread, vertical sample size, beam cross-fire angles, correlated wavelength spread and slit–sample–film distances[11]. There are constraints on these quantities to preserve the energy resolution in a diffraction streak and their effects depend on the location of the spot on the film[11]. The necessary use of a thin sample also reduced absorption effects, but even so in general absorption corrections will be needed which will require the determination of a complete absorption surface for all energies in the pass-band. These can be determined by recording direct beam transmission streaks as a function of spindle angle ϕ and inclination angle μ of the rotation camera.

We believe that the method has the greatest potential for phasing the reflections from protein crystals containing only one anomalous scatterer per asymmetric unit: in such a case the mass-fraction of the heavy atom is very small (typically $\approx 1\%$); the change in the absorption of the sample at the edge is, therefore, much smaller than with our trial heavy atom complex. Although the heavy-atom contribution to protein structure amplitudes is very small, the atomic scattering factor, f_0, falls off rapidly with increasing $\sin\theta/\lambda$ whilst the values of f' and f'' of an anomalous scatterer do not; for high-angle reflections for a typical protein crystal the anomalous effect may be as great as 40% of the *average* structure amplitude (U.W.A., unpublished calculation.) The relative accuracy to which an intensity absorption correction would need to be determined for a protein metal atom derivative would be $\approx 5\%$.

It may be thought that order-to-order resolution for broad diffraction spots may be lost for a dense diffraction pattern from a protein crystal. The change in inclination of the reflection streaks around an oscillation photograph does in fact preserve order-to-order resolution parallel to the horizontal mounting axis outside the blind region (compare for example native protein crystal photographs at the Guinier position and off Guinier position in ref. 10). The overlap perpendicular to the mounting axis is controlled in any case by the size of the rotation angle. However, the use of a small raster step is an inconvenience and it would be necessary to reduce the volume of data produced with a flat-bed densitometer by resorting to an on-line pre-prediction control programme.

We thank MRC and SERC for support, and the SERC Daresbury Laboratory for providing synchrotron experimental beam time and facilities. We also thank Dr J. Spencer of the Department of Inorganic Chemistry, Bristol University for supplying suitable samples, Dr M. Elder of SERC Daresbury Laboratory for providing film densitometry facilities, and Drs S. Ealick of the University of Alabama and G. Taylor of Birkbeck College, London University for helpful discussions.

Australian seismic refraction results, isostasy and altitude anomalies

Peter Wellman

Bureau of Mineral Resources, PO Box 378, Canberra,
Australia 2601

Although there have been extensive seismic refraction measurements over areas of continental crust, the causes of variation in crustal thickness, and of variation in mean crustal seismic velocity, are poorly understood. If there is regional (3° × 3°) isostatic equilibrium of the crust, such as suggested by many studies of regional gravity, then crustal thickness variation should be caused largely by variation in surface altitude and crustal density. Seismic refraction results from Australia are used here to confirm that these crustal isostatic effects are a major (40%) cause of variation of crustal thickness even in a continent of little surface relief. However, there is an equally important regional variation in crustal thickness unrelated to crustal isostasy—this is thought to be due to density variation in the lower lithosphere[1].

It is initially assumed that the Earth's crust is in isostatic equilibrium relative to the uppermost mantle and, in addition, that the upper mantle density (σ_m) does not vary horizontally or vertically from where its upper surface under continents is shallow to where it is deep. Consider any crust of mean density σ, surface altitude h, and depth to the base of the crust below sea level H. A standard crust has a surface at sea level, base H_s below sea level, and mean density σ_s. For isostatic equilibrium[2]

$$H = \frac{H_s(\sigma_m - \sigma_s) + h\sigma}{\sigma_m - \sigma} \qquad (1)$$

Average densities of $\sigma_m = 3.3$ tonne m^{-3} and $\sigma_s = 2.9$ tonne m^{-3} can be assumed[2], so $\sigma/(\sigma_m - \sigma)$ averages ~7.25. In Australia h is generally <0.6 km, and σ varies from ~2.75 to 3.06 tonne m^{-3}, so the effect of h on H can be evaluated with an error of <2 km.

We define a depth of the base of the crust when corrected for surface altitude as H' ($H' = H - 7.25h$)

$$H' = \frac{H_s(\sigma_m - \sigma_s)}{\sigma_m - \sigma} \qquad (2)$$

The Nafe–Drake empirical correlation between rock density and seismic P-wave velocity[3] is almost linear in the velocity range 5.5–8 km s^{-1}. Assuming linearity, using velocity subscripts with the same meaning as for density, and inverting equation (2) gives

$$\frac{1}{H'} = \frac{V_m}{H_s(V_m - V_s)} - \frac{V}{H_s(V_m - V_s)} \qquad (3)$$

so there should be linear correlation between $1/H'$ and mean crustal velocity V.

Table 1 and Fig. 1 give those crustal seismic refraction results for Australian continental crust where both mean P-wave velocity of the crust and crustal thickness have been determined. Results from regions A, B, C and D are considered less accurate because only travel-times of critically refracted waves were used in the interpretation. Other results were derived using all available crustal and upper mantle seismic P phases. The locations given are those of the crustal thickness determinations, not the shot points.

A least-squares straight-line fit of mean crustal velocity with the inverse of the corrected depth of the base of the crust below sea level for all data is

$$1/H' = (0.123 \pm 0.019) - (0.015 \pm 0.003)V \qquad (4)$$

where the uncertainty is the coefficient of variation. The correlation coefficient ($r = 0.59$) is statistically significant at the 95%

confidence level. Errors in V are thought to be relatively small, and in equation (4) are assumed to be zero. If errors are partitioned equally between V and $1/H'$ this infers very large errors in the velocity measurements. For example, Pilbara mean crustal velocity would have a systematic error of 0.3 km s^{-1}; this is unacceptably high either as an error in the mean velocity, or as an error in the density–velocity relationship.

The following calculations suggest that equation (4) is consistent with the assumptions. For these calculations I have adopted the mean values of quantities in Table 1, but with coefficients of variation increased by a factor of 3 to allow for sampling bias

$$V_m = 8.07 \pm 0.08 \ \text{km s}^{-1}, \qquad V_s = 6.43 \pm 0.11 \ \text{km s}^{-1},$$
$$H_s = 37.8 \pm 3.6 \ \text{km}$$

When H' is infinite, then equation (4) gives an estimate of the mean uppermost-mantle velocity (P_n) of 8.3 ± 2 km s^{-1}; this is consistent with the mean of the measured uppermost-mantle velocities. (Note that mantle velocities were not used in equation (4).) The slope of equation (4) is consistent within experimental error with the value of 0.016 ± 0.002 found by evaluating $1/(H_s(V_m - V_s))$ using the means of the measured values given above. It is also consistent within experimental error with the value of 0.020 ± 0.003 found by evaluating equation (3) by using the Nafe–Drake empirical relationship between crustal density and crustal velocity, together with Woollard's[2] preferred range of values H_s between 33.2 and 34.5 km, and $\sigma_m - \sigma_s$ between 0.383 and 0.415 tonnes m^{-3}.

The least-squares correlation of mantle P_n velocity with depth of the base of the crust below sea level (H) is $V_m = (7.76 \pm 0.14) + (0.0078 \pm 0.0033)H$. Hence there is a systematic change in V_m from 7.99 km s^{-1} at 30 m depth to 8.15 km s^{-1} at 50 km depth; this is equivalent to an increase in mantle density of 0.04 tonnes m^{-3}. This small change would have an effect of less than <1 km on H' in equation (4). Regions B, C,

E, F, Q and J have mantle velocities measured from directions near right angles. Significant upper mantle anisotropy is suggested only by results from the Pilbara Block[4].

I conclude that the effect on crustal thickness of variations of surface altitude and mean crustal density can be adequately modelled using equation (3). This equation assumes regional isostatic equilibrium relative to the uppermost mantle, assumes that the mantle has constant density down to the level of the deepest crust, and assumes a linear correlation between P-wave velocity and density.

The relative magnitude of the components of crustal thickness variation are evaluated as follows. The total variance from the measured crustal thicknesses listed in Table 1 is $66.0\ \mathrm{km}^2$. Surface altitude variation and its associated crustal root variation is calculated from the difference in variance of H and H' to be 2% of this. The change in crustal thickness associated with change in mean crustal density is $\sim$38% of the variance ($r^2 = 0.38$ for equation (4)). The remaining variance (that causes deviation from equation (4)) can be split into within-region variance of $11.3\ \mathrm{km}^2$ (17% of total variance), and between-region variance causing the remaining 43%.

The within-region variance is caused both by errors in determination of relative crustal thickness and relative mean crustal velocity within each region, and by crustal strength being sufficiently high in western and central Australia that areas $<3° \times 3°$ are not in complete isostatic equilibrium[5]. The variance due to departures from isostatic equilibrium is unlikely to be $>$8% of total variance (one-half within-region variance) and so is much smaller than the variance due to the isostatic effects of topography and crustal density changes (40% of total variance). This reinforces the conclusion that isostatic equilibrium relative to the uppermost mantle is largely achieved.

Between-region variance is $\sim$43% of total variance, so its origin is important both in understanding and predicting crustal thickness. It is unlikely that errors in crustal thickness and crustal velocity contribute significantly to within-region or between-region variance, because the within-region variance is small both in the better studied regions (F, G and I) and in regions where independent investigators have made independent measurements (regions I and J). Between-region changes in mean atomic number could, in theory, cause regional changes in the velocity–density relationship[6,7]. There is no good evidence for significant differences in the chemistry of the surface rocks from the various regions so significant change in mean atomic number seems unlikely. The remaining possible causes of between-region variance—horizontal density variations in the lower lithosphere, and dynamic forces on the base of the lithosphere—are considered below by comparing mantle altitude anomalies under continents with those under oceans.

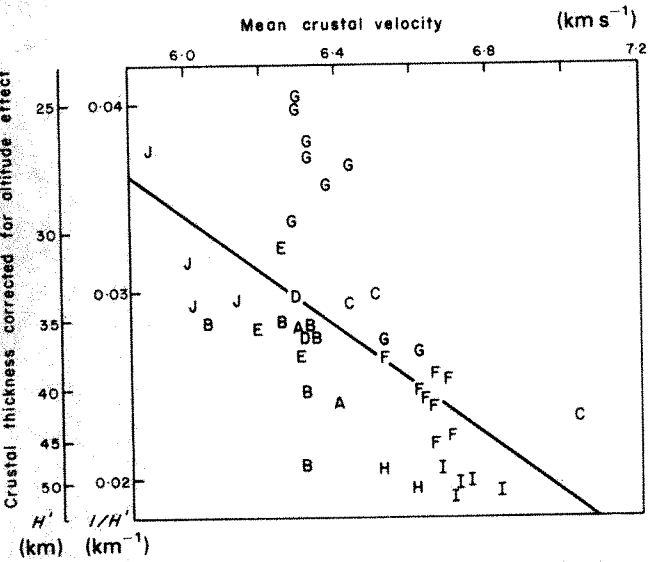

Fig. 1 Relation of inverse of corrected crustal thickness to mean crustal velocity. The letters refer to the regions of Table 1 and Fig. 2. The line gives the least-squares correlation.

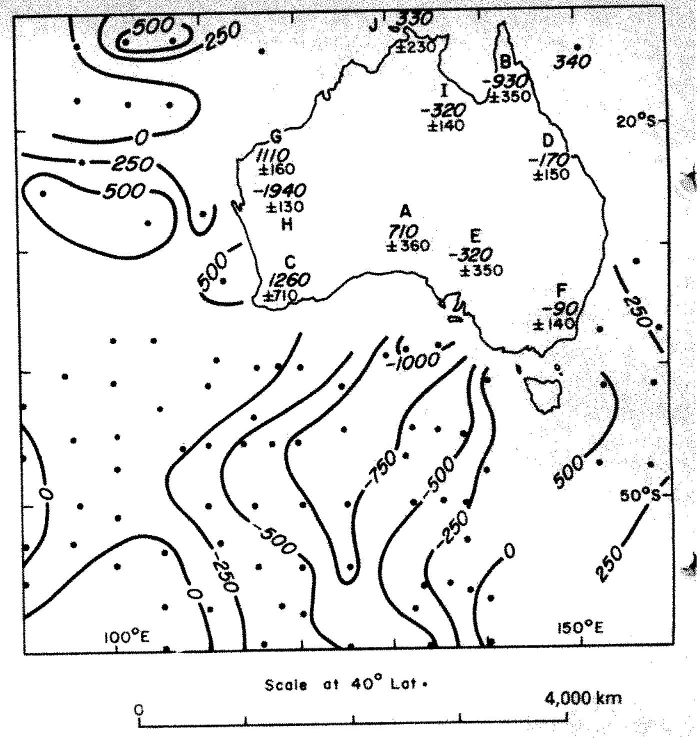

Fig. 2 Mean height anomalies in metres. Shallower areas have positive mean height anomalies. In oceanic areas dots show data points; contour interval, 250 m.

The between-region differences in H' residual are converted to equivalent differences in the upper level of mantle overlain by oceanic crust of assumed constant thickness and by seawater of density σ_w. A difference of p in the thickness of sea-level crust is equivalent to a difference of $p(\sigma_m - \sigma_s)/(\sigma_m - \sigma_w)$, or about $p/5.68$, in the upper level of oceanic mantle. For each region of Fig. 1, a mean altitude anomaly and its coefficient of variation has been calculated using H' residuals divided by 5.68.

In oceanic areas, altitude anomalies are calculated by subtracting from $1° \times 1°$ mean water depths, the expected water depth for that age crust, and correcting for the isostatic effect of sediment thickness[1]. The altitude anomalies used are the means of $5° \times 5°$ areas. Altitude anomalies derived for continental areas are assumed to have the same mean (zero) as those derived for areas of oceanic crust.

Figure 2 shows altitude anomalies derived from seismic refraction data in continental Australia, together with published altitude anomalies for the Indian and Southern Oceans[1]—these have been recontoured west of Australia. East of Australia in the Tasman and Coral Seas new rough estimates of altitude anomalies are given.

Altitude anomalies do not show a systematic trend across Australia, nor do they show a correlation with seismic P-wave residuals[8–10], heat flow variation[11], or long-wavelength gravity anomalies[1].

Continental and oceanic values do not show an overall pattern, as there seems to be a break between continental and oceanic values. The lack of systematic variation across the region indicates that altitude anomalies are unlikely to be due to dynamic asthenospheric forces on the base of the lithosphere as these would be continuous across lithosphere boundaries. The interpretation that altitude anomalies originate from horizontal density variation in the lower lithosphere[1] is therefore supported. Relative to oceanic altitude anomalies, those from the continent have a larger range and shorter wavelength; this supports models where the continental lithosphere has had a relatively long and diverse history[12]. An analysis of seismic refraction data from all continents would define the constants of equation (3) more precisely, and allow altitude anomalies to be mapped over the whole Earth.

I interpret variation in crustal thickness as being mainly due to two effects. (1) Because surface altitude and mean crustal density vary relatively rapidly on continents, the crust appears to be in isostatic equilibrium with an upper mantle of uniform density, so variation in surface altitude and mean crustal density show a strong correlation with variation in mean crustal thickness. (2) Isostatic equilibrium is actually between the whole lithosphere and the asthenosphere[13], so, to keep equal pressure on the asthenosphere and keep the continental crust near sea level, any regional variation in lower lithosphere density causes regional variation in continental crustal thickness.

Vertical distribution and isotopic fractionation of living planktonic foraminifera from the Panama Basin

A model[1,2], which explains the vertical and seasonal distribution of planktonic foraminifera was developed using data from the western North Atlantic and is comprised of three tenets: (1) The conditions in the photic zone (upper 80–100 m) exclusively dictate planktonic foraminifera species composition and abundance throughout the water column. (2) Species are vertically stratified within the photic zone according to their temperature preference. Depth distribution according to temperature preference has been proposed by several authors[3] based on isotope analyses of sediments. Due to seasonal temperature variations, seasonal variations in the $\delta^{18}O$ composition of seawater, and species-specific isotope fractionation, rigorous proof of this hypothesis cannot be provided from sediment analyses alone. (3) The chlorophyll maximum is a major food source zone, which is preferentially exploited by foraminifera. Our data from the Panama Basin, which are presented here, are confirmation of this model. The Panama Basin in the eastern equatorial Pacific, which has a shallow and steep thermocline, was sampled for living planktonic foraminifera. A multiple opening–closing net and environmental sensing system (MOCNESS)[4] was used to collect 13 sets of eight vertically stratified oblique samples. We report here the quantitative distribution and stable isotopic composition of planktonic foraminifera from four MOCNESS tows taken over 5 days, during August 1979 (RV *Knorr* cruise 73) at 5°20′ N, 8°50′ W. Each tow consisted of eight samples which integrated ~12.5-m intervals from 0 to 100 m for MOC 126, 25-m intervals from 0 to 200 m for MOC 127, 100–150-m intervals from 0 to 1,000 m on MOC 128 and 250-m intervals from 0 to 2,000 m on MOC 131.

Oxygen and carbon isotope analyses were made on planktonic foraminifera from the MOCNESS tows and the surrounding seawater. Isotope determinations were made on a triple collector mass spectrometer (Micromass 903). The carbonate samples were vacuum roasted at 375 °C for 1 h and reacted with 100% phosphoric acid at 50 °C. The precision for carbonate is ±0.05‰ for oxygen and carbon. The $\delta^{18}O$ composition of seawater was determined with a rapid equilibration-extraction method described in ref. 5. The $\delta^{13}C$ composition of total dissolved CO_2 was predicted using the PO_4–$\delta^{13}C$ relationship given in ref. 6 and PO_4 data for a station occupied in between MOCNESS tows. The 0–100-m series provided an ideal test of the previous model[1,2] for several reasons. (1) Eight MOCNESS oblique tows at 12.5-m intervals (MOC 126) provide high resolution sampling. (2) There is a 15 °C temperature gradient in the upper 100 m, encompassing one of the steepest thermoclines (0.5 °C m^{-1}) in the world's oceans which occurs between 25 and 37.5 m. (3) The region is extremely productive, and foraminifera are abundant. (4) A sharp chlorophyll maximum is well developed in the thermocline[7]. (5) The water column was sampled for measurement of $\delta^{18}O$ of seawater.

Twenty-three species of planktonic foraminifera were identified in the Panama Basin tows. In the 0–100-m tow, MOC 126 (Fig. 1*a*), 16 species averaged more than 10 per 1,000 m^3. The dominant species, *Globoquadrina dutertrei*, showed a pronounced abundance peak between 25 and 50 m, precisely the interval corresponding to the steep thermocline, highest primary productivity and the associated deep chlorophyll maximum (DCM) (Fig. 1*a*)[7]. Nine out of 16 species or morphotypes showed pronounced maxima in the steep thermocline. Note that the abundance axis is logarithmic. *Globigerinoides sacculifer* and *Globigerinoides conglobatus* were numerically dominant at the chlorophyll maximum, but they showed comparable abundances in the surface mixed layer. *Globigerinoides ruber*, *Globigerinita glutinata*, *G. sacculifer* (without final sac chamber), and *G. conglobatus* were very abundant in the less productive surface mixed layer. Two species which secrete morphologically distinct terminal chambers, *Orbulina universa* and *G. sacculifer*, showed sharp maximum concentrations of these morphologies in the chlorophyll maximum zone between 25 and 37 m (Fig. 1*a*). *Globigerina calida* and *Globorotalia theyeri* had maxima below the steep thermocline. Of particular significance is the observation that the *G. theyeri* population descended from a maximum at 100 m on 4 August, MOC 127 (Fig. 1*b*) to between 250 and 375 m on 5 August, MOC 128 (Fig. 1*c*) to a maximum between 500 and 750 m on 8 August, MOC 131 (Fig. 1*d*). This averaged to a 170 m per day descent rate.

Oxygen isotope measurements of seawater (Fig. 2) and continuous temperature and conductivity measurements during the MOCNESS tows permit the construction of an accurate calcite

0028–0836/82/340841—04$01.00

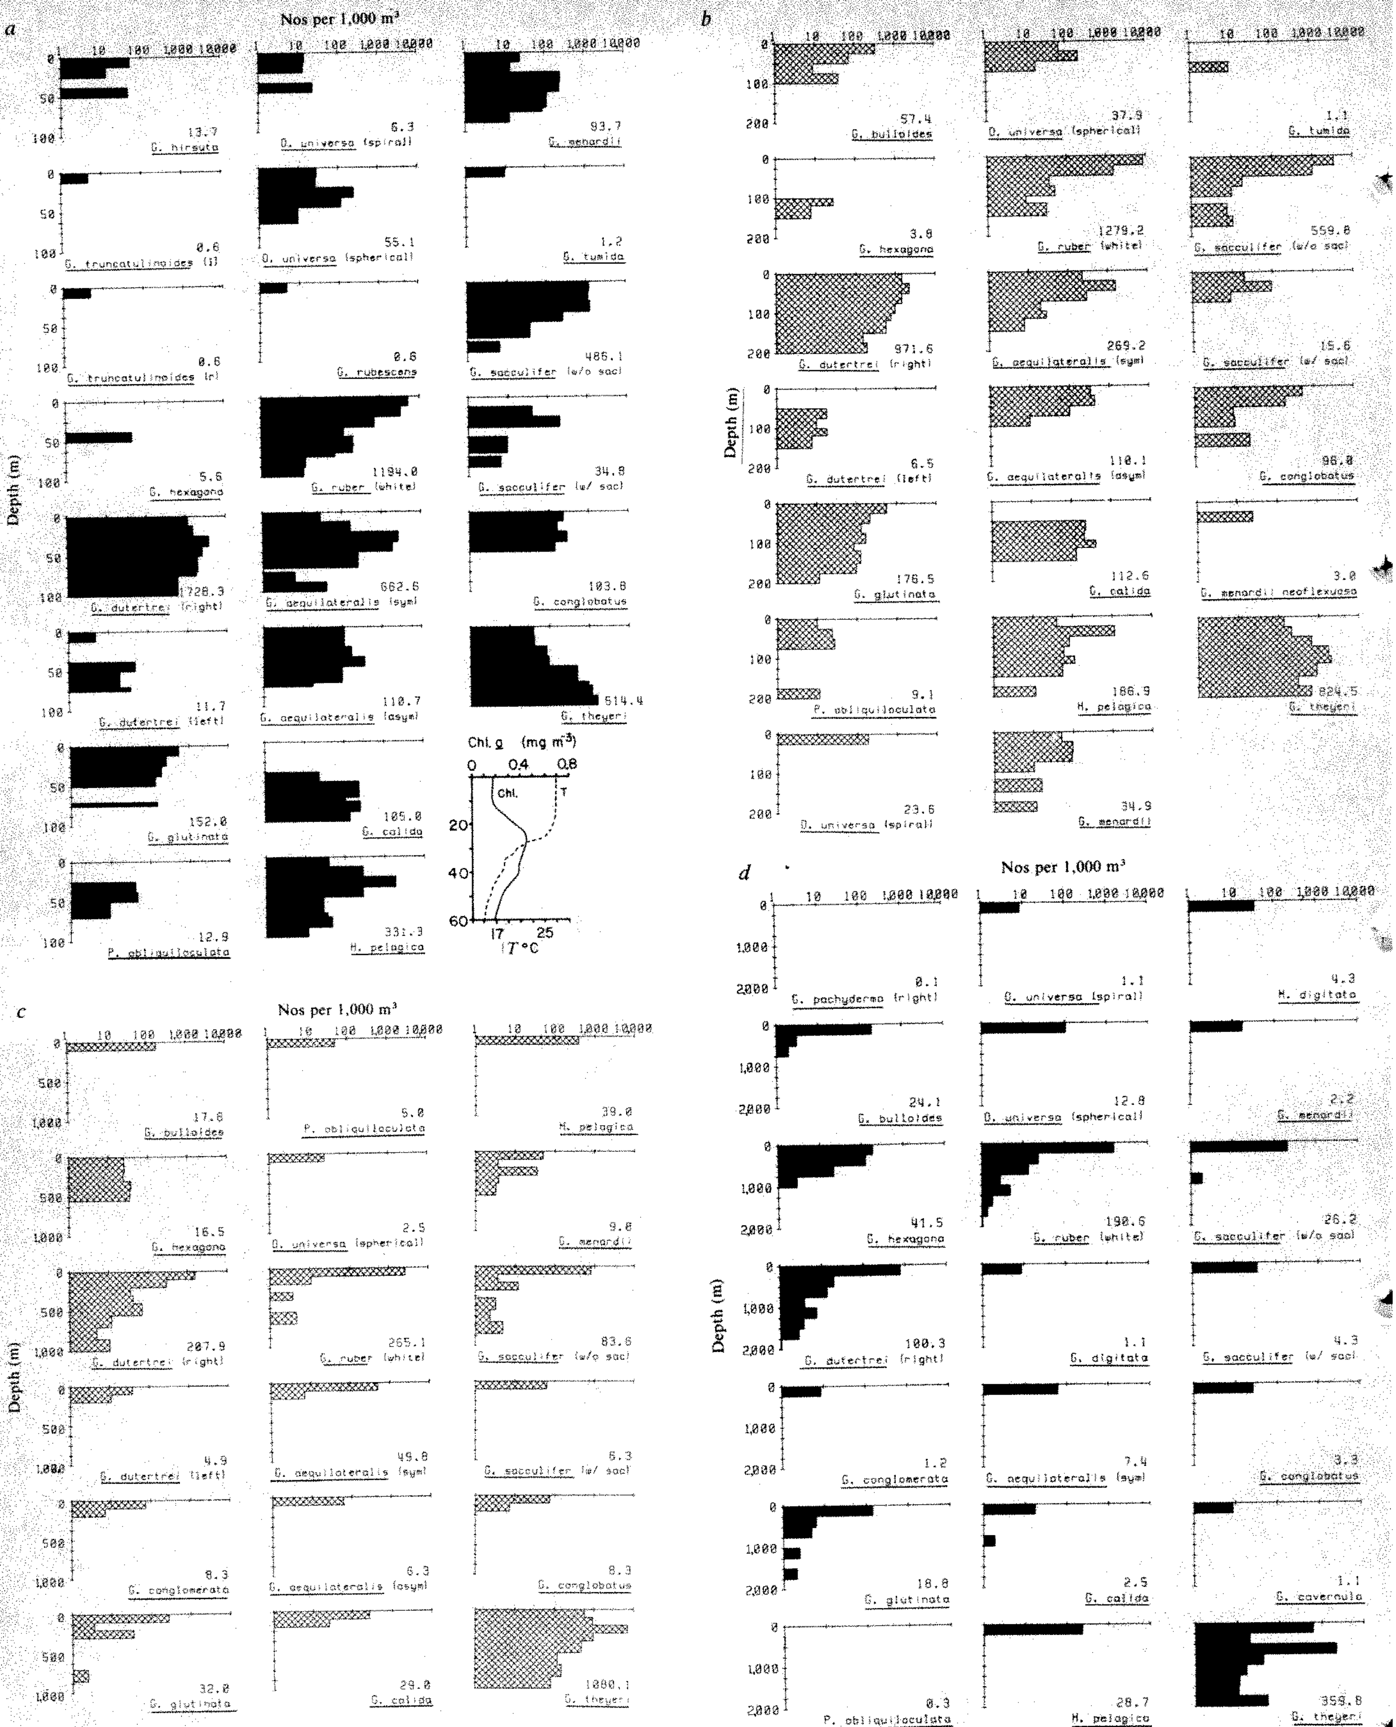

Fig. 1 *a*, Vertical profiles of living planktonic foraminifera caught in MOCNESS 126 oblique hauls in the Panama Basin between 0 and 100 m (3 August 1979; night). The number in the lower right corner of each histogram represents the average number per 1,000 m^3 over the interval towed, in this case 0–100 m. Temperature and chlorophyll profiles for this station are in the lower right corner. Chlorophyll data from Marra *et al.*[7]. *b*, Vertical profiles of living planktonic foraminifera caught in MOCNESS 127 oblique hauls in the Panama Basin between 0 and 200 m (4 August 1979; day). *c*, Vertical profiles of living planktonic foraminifera caught in MOCNESS 128 oblique hauls in the Panama Basin between 0 and 1,000 m (5 August 1979; day). *d*, Vertical profiles of living planktonic foraminifera caught in MOCNESS 131 oblique hauls in the Panama Basin between 0 and 2,000 m (8 August 1979; night).

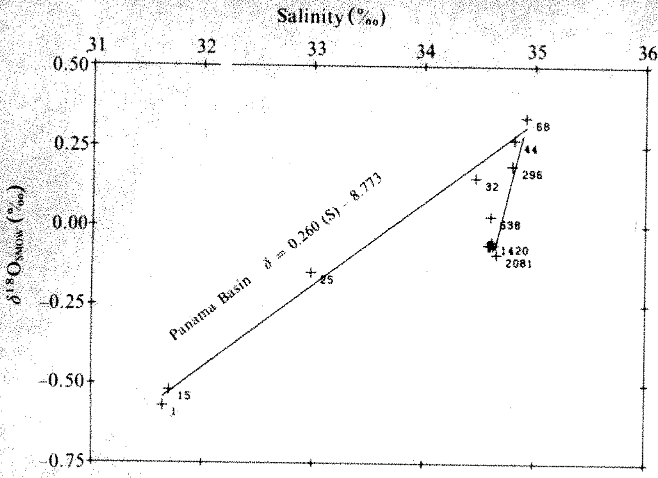

Fig. 2 Salinity versus $\delta^{18}O_{SMOW}$ for the Panama Basin. The numbers next to the symbols indicate water depth. The data indicate binary mixing between surface water and intermediate water, and deep water and intermediate water.

equilibrium profile (Fig. 3*a*) using the mollusc equation of Epstein *et al.*[8]. Oxygen isotope measurements of several different size fractions of nine foraminifera species or morphotypes show that shell growth is restricted to the upper 100 m, even though many species are found in abundance below 100 m. The oxygen isotope data indicate that specimens found below 100 m were simply descending through the water column while adding little or no additional calcite (Fig. 3*a*). It is also evident from the δ^{18}O versus depth plots (Fig. 3*a*) that most species generally grow within narrower depth intervals within the photic zone than their overall distribution would imply. For example, *G. ruber* is found in decreasing numbers between the surface and 100 m (Fig. 1*a*). Its δ^{18}O composition indicates that it is growing typically 0.5‰ lighter than equilibrium[1,2,9] in the surface mixed layer. Between 25 and 37.5 m *G. ruber* is adding some calcite, but below this level the data-point at 60 m indicates vertical descent from the mixed-layer.

G. dutertrei calcifies in oxygen isotope equilibrium[2] and the isotope data indicate growth in the thermocline, where *G. dutertrei* are found in maximum abundance (Fig. 1*a*). Between 37.5 and 100 m, *G. dutertrei* becomes only slightly enriched in δ^{18}O, and are far from equilibrium at these depths. This is evidence that they are descending from the steep thermocline (Fig. 3*a*). The slight δ^{18}O enrichment is probably due to shell thickening[2,3]. Scanning electron microscope observations are needed to confirm this hypothesis.

G. theyeri and *G. calida* appear to be in oxygen isotopic equilibrium between 50 and 100 m, where they are dominant in MOC 126 and MOC 127, but their isotopic values do not change when they are collected below the photic zone (approximately upper 100 m) even though they may be numerically dominant below 100 m. Again, vertical descent is obvious and, in these two examples, no additional calcite was added during descent, otherwise we would observe a shift towards the equilibrium line. Thus we feel confident that this sampling strategy adequately captures all adult stages of shell calcification and allows us to examine the entire calcification process.

There is a 2‰ decrease in the δ^{13}C of total dissolved CO_2 between the surface and 100 m at the site of MOC 126 (Fig. 3*b*). There is some evidence that the δ^{13}C compositions of *G. dutertrei* and *Globigerinella aequilateralis* are affected by this gradient. *G. dutertrei* decreases more than 1‰ δ^{13}C between the surface and 100 m (Fig. 3*b*). The largest drop in δ^{13}C for *G. dutertrei* is coincident with the 1.5‰ decrease in δ^{13}C of total dissolved CO_2 in the steep thermocline. *G. aequilateralis* show a less significant shift in δ^{13}C, but this species also parallels the seawater trend. The carbon isotope equilibrium line for inorganic calcite would fall to the right of the data, but parallel to the δ^{13}C of total dissolved CO_2 line (see ref. 9 for a discussion of calcite isotope equilibrium).

Note that *G. dutertrei* and *G. theyeri*, which calcify in oxygen isotope equilibrium, have the same carbon isotopic composition as ambient δ^{13}C of total dissolved CO_2 (Fig. 3*b*). As noted above, oxygen isotope measurements of *G. dutertrei* indicate equilibrium precipitation at ~30 m (Fig. 3*b*). Below 30 m *G. dutertrei* shows oxygen isotope enrichment, but the data are

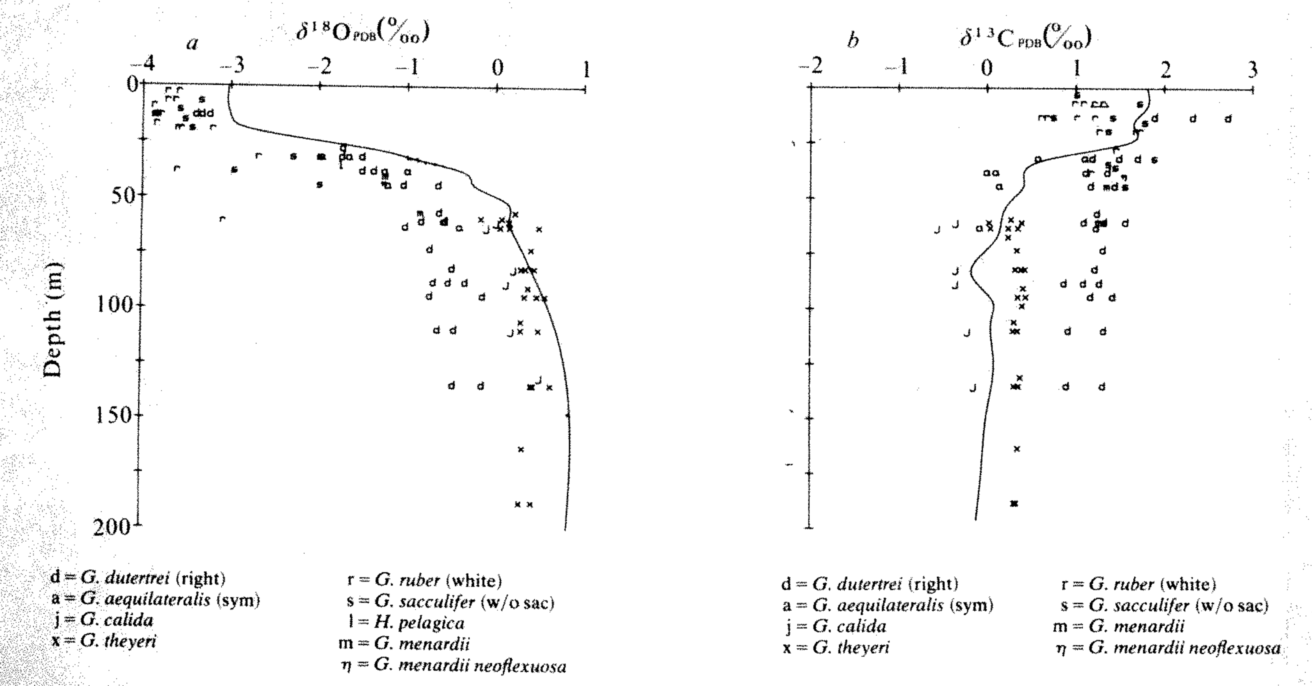

Fig. 3 *a*, Oxygen isotope composition of various size fractions of planktonic foraminifera as a function of depth in MOC 126, 0–100 m and MOC 127, 0–200 m. The solid line is the calculated equilibrium $CaCO_3$–δ^{18}O variation. All specimens plotted were protoplasm full. Corresponds to histograms in Fig. 1*a*, *b*. Carbon isotope composition of various size fractions of planktonic foraminifera as a function of depth in MOC 126, 0–100 m and MOC 127, 0–200 m. The solid line is the δ^{13}C of total dissolved CO_2.

significantly lighter than equilibrium, indicating vertical descent from 30 m. Similarly *G. dutertrei* calcite has the same $\delta^{13}C$ as the $\delta^{13}C$ of total CO_2 at 30 m and shows departure from the $\delta^{13}C$ of total CO_2 curve below 30 m, which is in agreement with the $\delta^{18}O$ data. *G. theyeri* is in oxygen isotope equilibrium between 50 and 75 m and also has the same $\delta^{13}C$ of carbonate as ambient $\delta^{13}C$ of total dissolved CO_2. *G. theyeri* differs from *G. dutertrei* by 1‰. The algal symbiont bearing species (such as *G. ruber*, *G. sacculifer*, *G. aequilateralis*) are generally depleted with respect to ^{13}C when compared with the ambient $\delta^{13}C$ of total dissolved CO_2.

We thank Greg Kolibas for stable isotope measurements, Ted Baker for computer programming and J. K. Bishop for providing PO_4 data. Trans-sexually grafted antennae influence development of sexually dimorphic neurones in moth brain

Anne M. Schneiderman*‡, Steven G. Matsumoto* & John G. Hildebrand†

* Department of Neurobiology, Harvard Medical School, Boston, Massachusetts 02115, USA
† Department of Biological Sciences, Columbia University, New York, New York 10027, USA

Observations in insects reveal sexual differences in the central nervous system (CNS), associated with sexually dimorphic patterns of reproductive behaviour[1-9]. For example, in certain species of moths, including the sphinx moth *Manduca sexta*, only males fly towards a sexually receptive female or towards a source of the female sex pheromone[10,11]. In *Manduca*, specialized olfactory receptor cells found only on male antennae[12,13] respond sensitively and selectively to the female sex pheromone (unpublished experiments with K.-E. Kaissling and R. J. O'Connell). Their axons project into the macroglomerular complex (MGC), which is characteristic of male, but not female, antennal lobes (ALs; Fig. 1*b*, *d*)[1-3,5,8,9,14]. These afferents to the MGC presumably synapse with male-specific AL neurones[8,15] to begin the processing of phenomonal information. We have now devised a surgical procedure for producing antennal gynandromorphs of *Manduca* in which one of the two ALs receives sensory innervation from an antenna formed by a transplanted imaginal disk of the opposite sex. We report here that in these gynandromorphs, the physiological and morphological properties of certain AL neurones are influenced by the gender of the antennal sensory axons contacting them. In particular, neurones resembling the male-specific AL neurones appear in female ALs innervated by sensory axons from a grafted male antenna.

We produced 329 gynandromorphic larvae (Table 1, group 1), of which 78% metamorphosed and eclosed as adult moths. In 49% of these moths, the transplanted imaginal disk had everted and formed an antenna. All transplanted antennae exhibited structure characteristic of the donor's sex; none appeared to be modified by transplantation into a host of the opposite sex.

In 59% of the animals with everted grafts, the AL on the operated side was innervated by the nerve from the transplanted antenna. In these animals, the ingrowing sensory axons found their targets, the AL neurones, even though the pupal antennal nerve, comprising axons believed to provide contact guidance for antennal afferents[13,16], had been severed during surgery. We presume that the axons followed stumps of the 'guide fibres' still associated with the AL and suspect that the growing axons failed to do so in the remaining animals (41% of those with everted grafts). In the latter, the antennal nerve either ended abruptly as a mass of fibres near the base of the antenna or grew into the lateral protocerebrum, proboscis, or suboesophageal ganglion. In these animals, the operated AL was stunted, as in the deafferented AL in a deantennated moth[17,18]. No innervation of the contralateral AL by the graft was ever observed.

We examined histological sections from the brains of unoperated moths and antennal gynandromorphs (Fig. 1; Table 1,

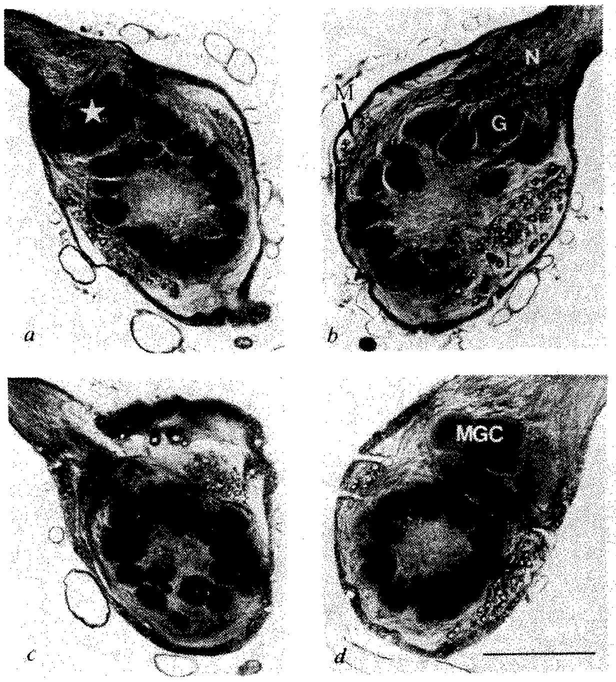

Fig. 1 Frontal sections through the operated (gynandromorphic) and control (normal) ALs of female (*a*, *b*) and male (*c*, *d*) moths, prepared from paraffin-embedded preparations and stained with Cresylecht violet and Luxol fast blue[18]. To produce antennal gynandromorphs of *Manduca*, antennal disks are transplanted unilaterally on the first or second day of the fifth (last) larval instar. Larvae are restrained in aluminium tubes and anaesthetized by chilling in a bath of ice-cold water. The antennal disk[14], which lies within the head capsule near the base of the larval antenna, is excised and replaced with the corresponding disk from a donor of the opposite sex. A mixture of phenylthiourea, streptomycin sulphate and penicillin (2 : 1 : 1)[19] is placed in the wound, which is then sealed by melted myristic acid (W. Harris, personal communication). In *b*, the antennal nerve (N) enters the normal female AL. The glomeruli (G) are arrayed around a central region of coarser neuropil. The cell bodies of the AL neurones are gathered in three cortical groups: a large lateral cluster (L), a smaller medial cluster (M) and a small group anterior to this plane of section. The normal male AL (*d*) characteristically exhibits the MGC, which lies near the entrance of the antennal nerve and is not present in the normal female AL (*b*). In the gynandromorphic female AL (*a*), a structure resembling the MGC (☆) lies near the entrance of the antennal nerve from the grafted male antenna. The gynandromorphic male AL (*c*) lacks a MGC. Scale bar, 200 μm.

---

‡ Present address: Department of Biological Sciences, 901 Fairchild, Columbia University, New York, New York 10027, USA.

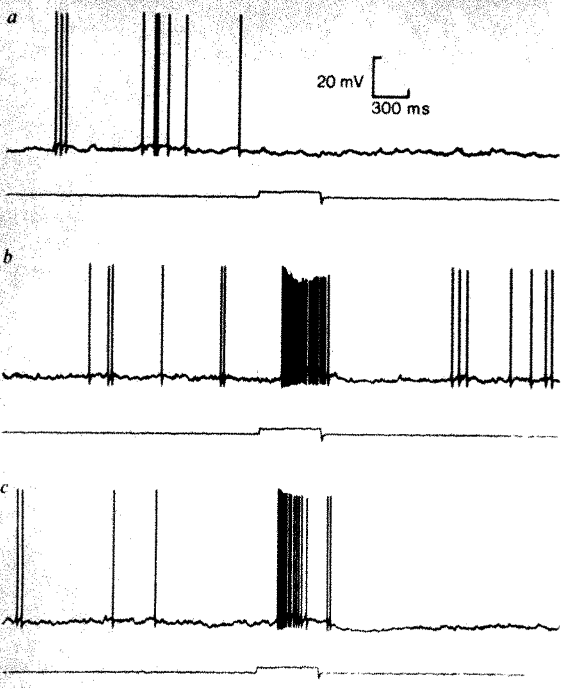

Fig. 2 Intracellular recording from a neurone in the operated AL of a female gynandromorph. Recordings were made with microelectrodes filled with a solution of 4% $CoCl_2$ in 0.75 M KCl and having impedances of 50–75 MΩ (ref. 8). This recording shows the postsynaptic responses elicited by directing pulses of air (*a*), *trans*-2-hexenal (*b*), or bombykal (*c*) on to the grafted male antenna. Odourants were delivered in carrier pulses (500–600 ms duration) of charcoal-filtered air. This cell was stimulated when the antenna was exposed to *trans*-2-hexenal or bombykal. AL neurones responsive to antennal stimulation with bombykal were not found in unoperated females or in the control AL of gynandromorphic females. Conversely, in gynandromorphic males, bombykal never elicited responses from neurones in the AL innervated by the grafted female antenna, although neurones in the control AL responded normally to pheromonal stimulation of the male's own antenna. Injection of cobaltous ions at the completion of recording was accomplished by passing 10 nA depolarizing current pulses of 200–300 ms duration for 15 min at 1 Hz.

group 1). In the brains of male gynandromorphs, the MGC was always missing from the AL innervated by the female graft (Fig. 1*c*). Conversely, the brains from female gynandromorphs invariably exhibited a structure resembling the MGC in the AL innervated by the male graft (Fig. 1*a*). In 100 control larvae, we transplanted a disk of the same sex into a host (Table 1, group 2) or re-implanted its own imaginal disk (Table 1, group 3). Of these animals, 86% survived; in 53% of the survivors, the graft formed an antenna; and in 72% of these the operated AL was innervated by the antennal nerve from the graft. Under the light microscope, the ALs of the latter animals were indistinguishable from those of unoperated animals: a male AL innervated by a male graft formed a MGC, but a female AL innervated by a female graft did not. We have observed that the degree of innervation of the AL by grafts ranges from none (where the antennal nerve does not reach the AL) to complete (where there is a full-size antennal nerve). Even in ALs innervated by reduced numbers of male antennal axons, a readily identifiable MGC-like structure developed.

Table 1 Summary of antennal disk-implantation experiments

Group	Type of disk grafted	Total animals* Female	Total animals* Male	Everted graft Female	Everted graft Male	Innervated AL† Female	Innervated AL† Male
1	Opposite sex	163 (122)	166 (135)	65	60	44 (12)	30 (13)
2	Same sex	13 (12)	34 (29)	8	14	6 (4)	10 (5)
3	Self	19 (18)	34 (27)	13	11	10 (7)	7 (4)

* Values in parentheses indicate number of animals that survived surgery.

† Values in parentheses indicate number of ALs sectioned for light-microscopic examination.

With the use of intracellular recording and staining[8], we characterized neurones in the ALs of gynandromorphic moths. In 14 of 16 females with ALs innvervated by male antennal grafts, male-like interneurones were present (21 out of 34 cells tested) that are never observed in normal females. Intracellular recordings from such cells (Fig. 2) showed that they responded postsynaptically when the transplanted antenna was stimulated with bombykal. Intracellular staining with cobalt sulphide revealed, moreover, that these cells sent dendritic processes into the MGC-like region of neuropil (Fig. 3). In four gynandromorphic males, whose operated ALs received sensory inputs from transplanted female antennae (lacking pheromone receptors), the characteristic male interneurones were not found. The MGC was missing in these ALs, and no interneurones were observed that either responded when the transplanted antenna was stimulated with bombykal (11 cells tested) or had neurites in the region of the AL where the MGC would normally form. We recorded intracellularly from AL neurones in four males with the same-sex grafts (from group 2 of Table 1) and one male whose own antennal disk had been re-implanted (from group 3 of Table 1). We observed AL neurones that were responsive to bombykal (5 out of 13 cells tested) and had arborizations in the MGC. Finally, normal females and males have AL neurones that respond when the antenna is stimulated with *trans*-2-hexenal ('leaf aldehyde') but not with bombykal, and these cells have arborizations in 'ordinary' glomeruli but not in the MGC[8]. We have observed analogous cells in female and male gynandromorphs. Thus, we note a positive correlation in AL neurones between physiological responsiveness on stimulation of the antenna with pheromone and possession of dendritic arborizations in the MGC.

These observations reveal a remarkable degree of plasticity in the development of sexually dimorphic neurones in the moth's AL. We find that the gender of afferent axons has a pronounced role in the differentiation of AL neurones. A MGC-like structure develops only in ALs, female or male, innervated by axons from a grafted male antenna. In female gynandromorphs, certain AL neurones show masculine patterns of arborization in the MGC-like structure. Moreover, these neurones establish functional connections with axons from the grafted male antenna and respond postsynaptically when the antenna is stimulated by the female pheromone. Whether the axons from the grafted antenna of one sex serve to sustain or suppress the development of gender-specific interneurones in the ALs of their host of the opposite sex, or to remodel or induce response properties and patterns of dendritic branching

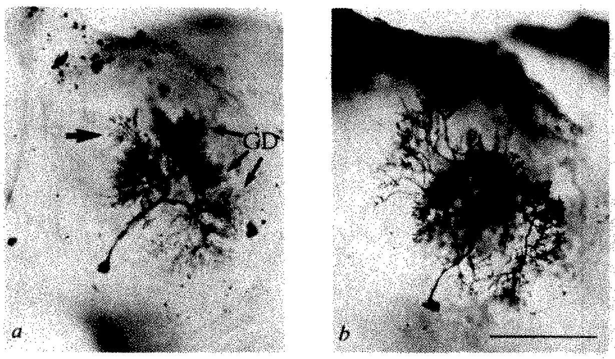

Fig. 3 *a*, Gynandromorphic female interneurone from which the intracellular recording in Fig. 2 was obtained. The cell was stained intracellularly with cobaltous sulphide, intensified with silver and viewed frontally in a whole-mount[8]. Like the normal male-specific, type-II local interneurone[8] shown in *b*, the cell in *a* lacks an obvious axon and has dendrites (GD) ramifying within the glomerular neuropil and within the MGC-like structure (arrow).● The cell body is located at the end of the primary neurite in the lateral cell cluster. Scale bar, 200 μm.

characteristic of the graft's gender, is an intriguing but unanswered question. Its answer will lead to a better understanding of the mechanisms underlying development of sexually dimorphic components in the CNS, and possibly those underlying developmental plasticity of neurones in general.

Exaggerated salt appetite of spontaneously hypertensive rats is decreased by central angiotensin-converting enzyme blockade

Injection of angiotensin II (AII) into the cerebral ventricles at doses as low as 1 pmol h^{-1} results in a marked stimulation of salt and water ingestion in the rat[1,2]. Evidence that AII is produced in the central nervous system independently of the circulating renin–angiotensin system (RAS)[3,4] raises the possibility that endogenous brain AII is involved in the physiological regulation of thirst[5]. The role of brain AII in salt appetite is still unclear[6]. Here we confirm that the spontaneously hypertensive rat (SHR), believed to have elevated levels of brain AII[7], possesses an exaggerated salt appetite compared with its normotensive controls. We also show that this exaggerated salt appetite is reduced by chronic central treatment with the angiotensin-converting enzyme inhibitor, captopril, while that of the normotensive controls is unaffected. Our study suggests that a central neuropeptide, probably AII, is involved in the maintenance of the exaggerated salt appetite in this model of hypertension.

Intracerebroventricular (i.c.v.) administration of AII receptor antagonists[8] or angiotensin-converting enzyme inhibitors[9] to the spontaneously hypertensive rat of the Okamoto strain, but not to the normotensive control Wistar Kyoto (WK) rat results in a marked, rapid, hypotensive response independent of the circulating RAS. Furthermore, an increased density of immunoreactive AII has been reported in hypothalamic neurones of the SHR[10]. As the circulating RAS in the SHR does not differ from that in the WK rat[11], these findings sugges an overactivity of the brain RAS in the SHR. The SHR have an exaggerated salt appetite compared with WK rats[12]. This given the evidence for overactivity of the brain RAS in the SHR, may be due to overproduction of central AII. To tes this hypothesis, we have monitored fluid intake in groups o SHR and WK animals offered a choice of water or saline before and after chronic infusion of captopril into the left latera cerebral ventricle in an attempt to block angiotensin II production.

Figures 1 and 2 show the fluid intakes of SHR and WK rats offered a choice of saline or water before and after infusion of either captopril, 80 μg h^{-1}, or vehicle. In the pretreatment control period, SHR drank 23.3 ± 1.0 ml per 100 g body weight per day (mean ± s.e.m. of 100 observations) of saline and 4.8 ± 0.3 ml per 100 g per day ($n = 100$) of water; this represents a saline preference of 83% of total fluid intake. In the same period, WK rats drank 7.1 ± 0.5 ml per 100 g per day ($n = 100$ of saline and 9.3 ± 0.3 ml per 100 g per day ($n = 100$) of water saline representing 43% of fluid intake. Therefore, SHR had nearly double the total fluid intake of the WK rats ($t = 8.3$ $P < 10^{-13}$) and also a significantly higher proportion of saline in this intake ($t = 12.7, P < 10^{-24}$). The effect of central captopril on the intake and choice of fluid of SHR is shown in Fig. 1 Vehicle-treated SHR showed no change in saline intake during the infusion period compared with the pre-implantation period ($F_{1,120} = 0.3, P > 0.6$). In contrast, captopril-infused rats showed a significant decrease (23%) in saline intake during the treatment period compared with either the pre-implantation period ($F_{1,108} = 20.3$, $P < 10^{-4}$) or vehicle-infused rats ($F_{1,112} = 9.2$ $P < 3 \times 10^{-3}$). Captopril-treated SHR also showed an increased (172%) water intake compared with the vehicle-infused SHR during the treatment period ($F_{1,112} = 33.9$, $P < 10^{-7}$), while no significant differences existed between the two groups during the pretreatment period ($F_{1,112} = 2.5, P > 0.12$). Whereas saline represented 83 ± 1% of total fluid intake of SHR before treatment, this fell to 77 ± 2% after captopril ($F_{1,112} = 6.4, P < 0.01$). Vehicle-treated SHR showed an increase of proportional saline intake from 84 ± 1% to 88 ± 1% ($F_{1,126} = 13.7$, $P < 3 \times 10^{-4}$). In contrast, as shown in Fig. 2, WK rats showed no changes in saline intake, water intake or proportional saline intake with either captopril or vehicle treatment.

The food intake of captopril-infused SHR did not differ from that of vehicle-infused SHR either before (68 versus 67 g per day, respectively; $F_{1,80} = 0.1, P > 0.8$) or during i.c.v. treatment (70 versus 68 g per day; $F_{1,80} = 0.9, P > 0.3$). Similarly, the food intake of captopril-infused WK rats was not different from that of vehicle-infused WK rats either before (66 versus 64 g per day, respectively; $F_{1,56} = 1.6, P > 0.2$) or during i.c.v. treatment (64 versus 61 g per day; $F_{1,70} = 1.4$, $P > 0.2$). The growth rate of captopril-infused SHR did not differ from that of vehicle-infused SHR either before (0.4 versus 0.01 g per day, respectively; $F_{1,80} = 0.1, P > 0.8$) or during i.c.v. treatment (2.0 versus 2.1 g per day; $F_{1,80} = 0.05, P > 0.8$). Similarly, the growth rates of captopril- or vehicle-infused WK rats were also similar before and during treatment (0.01 versus 0.5 g per day, respectively; $F_{1,56} = 0.6$, $P > 0.4$; and 0.4 versus 0.8 g per day, respectively; $F_{1,70} = 0.1$, $P > 0.8$). There was no significant difference in total fluid intake between either central captopril- or vehicle-infused SHR during the treatment period (24 versus 26 ml per 100 g per day, respectively; $F_{1,112} = 2.3$, $P > 0.1$).

It is possible that the fall in salt appetite during central captopril was secondary to renal sodium retention due to a fall in blood pressure. However, the animals showed no change in blood pressure during chronic infusion of captopril at this dose (pre-infusion: 187 ± 5 mmHg, post-infusion: 188 ± 4 mmHg; $F_{1,60} = 0.02$, $P > 0.5$). To examine this possibility further, five male SHR were treated with hydrallazine (5 mg per kg per day, orally) over a 4-day period. Blood pressure, measured by a tail cuff method, fell from a control value of 210 ± 10 mmHg to

149 ± 4 mmHg on day 4 of treatment. Saline consumption was significantly depressed on day 1 of treatment compared with the pretreatment period (14.1 versus 24.7 ml per 100 g per day, respectively; $F_{1,20} = 8.8$, $P < 0.01$), but this was not maintained and there was no difference in saline consumption on the following 3 days of treatment relative to the pretreatment period (22.3 versus 24.7 ml per 100 g per day; $F_{1,28} = 2.2$, $P > 0.1$), despite a maximal fall in blood pressure at this time.

To examine the potency of the effect of captopril on the salt appetite of the SHR, the experiments were repeated using a 10-fold lower dose of captopril (8 μg h^{-1}) infused into the lateral cerebral ventricle over a 7-day period in nine adult male SHR. This dose of captopril produced no change in blood pressure over the treatment period when compared with the 7-day control period (175 ± 4 versus 178 ± 4 mmHg, respectively; $F_{1,48} = 0.3$, $P > 0.5$). Mean saline consumption was 37.2 ± 2.2 ml per 100 g per day during the control period compared with 22.4 ± 1.0 ml per 100 g per day during the last 4 days of captopril infusion ($F_{1,88} = 22.3$, $P < 10^{-5}$). No change in saline intake occurred in nine vehicle-infused SHR during this period when compared with the pretreatment period (28.1 ± 2.0 versus 31.2 ± 2.0 ml per 100 g per day, respectively; $F_{1,88} = 1.1$, $P > 0.7$).

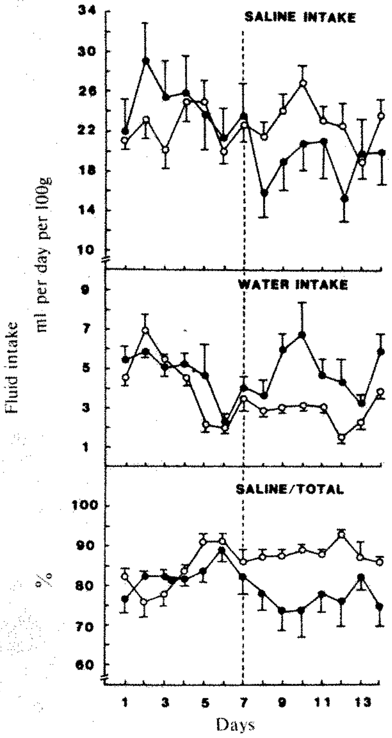

Fig. 1 Fluid intake of male SHR offered a choice of 0.9% saline or tap water. We used 20 male SHR and 20 male WK rats (weight range 320–410 g) housed in individual metabolic cages in conditions of 12-h light and 12-h dark (lights on 0700–1900 h), with room temperature maintained at 22 °C. Standard pelleted laboratory chow (Clarke King GR 2+, Melbourne) was available *ad libitum* and daily food intake was estimated by weighing uneaten and spilt food. A choice of tap water and 0.9% saline was available from individual bottles fitted with dripless stainless steel spouts (Gelman Clemco, Melbourne). Fluid intake was measured daily at 1700 h by weighing the bottles and the positions of saline and water bottles in individual cages were alternated daily. Following a 4-day acclimatization period, a further 7-day period was used to obtain control values of fluid and food intakes. Daily body weight was recorded at 1700 h and fresh saline prepared every second day. Following this control period, animals were lightly anaesthetized with ether and a 27-gauge stainless steel cannula was implanted into the left lateral cerebral ventricle at coordinates AP 1.0, L 1.5, H 4.0 using the bregma as reference. Cannulae were attached by PE 60 tubing to an Alzet osmotic minipump (Alza Corporation), with 10 SHR and 10 WK rats receiving captopril at 80 μg h^{-1} and 10 SHR and 10 WK animals receiving artificial cerebrospinal fluid as the vehicle. The minipump was inserted subcutaneously into the interscapular region. Following surgery, the animals were returned to their individual cages and the measurements continued for a further 7 days. At the end of this period, rats were decapitated and post-mortem examination of the brain performed to verify correct placement of the cannulae. The significance of changes in fluid intake was assessed by two-way analysis of variance. Fluid intakes were expressed per 100 g of body weight and the saline preference represents the percentage saline intake as a proportion of the total fluid intake. The dotted line indicates the start of the i.c.v. infusion of either captopril (●) or vehicle (○).

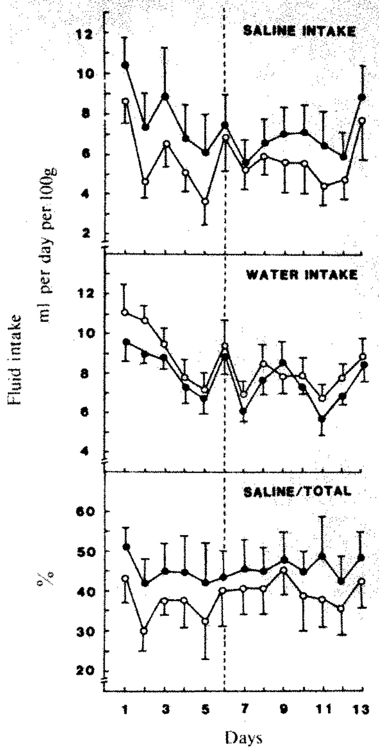

Fig. 2 Fluid intake of male WK rats offered a choice of 0.9% saline or tap water (see Fig. 1 legend). ●, Rats given i.c.v. captopril; ○, vehicle-treated rats.

The selective attenuation of the exaggerated salt appetite of the SHR by central captopril, as shown here, suggests that elevated central AII may contribute to this elevated salt appetite. The fact that central captopril had no effect on the food intake or growth rate of the SHR, and that central captopril was without any effect in the WK rat argues against a nonspecific effect of the drug. Furthermore, whereas a specific decrease in the proportional saline intake was seen in SHR treated centrally with captopril, total fluid intake remained unchanged, suggesting a specific action on sodium appetite.

The possibility that blockade of the circulating RAS, following leakage of captopril from central sites, contributed to the effects seen here may be excluded, as peripherally administered captopril not only lowers the threshold for salt detection but also increases saline ingestion in the rat[13].

As bradykinin[14,15] and the enkephalins[16] are substrates for angiotensin-converting enzyme, it is possible that the effects of captopril in our study are mediated by changes in these or other neuropeptides. However, the opioids seem to stimulate ingestive behaviour[17,18] and elevation of their central levels by captopril would not explain the results observed. According to one study, central administration of bradykinin failed to cause drinking[19], although a large dose of bradykinin has been reported to attenuate AII-induced drinking[20]; potentiation of this peptide might therefore contribute to the actions of central captopril in the SHR.

Centrally administered saralasin did not decrease thirst[21] or salt appetite[6] in previous reports. However, saralasin has agonist activity in most systems[22] and actually potentiated drinking in one study[23]. Furthermore, this peptide is of relatively high molecular weight and it has been suggested that captopril may have access to sites inaccessible to saralasin[24].

The cerebrospinal fluid of hypertensive humans has been reported to contain elevated levels of angiotensin I[25] and angiotensinogen[26]. It is intriguing to note, therefore, that hypertensives show a preference for sodium chloride and exhibit increased daily fluid intake[27], a pattern strikingly similar to that observed in the SHR. The present findings therefore raise the possibility that the brain RAS may be hyperactive in some forms of human essential hypertension.

Interphotoreceptor retinol-binding proteins: possible transport vehicles between compartments of the retina

Y. L. Lai*, B. Wiggert†, Y. P. Liu† & G. J. Chader†

* Bethesda Eye Institute, St Louis, Missouri 63110, USA
† National Eye Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

In the eye, vitamin A (retinol) is mainly stored in the retinal pigment epithelium (RPE) although its primary function is in the visual process in the photoreceptor organelles of the neural retina (NR). It is well established that during light adaptation, the amount of retinol drops in the NR but rises in the RPE[1]. During dark adaptation, the converse occurs. This indicates a migration of retinoid between the two tissues, the direction of which is dictated by the state of light or dark adaptation of the photoreceptors. The mechanism by which this migration is effected is unknown. We now present evidence that at least one protein exists in the subretinal space or on the cell surfaces which demonstrates many of the unique characteristics one would expect of an interphotoreceptor retinol-binding protein and could function as a vitamin A transport vehicle between NR and RPE.

A technique in which sub-retinal fluid is collected by washing the inner photoreceptor space of the detached retina and by irrigating the apical surface of the RPE and the sub-choroidal space has made possible the study of biochemical parameters involved in the dynamic interaction of these tissues[2]. Previously, gel electrophoresis and scanning electron microscopy have given strong evidence that the tissues do, in fact, remain intact during the lavage procedure[2]. We have now measured ^{3}H-retinol binding in four retinal compartments in the rabbit eye: (1) supernatant of homogenized neural retina, (2) washes of the photoreceptor surface (retinal fraction of the sub-retinal fluid space (SRF/NR), (3) washes of the apical surface of the retinal pigment epithelium (RPE fraction of the sub-retinal space (SRF/RPE) and (4) supernatant of homogenized RPE-choroidal tissue. Eyes from young adult New Zealand albino rabbits were removed under light anaesthesia, NR and RPE gently separated and the surfaces washed with isotonic saline as previously described[2]. Animals were light- or dark-adapted overnight before experimentation. Manipulations involving dark-adapted samples were performed under dim red light. Preparation of the supernatant fraction of tissue homogenates and gradient analysis techniques have already been described[3].

We have previously shown that a 7S retinol-binding protein is present in the supernatant fraction of adult retina of several species as well as the more ubiquitous 2S cellular retinol-binding protein, CRBP[4,5]. Retinol is bound endogenously to the 7S species as well as to the 2S protein, as assessed by relative fluorescence intensity measurements[5]. The 7S species appears to be primarily associated with the photoreceptor outer segments since (1) it is not apparent before outer segments appear in the embryonic retina[6], (2) it is not present when outer segments are absent, as in the disease retinitis pigmentosa[7] and (3) its concentration is increased when outer segments are partially purified although it is lost on extensive purification[6]. Moreover, the 7S retinol-binding activity is greater in the soluble extract of light-adapted frog retina and outer segments than in those of the dark-adapted state[8]. In the present study with rabbit, we observed both 7S and 2S ^{3}H-retinol-binding proteins in the retinal supernatant fraction after sucrose gradient analysis (results not shown). Both binding proteins (7S at about fraction 13; 2S at about fraction 28) can also be observed in the washings of the photoreceptor surface of the retina, the subretinal fluid area (SRF/NR; Fig. 1*a*, *b*). 7S binding is appreciably greater (three times) in the light-adapted state than in the dark-adapted while the amount of 2S binding is virtually identical in the two samples (Table 1).

The specific activities of the 7S and 2S binding are much higher in the subretinal compartments than in the supernatant fraction of retinal homogenate (Table 1). In the light, this amounts to a 24-fold difference in 7S and a 65-fold difference in 2S binding when the SRF/NR wash is compared with the retinal supernatant. Examination of the washings of the pigment epithelial surface (SRF/RPE) reveals a similarly dramatic light/dark difference in 7S receptor binding, although there is a pronounced light effect on 2S binding as well which is not observed in the SRF/NR wash (Fig. 1*c*, *d*; Table 1). 7S binding is 6.6-fold higher in the light than the dark while 2S binding is 4.7-fold higher in the light. 2S ^{3}H-retinol binding is present in the supernatant fraction of RPE-choroidal tissue homogenate

Table 1 ^{3}H-retinol binding in retinal compartments

Compartment	pmol ^{3}H-retinol bound per mg protein 7S Light	Dark	2S Light	Dark
Retinal supernatant	3.4±0.5	2.1±0.4	1.5±0.3	2.6±0.5
SRF/NR wash	83.0±10	28.0±5	97.0±12	90.0±10
SRF/RPE wash	19.2±4	2.9±0.6	198.0±25	42.6±7
RPE choroidal supernatant	*	*	4.0±0.6	4.6±0.8

Conditions as given in Fig. 1 legend. Values given are averages±s.d. of duplicate gradients from three separate experiments.
* Below the limits of detection.

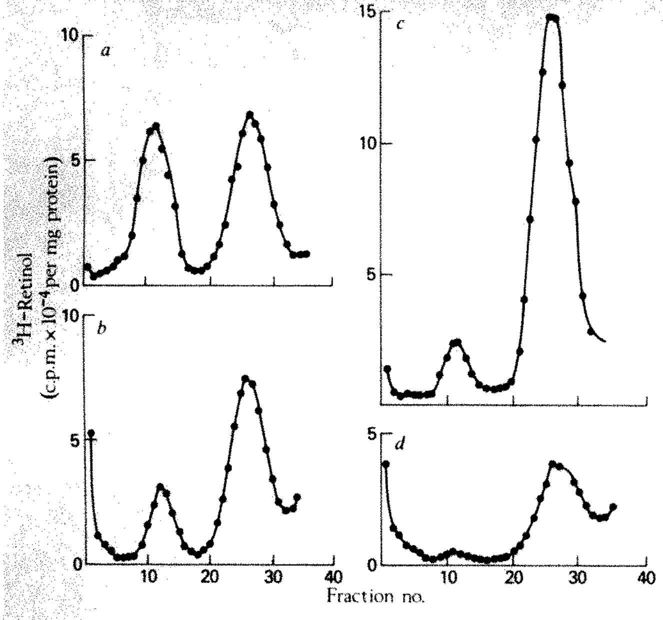

Fig. 1 Sucrose density gradient centrifugation patterns of ^{3}H-retinol binding to washings of *a*, *b*, the retinal photoreceptor surface (SRF/NR); *c*, *d*, the pigment epithelial surface (SRF/RPE). *a*, *c*, From light-adapted animals; *b*, *d*, from dark-adapted animals. The saline washes of the tissue surfaces were diluted 1:2 with Tris buffer (10 mM Tris, 10 mM KCl, 1 mM EDTA, 1 mM dithiothreitol) before gradient analysis and then incubated with 2.8×10^{-7} M all-*trans*, 1-^{3}H-retinol (5 Ci mmol^{-1}; NEN) for 2 h at 4°C in the dark. 250 µl aliquots were then layered on 4.6 ml continuous sucrose gradients (5–20% sucrose) in the Tris buffer and centrifuged for 16 h at 243,000 *g*. About 35 fractions were collected and their radioactivity determined. The top of the gradient is at higher fraction numbers. Protein concentration was determined by the method of Lowry *et al.*[15]. Binding specificity was checked by incubating parallel samples with a 500-fold molar excess of unlabelled retinol. The total amount of specific binding in each peak was determined by summing the total c.p.m. under the peak area and then subtracting the non-specific counts which lay below the peak nadirs. Patterns given are representative patterns from three separate experiments, each having duplicate analysis within the separate experiment.

but has a much lower specific activity than in either the SRF/NR or SRF/RPE fractions (Table 1). There is no detectable 7S binding in this compartment.

Kuhn[9,10] has shown that several proteins are differentially bound to photoreceptor membranes in light and dark. This offers the simplest explanation for our results—that the 7S and perhaps the 2S species are 'peripheral' proteins, loosely bound at the membrane surface. The enhancement in binding in the SRF washes compared with the tissue homogenates and the light/dark effect are both consistent with this postulate. As ^{3}H-retinoid binding studies do not measure the actual amount of binding protein, however, but rather the number of unoccupied binding sites, our results could be affected by several factors. For example, the decreased ^{3}H-retinol binding observed at 7S in the SRF/NR and SRF/RPE compartments and at 2S in the SRF/RPE compartment following dark adaptation could be due to an increase in endogenous unlabelled retinol in these compartments, a decrease in the actual amount of binding protein (turnover) or a change in the binding properties of the proteins. It will be of interest to investigate this in subsequent studies. Whether either of these proteins exhibits enzymatic activity is unclear but should also be investigated in light of the interesting finding that a defect in vitamin A metabolism may be involved in hereditary retinal degeneration in an animal model of retinitis pigmentosa[11]. LaVail *et al.*[12] have also established striking differences in inter-photoreceptor matrix mucosubstances between normal rats and those with inherited retinal dystrophy. What is clear from the present study is that the specific activities of the 7S protein and the 2S CRBP are extremely high in the extracellular subretinal space and that the apparent binding activities are markedly affected by light.

Since free retinol is labile and a potentially toxic substance which can alter cellular membranes[13], as exemplified by retinoid-evoked release of enzymes from NR and RPE lysosomes[14], some sort of carrier might be expected to be present at the various stages of retinoid transit into and through the cells. Moreover, retinoid, used in the visual cycle of the retina, is supplied through the PE cell from the choroidal blood supply, necessitating a generalized vectorial movement of retinoid as well as the more localized, light-evoked 'shuttle' movement between PE and retina during the visual cycle. It would seem likely, then, that the 7S binding protein and the 2S CRBP are both likely candidates for the role of retinoid transport vehicle between the sensory retina and the pigment epithelium. The 7S protein which we call interphotoreceptor retinol-binding protein seems to be a particularly interesting protein for further study due to its restricted presence in the retina, its localization and high concentration in the subretinal photoreceptor matrix and at the membrane surface and its apparent control of binding by light.

Detection of K$^+$ and Cl$^-$ channels from calf cardiac sarcolemma in planar lipid bilayer membranes

Roberto Coronado & Ramon Latorre

Department of Physiology and Biophysics, Harvard Medical School,
Boston, Massachusetts 02115, USA

The ionic currents underlying the cardiac action potential are believed to be much more complex than those in nerve[1,2]. During the cardiac action potential, various membrane channels control the flow of K$^+$, Na$^+$, Ca^{2+} and Cl$^-$ across the sarcolemma of cardiac muscle cells[2–7]. Thus, it has become increasingly clear that a detailed knowledge of the mechanisms that activate (or inactivate) heart channels is required to understand cardiac excitability[8,9]. We report here the use of planar lipid bilayer techniques to detect and characterize K$^+$ and Cl$^-$ channels in purified heart sarcolemma membrane vesicles. We have identified four different types of channel on the basis of their selectivity, conductance and gating kinetics. We present in some detail the properties of a K$^+$ channel and a Cl$^-$ channel. We have tentatively identified the K$^+$ channel with the i_x type of current found in Purkinje[10], myocardial ventricular[11] and atrial[12] fibres. The chloride channel might be related to the transient chloride current found in Purkinje fibres[5,6,13].

We have used sarcolemmal membranes isolated from calf myocardium by a method similar to that described in ref. 14. This method is particularly suitable for our purposes because it minimizes contamination by sarcoplasmic reticulum. Ionic channels present in membrane vesicles purified from heart

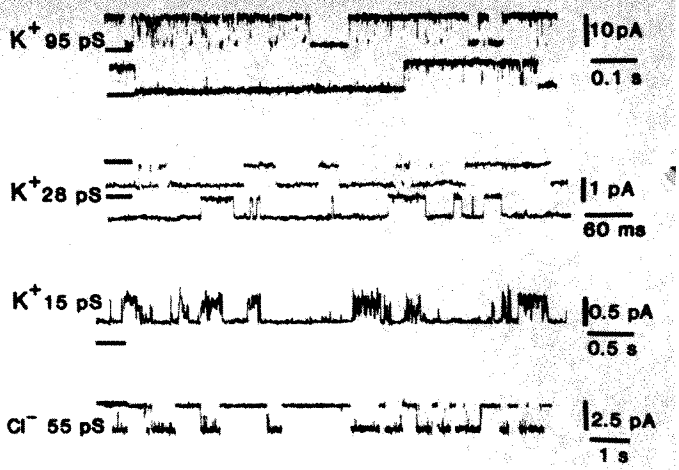

Fig. 1 Calf cardiac channels incorporated into planar lipid bilayers. Planar lipid bilayer membranes were formed from a mixture of bovine brain phosphatidylethanolamine (PE) and bovine brain phosphatidylserine (PS) at a PE/PS ratio of 1 : 1 in decane. This solution was made at a concentration of 50 mg ml^{-1}. Lipid bilayers were formed in Teflon partitions with apertures of 5×10^{-4} cm^2. The bilayer separated two aqueous chambers, each with a volume of ~100 µl. Electrical measurements were made with a two-electrode voltage clamp[17]. One of the chambers (*cis* side) was connected to a function generator to control membrane potential, while the second chamber (*trans* side) was connected to a current-to-voltage converter. Thus, the *trans* side is virtual ground. A positive current is defined as cation flow into the *trans* side. Ag/AgCl electrodes in series with 0.2 M KCl agar bridges served to connect the bilayer solutions to the electronics. Cardiac sarcolemma was prepared from calf ventricle using the procedure of Jones *et al.*[14]. Membranes were stored at −40 °C in 0.4 M sucrose, 10 mM HEPES-Tris, *p*H 7.4. The protocol used to incorporate single channels into the bilayer was as follows. Thawed vesicles were diluted to a final concentration of 50–100 µg protein per ml in 0.1 M KCl, 1 mM CaCl$_2$, 5 mM HEPES-Tris, *p*H 7.2. After forming the bilayer in symmetrical 0.1 M KCl, 5 mM HEPES-Tris, *p*H 7.2, the *cis* chamber was perfused with the vesicle-containing solution. Once the initial jump in conductance was observed, the *cis* chamber was extensively perfused with 0.1 M KCl, 5 mM HEPES-Tris, *p*H 7.2, to remove non-incorporated protein. All single-channel records were stored on FM tape for further analysis. By convention, in all records shown, the channel opening is an upward deflection (that is, 95 pS and 15 pS K$^+$ channels) if the applied voltage is positive, or a downward deflection if the applied potential is negative (that is, 28 pS K$^+$ channel and 55 pS Cl$^-$ channel). The conductance of the bare bilayer (≤5 pS in all cases) is indicated by the horizontal mark at the beginning of each single-channel trace. For the recordings shown, the applied potential was +100 mV for the 95 pS channel, −40 mV for the 28 pS channel, +30 mV for the 15 pS channel and −50 mV for the 55 pS channel. (K$^+$) or (Cl$^-$) indicates whether a given type of channel is Nernst selective for K$^+$ over Cl$^-$ (labelled K$^+$) or vice versa (labelled Cl$^-$). Experiments were performed at room temperature, 22 ± 2 °C.

sarcolemma can be transferred to planar membranes by a Ca^{2+}-induced fusion procedure[15,16]. Incorporation of channels proceeds very quickly, eliciting in a few minutes an increase in bilayer conductance of two or three orders of magnitude provided that two conditions are met: the presence of an osmotic gradient across the bilayer (the vesicle-containing side hyperosmotic), and the presence of Ca^{2+} in the vesicle-containing side. As described elsewhere, these conditions favour fusion of purified membrane vesicles[15–17] and liposomes[18] to planar bilayers. However, when the solutions bathing the membrane are kept symmetrical, and the Ca^{2+} concentration in the vesicle-containing compartment is low (1 mM), we usually observe the incorporation of single channels of one type. Figure 1 shows four types of single-channel current (which are also the most common) in the planar membrane. The first three records correspond to channels having reversal potential values typically observed when Cl$^-$ is completely excluded. The fourth record corresponds to a channel permeable to Cl$^-$ but not K$^+$. The 95 pS channel shown in Fig. 1 has a complicated gating kinetics consisting of one open and at least two closed states, is voltage independent and does not discriminate between K$^+$ and Na$^+$, or among other alkali cations. The 15 pS channel shows a 'noisy' open state and a permeability ratio, $P_{\mathrm{K}^+}/P_{\mathrm{Na}^+}$, of 3. None of the channels shown above is activated by Ca^{2+}, as they persist even if the Ca^{2+} concentration is 10^{-8} M. The kinetics of the 95 pS channel is, however, substantially modified

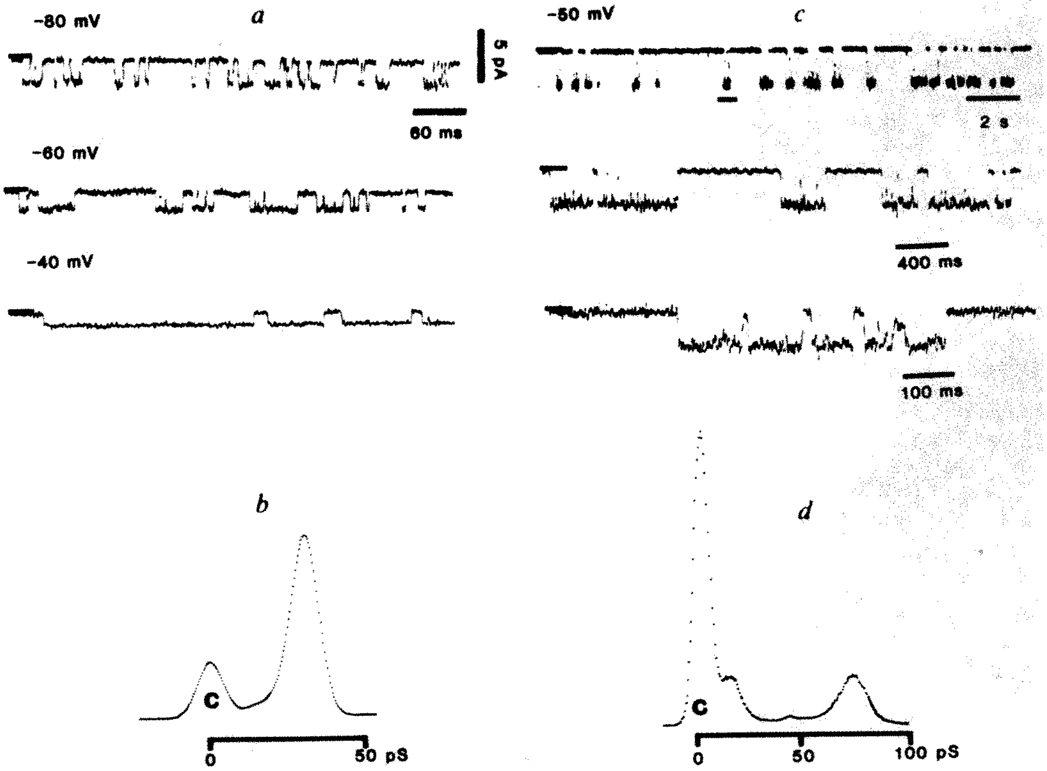

Fig. 2 Electrical characteristics of a K$^+$ and a Cl$^-$ channel. *a*, Recordings of the 28 pS K$^+$-conducting channel from the same membrane, at the voltages indicated. 1 KHz filtering. *b*, Histogram showing the relative occurrence of the two conductance levels of the 28 pS channel at −40 mV. It was obtained by feeding long records (>10 s) of current fluctuations, like those in *a*, into a pulse height analyser and sampling the current at a rate of 10^4 s^{-1}. The histogram is built by placing the sampled current in the bin corresponding to that particular current value. Thus, the peaks represent the most frequent values of conductance for a given record. The mean conductance value for the open state is 28 pS. *c*, Recordings of the 55 pS Cl$^-$-conducting channel at −50 mV. The bar underlying the single burst in the top trace is expanded in the bottom trace. The bar underlying the last three bursts is expanded in the middle trace. 1 KHz filtering. *d*, Histogram showing the relative occurrence of all current levels present in *c*. All measurements were done on symmetrical 0.1 M KCl, *p*H 7.2. C indicates the closed state peak.

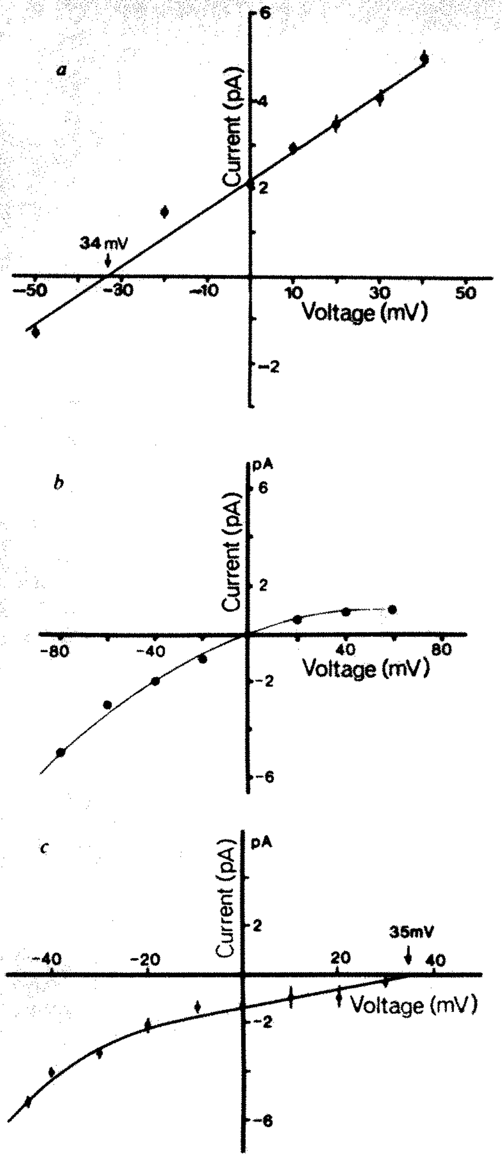

Fig. 3 Single-channel current–voltage curves for the 28 pS K^+ channel and 55 pS Cl^- channel. *a*, Mean single-channel currents obtained from histograms, such as that shown in Fig. 2*b* for the K^+ channel, were plotted for a membrane formed in 0.5 M KCl *cis* side, 0.1 M KCl *trans* side, 5 mM HEPES-Tris, *p*H 7.2, both sides. *b*, Single-channel current–voltage curve for the Cl^- channel in symmetrical 0.1 M KCl, 5 mM HEPES-Tris, *p*H 7.2. Time-average currents through the open states were measured by filtering bursts at 5–10 Hz and computing the mean current. *c*, Current–voltage curve for the same channel in 0.5 M KCl *cis* and 0.1 M KCl *trans*. Voltage indicated at the arrow corresponds to the extrapolated zero-current voltage.

by *cis* Ca^{2+}. As the *cis* Ca^{2+} is decreased below 1 mM, the long closing events (clearly seen at the bottom record of the 95 pS channel in Fig. 1) generally disappear. The properties of the 28 pS K^+ channel and the 55 pS Cl^- channel are described in more detail below.

The 28 pS K^+ channel shows well defined rectangular single-channel currents (Fig. 2*a*). The current step size is directly proportional to voltage; however, the time the channel remains in a given conductance state is voltage dependent. As the voltage is made more positive, the channel remains longer in the open configuration. For the records shown in Fig. 2*a*, the mean open time increases from 6 ms at −80 mV to 60 ms at −40 mV. The probability histogram (Fig. 2*b*) further corroborates the two-conductance-state nature of the channel, as only two peaks can be observed. The open state is, however, interrupted by fast closing events which are noticeable at high negative potentials. The mean closed time of these interruptions is 2–4 ms and may indicate the presence of a second kinetically distinguishable closed state. The electrical activity of the Cl^- channel is much more complicated (Fig. 2*c*). The channel may stay closed for several seconds, then it opens and begins to fluctuate rapidly between several conductance states (see bottom record of Fig. 2*c*). We interpret this type of record to represent the fluctuations of a single channel between several open conductance states and at least two closed states. The probability histogram in Fig. 1*d* shows clearly at least three open conductance states with conductances of 15, 39 and 61 pS.

For the K^+ channel shown in Fig. 2*a*, we also measured the current passing through a single channel in the presence of a fivefold KCl concentration gradient (Fig. 3*a*). The reversal potential for the current transported through a single channel is −34 mV, in agreement with that predicted by the Nernst equation for a K^+-selective channel. We have also measured the bi-ionic potential for 0.1 M KCl (vesicle-containing side)/0.1 M NaCl and found a reversal potential of −40 mV. This implies a permeability ratio $P_{K^+}/P_{Na^+} = 5$.

For Cl^- channels, because of the complexity of the records, we have plotted the average of the weighted mean current through the channel as a function of voltage. Figure 3*b* shows that the mean current through the single channel is a nonlinear function of potential. For negative potentials, current increases more than linearly. For positive potentials, however, the current reaches a limiting value. Analysis of histograms, such as that shown in Fig. 2*d*, indicates that the shape of the curve in Fig. 3*b* arises as a consequence of the voltage dependence of the number and distribution of the different conductance levels. Figure 3*c* shows the current passing through the channel in the presence of a fivefold KCl gradient. From Fig. 3*c*, we obtained a reversal potential of +35 mV. The diffusion potential expected when cations are completely excluded is +36 mV.

At this point, we would like to discuss the physiological role of K^+ channels in the heart. In Purkinje fibres, Noble and Tsien[10,19] described three time- and voltage-dependent outward currents in which the main current-carrying species was K^+. These currents are the pacemaker currents, i_{K_2} (but see ref. 20), and the repolarizing currents i_{x_1}, i_{x_2}. In addition, a fourth time-independent K^+ conductance showing inward-going rectification, i_{K_1}, is also present. More recently, Ca^{2+}-activated K^+ conductances have been shown to contribute to the early repolarization phase of Purkinje action potential[21] as well as to the steady-state K^+ conductance[22]. Many of these currents

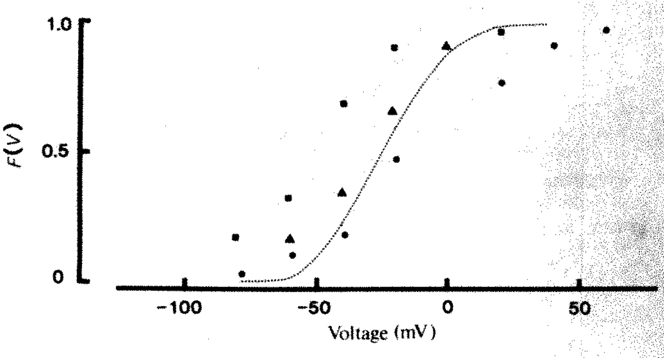

Fig. 4 Single-channel activation curves. The fraction of time in the open state [$F(V)$] of the 28 pS K^+ channel was obtained in three different membranes containing one channel in different ionic conditions. $F(V)$ was calculated from histograms such as that shown in Fig. 2*b*. ■, $F(V)$ in symmetrical 0.1 KCl, 5 mM HEPES-Tris, *p*H 7.2. ●, $F(V)$ in 1 M KCl, 5 mM HEPES-Tris, *p*H 7.2. ▲, $F(V)$ in 0.2 M KCl, 5 mM HEPES-Tris, *p*H 7.2 *cis*, 0.1 M KCl, 5 mM HEPES-Tris, *p*H 7.2 *trans*. Dashed line is the steady-state conductance voltage curve of the repolarizing current, i_{x_1}, and was taken as described in ref. 2.

are also present in ventricular and atrial fibres[11,12]. In agreement with the findings in cardiac muscle, we describe here several types of channel in which K^+ is the major current carrier. In particular, Fig. 4 shows that the voltage dependence of the 28 pS K^+ channel is comparable with that of the i_x currents (dashed line) described in ref. 2. Furthermore, a $P_{K^+}/P_{Na^+} = 5$ for this channel correlates well with the finding that i_x currents are not purely K^+ currents[10]. Although the assumption that i_x and the 28 pS channel activate with the same polarity of voltage is arbitrary, we are inclined to view the *cis* chamber as equivalent to the cytoplasmic side of the incorporated channel based on the following observations: (1) all 28 pS channels studied gate in the same direction, that is, the direction of Fig. 4; (2) inside-out cardiac sarcolemma vesicles fuse more readily than right-sided vesicles, which in the most simple model of fusion would leave the cytoplasmic face of the incorporated channels in the *cis* side[16]; and (3) the same incorporation procedure described here when applied to skeletal muscle membranes results in the incorporation of Ca^{2+}-activated K^+ channels with the Ca^{2+} site on the *cis* side[17]. Nevertheless, if the 28 pS channel were, in fact, to be activated in the cell by hyperpolarizing voltages, it would have the gating characteristics of the recently described inward pacemaker current, i_f (ref. 20). Thus, i_f is a time- and voltage-dependent inward current which activates by hyperpolarizing voltages and is a mixed K^+, Na^+ current[20]. Chloride ions, on the other hand, although clearly involved in the generation of the cardiac action potential, have not been unambiguously identified with a particular current component[5,6,13]. This makes it difficult to assign a physiological role to the Cl^- channel found in the present work, so that more experiments need to be performed in both cardiac cells and bilayers to make a complete identification of this channel. Finally, the channels from cardiac sarcolemma can be incorporated into bilayers made from monolayers (data not shown). This method has been recently used to reconstitute the acetylcholine channel[23-26]. In this type of membrane, we found that the electrical activity is quite complex and indicative of the presence of several types of channel. Using this method, we have been able to identify the 55 pS Cl^- channel and several of the K^+ channels described above. Our choice of the fusion method reported here to incorporate cardiac sarcolemma channels was based on the observation that membranes containing a single channel can be obtained easily. This enormously simplified the analysis of the data.

This work was supported by NIH grants GM-25277 and GM-28992 and by a postdoctoral fellowship to R.C. from the Muscular Dystrophy Association of America. We thank Marianita Sanchez for secretarial help.

Macrophage binding of *Staphylococcus albus* is blocked by anti I-region alloantibody

John Stewart, Elizabeth J. Glass & Donald M. Weir

Department of Bacteriology, University Medical School,
Teviot Place, Edinburgh EH8 9AG, UK

Cell surface interactions involving carbohydrate may be important in immune recognition. Previous work from this laboratory has demonstrated the presence of 'lectin-like' receptors on mouse peritoneal macrophages that bind bacteria by means of their cell wall sugars[1-4]. Others have shown that Ia molecules can bind antigen at specific sites which may be involved in presenting antigen to the immune system[5] and recent work has shown that these molecules can carry carbohydrate determinants[6-7]. It has also been found that human Ia molecules can bind to carbohydrates[8]. As cell surface carbohydrate recognition mechanisms have been implicated in other immune interactions[9-11] sugar-specific receptors may have a function in self—non-self recognition. We show here that the binding of the bacterium *Staphylococcus albus* to mouse peritoneal macrophages was inhibited by various conventional and monoclonal antibodies to Ia antigens suggesting that an I-region gene product may be associated with the binding of unopsonized bacteria.

The binding of *S. albus* to glass adherent mouse peritoneal macrophages was measured at 0°C in serum free buffer using a predetermined concentration (approximately 5×10^6 organisms per ml) that gave 25–50% binding to control macrophage preparations[4]. When macrophage monolayers from C3HfBu/Kam mice were pretreated with conventional alloantisera of defined specificity there was dose-dependent inhibition of binding (Fig. 1) as compared to untreated controls, with A.TH anti-A.TL at 1:100, 1:300 and 1:600 ($P < 0.05$) and WS9 at 1:100 ($P < 0.01$) and 1:333 and 1:1,000 ($P < 0.05$). However, A.TL anti-A.TH and WS4 were without effect at all dilutions of antibody used. At a dilution of 1/10 of WS4 (anti D^k) maximal fluorescence was obtained in a direct immunofluorescence test confirming that at the dilution used macrophages were maximally binding this antiserum. Both A.TH anti-A.TL and WS9 react with $H\text{–}2I^k$, as well as $H\text{–}2S^k$ and $H\text{–}2K^k$ respectively. A.TL anti-A.TH is directed against $H\text{–}2I^s$ and S^s while WS4 recognizes $H\text{–}2I\text{–}C^k$, S^k and D^k. These results suggest that an I-region determined product is involved

Table 1 Inhibition of binding of *S. albus* to macrophages by antibody H10–2.16 and anti-macrophage antibody

	Inhibition of binding (%)
a H10–2.16	
Unadsorbed	19.9±5.7
Adsorbed	32.6±7.9
b Anti-macrophage antibody	
Dilution	
$\frac{1}{2}$	2.6±11.2
$\frac{1}{4}$	1.9±5.9
$\frac{1}{8}$	−3.1±6.7

a, 1 ml of 1:10 dilution of H10–2.16 antibody incubated with 3×10^9 *S. albus* at 0 °C for 2 h. The bacteria were removed by centrifugation and antibody used at a final dilution of 1:50 as described in Fig. 1. Unabsorbed antibody was treated as above but without the addition of *S. albus*. Each figure represents the mean ±1.s.e. of four experiments. *b*, The monoclonal antibody specific for macrophages (rat IgG against mouse macrophages. Sera-lab, Sussex) was incubated with macrophage monolayers for 40 min at 0 °C before incubation with bacteria as described previously. Each figure represents the mean ±1.s.e. of three experiments.

in bacterial attachment to macrophages in the absence of opsonins.

In order to further investigate the H-2 region involved, the effect of two monoclonal antibodies on *S. albus* binding to C3HfBu/Kam peritoneal macrophages was determined (Fig. 1). Both antibodies which react with I-A products gave significant inhibition (H 8-109.13; 1:1,000 $P<0.001$; 1:10^4, 1:10^5 and 1:10^6 $P<0.01$: Antibody H 10-2.16; 1:20, 1:60, and 1:180 $P<0.05$), indicating a possible role for an I-A subregion product in bacterial binding. The possibility that the inhibition observed might be due to cross-reactivity of Ia antigens and the bacterial surface is excluded (1) by the extensive washing of the monolayers prior to the addition of bacteria and (2) by adsorption of the monoclonal antibody H 10-2.16 with *S. albus*. The latter treatment did not significantly alter the inhibitory capacity of the antibody (Table 2). Table 2 also shows that antibody directed against macrophage membrane determinants other than H-2 has no effect on bacterial binding. This indicates that the observed inhibition is a function of the alloantibody used.

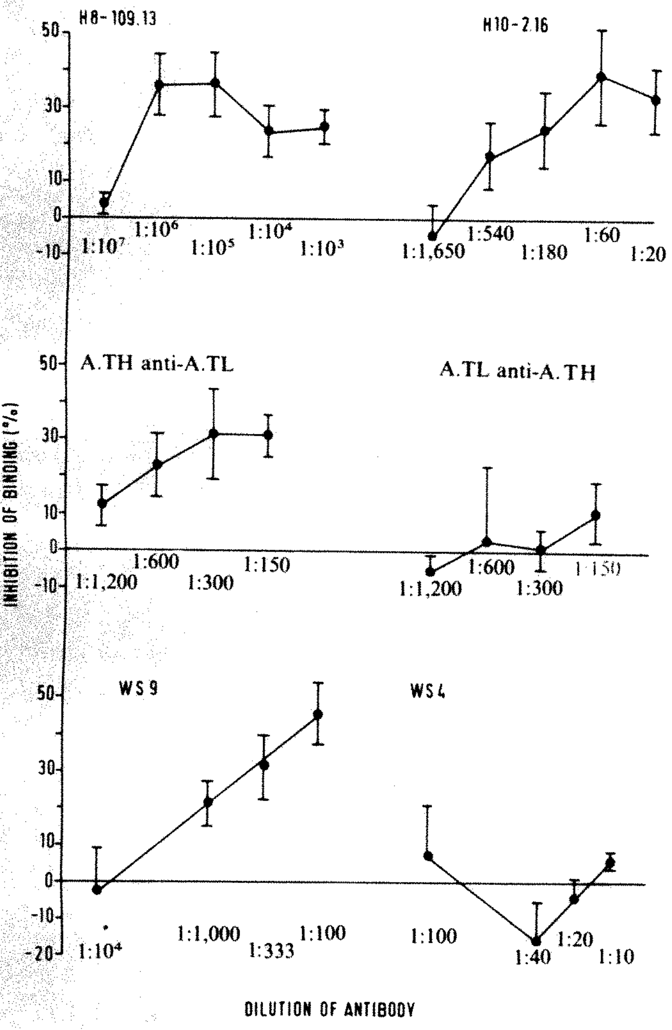

Fig. 1 The effect of various alloantisera on the binding of *S. albus* to C3HfBu/Kam peritoneal macrophages. Each point represents the mean ±1.s.e. of between 3 and 8 experiments. *S. albus* was grown in horse digest broth containing 2.5% glucose, cells were collected in log phase and killed by exposure to 0.5% formalin at 4 °C for 24 hours. Mouse peritoneal macrophages, obtained by lavage, were suspended in Eagles minimal essential medium (Wellcome Research Laboratories) without serum, buffered with HEPES and supplemented with penicillin streptomycin and glutamine, at a concentration of 2×10^5 macrophages per ml. One ml of the cell preparation was layered onto 13-mm diameter (No. 1) glass coverslips in 16-mm diameter tissue culture plates (Costar) and incubated for 1 h at 37 °C. Non-adherent cells were removed by washing with Dulbecco's phosphate-buffered saline containing Ca^{2+} and Mg^{2+} ions (D.PBS+B). Monolayers were incubated with 0.25 ml of appropriate dilution of alloantibody or diluent control (D.PBS+B) at 0 °C for 40 min and then washed twice with D.PBS+B. Coverslips were overlaid with 1 ml *S. albus* in D.PBS+B and incubated for 2 h at 0 °C. Cell viability was unaffected during incubations as judged by trypan blue exclusion and general morphology. Non-attached organisms were removed by repeated washing with D.PBS+B and the coverslips air dried, fixed in methanol and stained with May Grünwald/Giemsa. The degree of bacterial binding was estimated microscopically by determining the percentage of macrophage with organisms attached at two or more discrete points. Two hundred macrophages were counted on duplicate coverslips and % inhibition was calculated as the difference between control and test divided by the control × 100.

Table 2 The effect of antibody from cell line 8-109.13 on the binding of *S. albus* to macrophages

Dilution	Inhibition of binding (%) C57BL/6	BALB/c	C3H.OH
1:10^3	3.0±6.1	9.1±11.4	−6.1±5.0
1:10^4	−4.8±11.4	0.9±1.9	1.9±7.6
1:10^5	−2.7±3.1	10.1±5.6	−3.3±5.0
1:10^6	10.0±6.6	−10.1±9.2	6.9±2.2

C57BL/6 (b haplotype) and BALB/c (d haplotype) mice were from the Moredun Institute, Edinburgh, C3H.OH (o2 haplotype) were from Olec 76, Bicester and C3HfBu/Kam were from the departmental breeding colony. Each figure represents the mean ±1.s.e. of three experiments. Female mice age 6–8 weeks were used.

The monoclonal antibody from clone 8-109.13 is specific for a private determinant of I-A^k. Therefore this antibody should only inhibit bacterial binding to macrophages from a mouse with k haplotype. The effect of H8-109.13 on the binding of *S. albus* to peritoneal macrophages from various mouse strains, with different haplotypes is shown in Table 3. As described above binding to cells from C3HfBu/Kam mice (k haplotype) was blocked by this antibody (Fig. 1). However, the attachment was unaffected by pretreatment of macrophage monolayers prepared from mice with b, d or o2 haplotypes with this antibody. This observation further suggests that a product of the I-region is involved in unopsonised bacterial recognition and that the observed inhibition by the various alloantibodies was not due to crossreactivity with a general 'lectin-like' receptor showing similar antigenic determinants to a product of I-A^k.

The data do not necessarily imply the 'lectin-like' receptor for bacterial cell wall sugars and the Ia antigen on mouse peritoneal macrophages are identical and there are a number of possible explanations for the findings. For example, Ia antigens may bind bacteria, and possibly other antigens, directly or as postulated by Higgins *et al.*[7] protein-Ia acting as a glycosyl transferase could catalyse the attachment of bacteria to glycolipid Ia. The observed inhibition of bacterial binding by various alloantibodies could be due to blocking of these structures or inhibition of glycosyl transferase activity. The possibility has also not been excluded that the bacteria bind to a separate receptor which is in close proximity to the I-region determined structure and that the decrease in binding is due to steric hindrance.

Complete inhibition of bacterial binding was never obtained with any of the antibodies used. Similarly, in sugar inhibition studies with glucose or galactose, bacterial binding with *S. albus* to various phagocytes was only partially inhibited by the sugars[4]. These results indicate that the interactions of unopsonised bacteria with macrophages involve a number of recognition processes. These could include binding of bacteria by macrophage 'lectin-like' receptors[1] and attachment mediated by lectin molecules in the bacterial cell wall[12,13]. It has also been proposed that phagocytes can bind particles by nonspecific mechanisms[14] including hydrophobic interactions.

Results to date in which monolayers were treated with alloantibody and then with glucose or galactose showed no additional inhibition to that seen with alloantibody alone. This suggests that both reagents are reacting with the same site. Further work including cell membrane fractionation procedures is planned to determine the relationship between the macrophage 'lectin-like' receptor previously described by this laboratory and the I-A associated product responsible for the attachment described here.

The I-region of the murine MHC has a major role in regulating the immune system including cell–cell interactions and antigen presentation to lymphocytes. The data described above suggests that macrophages bearing an I-A gene product bind unopsonized bacteria. This interaction may lead to phagocytosis and initiation of the immune response in the non-immune animal.

This work was supported by a grant from the MRC. The monoclonal antibody from cell line 8–109.13, the WS9 and WS4 antisera were a gift from Professor H. Festenstein. The A.TH anti-A.TL and A.TL anti-A.TH were donated by Dr Jana McBride. The monoclonal antibody from cell line 10–2.16 was a gift from Dr E. Unanue.

The major histocompatibility complex(MHC)-linked fourth component of complement (C4) shows a high degree of polymorphism in several animal species[1-4]. In man C4 polymorphism was detected by distinct charge differences of the variants[5-7]. O'Neill *et al.*[8] showed that this C4 polymorphism was controlled by two closely linked genetic loci, *F* (*C4A*) and *S* (*C4B*) and these results were extended by Awdeh *et al.*[9] with an improved typing method. Biochemical analysis of human C4 has revealed that it consists of three polypeptide chains, α, β and γ[10]. In all reports so far on the molecular analysis of human C4[10-13], no molecular weight differences between the *A* and *B* locus-encoded molecules have been noticed. Here we demonstrate that the *C4A* and *C4B* locus-encoded α-chains have a molecular weight (MW) of 96,000 and 94,000, respectively, presenting for the first time a molecular basis for the difference between all C4A and C4B variants tested. Even rare variants that are difficult to allocate to the *A* or *B* locus on the basis of charge differences[14,15] could be identified as C4A or C4B variants in this way, thereby providing new insights into the relationships between the *C4A* and *C4B* loci.

Previous analysis of human C4 by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) showed that the α-, β-, and γ-chains have a MW of about 95,000, 75,000 and 30,000 respectively for C4 from both loci[10-13]. By modifying the ratio of acrylamide to *N,N'*-methylene bisacrylamide (bis) in the gels, the separation properties of the gels are changed since both size and shape of the molecule determine the electrophoretic mobility in the gel. Thus, when C4 from several phenotypes, typed by agarose electrophoresis, was analysed by modified SDS-PAGE, a difference in MW between the α-chains encoded by the *A* and *B* loci became visible (Fig. 1). Plasma C4 phenotypes were determined by agarose electrophoresis according to the method of Awdeh *et al.*[9], designating the C4A variants A1, A2 and so on, the C4B variants B1, B2 and so on, and silent alleles *QO*. Figure 1*a* shows the SDS-PAGE analysis of the most common variants for each locus, A3 and B1, present in three phenotypes A3,3BQ0,Q0, A3,3B1,1,AQ0,Q0,B1,1 and as a negative control AQ0,Q0BQ0Q0 (lanes 1–4). The α-chain of the A3 variant has a MW of 96,000, while the α-chain of the B1 variant has a MW of 94,000. No difference in the β- and γ-chains was visible. As agarose typing of the C4 variants is usually carried out after removal of sialic acid with neuraminidase[9] we also analysed the same phenotypes after desialization (see Fig. 1*a*, lanes 5–7). A similar reduction of ~3,000 in the MW of both the C4A and C4B α-chains was visible. No change in MW of the β- and γ-chains was found.

To confirm the difference in MW between *A* and *B* locus-encoded α-chains, anti-Rodgers ($\mathrm{Rg^a}$) and anti-Chido ($\mathrm{Ch^a}$) sera, which have a known specificity for C4A and C4B molecules respectively[16-18] were used. C4, precipitated from neuraminidase-treated plasma of different haplotypes, was analysed by SDS-PAGE, followed by blotting of the proteins in the gel onto nitrocellulose sheets as described previously[19]. The sheets were then reacted with anti-$\mathrm{Ch^a}$, anti-C4 or anti-$\mathrm{Rg^a}$; the results are shown in Fig. 1*b*. The three C4 phenotypes reacted with anti-C4, revealing the C4 α-, β- and γ-chains (lanes 4–6), in addition to some background bands (lane 11). With anti-$\mathrm{Ch^a}$ only the C4B α-chains became visible (Fig. 1*b*, lanes 1–3), and with anti-$\mathrm{Rg^a}$ only the C4A α-chains were detected (lanes 7–9) over the background (lane 10). Samples which had not been treated with neuraminidase gave qualitatively similar results. Also, when unreduced C4 was analysed by SDS-PAGE in a 6% gel, a MW difference was found between native C4 from the *A* and *B* loci. After blotting and analysis of the variants A3 and B1 with anti-$\mathrm{Ch^a}$ and anti-$\mathrm{Rg^a}$ a reaction of the C4A molecule with anti-$\mathrm{Rg^a}$, and a reaction of the C4B molecule with anti-$\mathrm{Ch^a}$ was found (data not shown).

To establish whether the difference in α-chains between C4A and C4B variants applies also to other variants than the most common ones, we have analysed several different phenotypes, including some with rare and new C4 variants. The agarose electrophoresis patterns of 14 phenotypes are shown in Fig. 2*a*; as the pattern is highly complex a schematic presentation of the individual C4A and C4B variants is shown in Fig. 3. The C4A variants show generally a higher mobility than the C4B variants but some variants do overlap. This is especially the case for the B4, B5 and B5.1 variants which do overlap with most C4A variants and for the A1 variant which overlaps with most C4B variants. In this case C4A or C4B variants can only be identified by genetic studies and by analysing the functional activity with a lytic overlay (Fig. 2*b*), since the functional activity of the C4B variants is about 10-fold higher than C4A variants[9,14]. As can be seen from Fig. 2*a* and *b* the A1 variant (lane 5), like other C4A variants, does not show lytic activity, while the B4, B5 and B5.1 variants show a lytic activity similar to all other C4B variants. When the different phenotypes were analysed by SDS-PAGE (Fig. 4) all the C4A variants A1, A2, A3, A4, A5.1 and A6 (A5.1 not shown), showed an α-chain with a MW of 96,000 while all the C4B variants, B-2, B1, B1.1, B2, B4, B5 and B5.1 (B-2 and B4 not shown) showed α-chains with a MW of 94,000. Thus with this method even variants that overlap in the agarose gel electrophoresis can be identified structurally as C4A or C4B variants.

As some informative phenotypes were not available, however, our experiments do not exclude the possibility that the A4 and A5.1 variants contain an α-chain with a 94,000 MW in addition to the 96,000 α-chain; nor can it be excluded that the B-2, B1.1, B2, B4, B5 and B5.1 variants contain a 96,000 MW α-chain in addition to the 94,000 α-chain. This is, however, unlikely as the variants A1, A3, A6 and B1, which

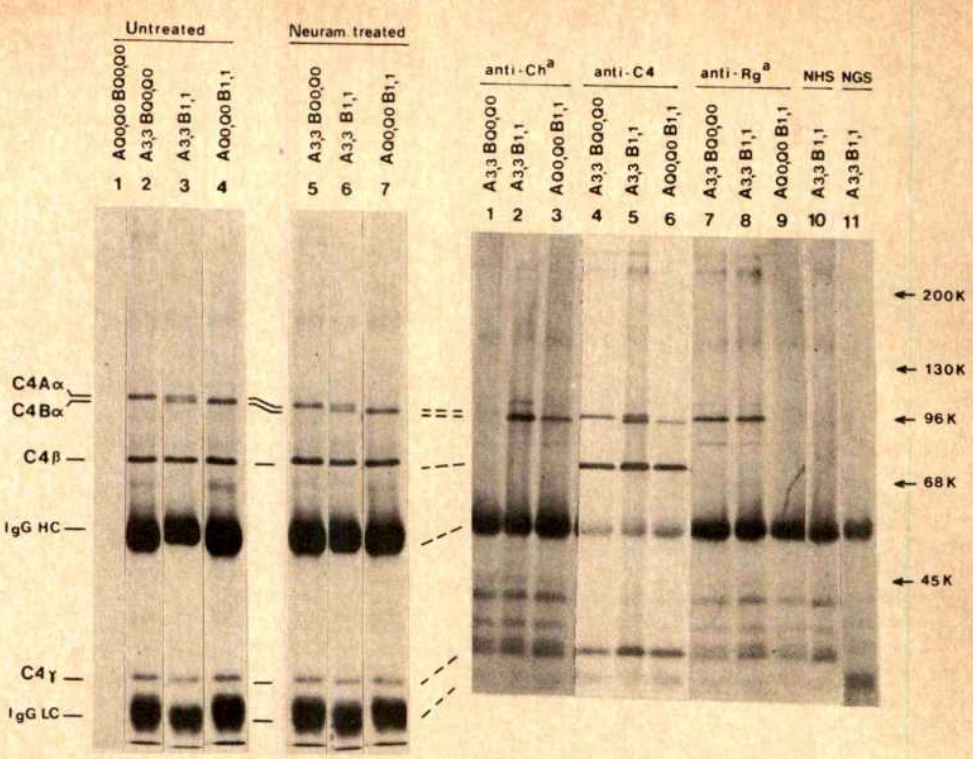

Fig. 1 Polymorphism of the C4 α-chains as detected by SDS-PAGE of human C4 and neuraminidase-treated human C4. *a*, C4 was immunoprecipitated from human EDTA–plasma with goat anti-human C4 (Atlantic Antibodies). The precipitates were washed, disintegrated and reduced as described previously[20], except that 10% 2-mercaptoethanol was used. SDS-PAGE was carried out according to a modification of the method of Laemmli *et al.*[28]; a 10% acrylamide gel was used with a ratio acrylamide: *N,N'*-methylene bisacrylamide (bis) of 1:0.006. For the separation of unreduced C4, a 6% acrylamide gel was used with an acrylamide : bis ratio of 6:0.0013. To prevent the gel from sticking to the glass plates, 0.3% agarose (Ultra Pure; Bio-Rad) was incorporated in the gel. *b*, After electrophoresis, proteins in the gel were blotted on to nitrocellulose sheets by compressing the gel for 1 h between two of these sheets and a 2-cm layer of tissues[19]. Thereafter, the gel was stained with Coomassie blue R250. The nitrocellulose sheets were incubated overnight with 15 ml blotting buffer (500 mM NaCl, 10 mM sodium phosphate (*p*H 7.3), 10 mM EDTA, 0.25% gelatin, 0.5% Triton X-100) supplemented with 50 µl anti-Ch^a serum, 20 µl anti-C4 serum or 50 µl anti-Rg^a serum. Then the sheets were washed for 1 h with 50 ml blotting buffer, incubated for 1 h with horseradish peroxidase-conjugated rabbit antiserum prepared against human IgG or goat IgG (DAKO). The sheets were washed for 1 h before a fresh solution containing 0.5 mg ml^{-1} phosphate-buffered saline (PBS) of the peroxidase substrate, 3-3'-diaminobenzidinetetrahydrochloride and 0.3% H_2O_2. The reaction was stopped after 10 min by washing with PBS. Neuraminidase treatment of human plasma was carried out according to Awdeh *et al.*[9]. *a*, SDS-PAGE: lanes 1–4, C4 precipitated from EDTA–plasma; lanes 5–7, C4 precipitated from neuraminidase-treated EDTA–plasma. *b*, Blots treated with: lanes 1–3, anti-Chido serum; lanes 4–6, anti-C4 serum; lanes 7–9, anti-Rodgers serum; 10, normal human serum (NHS); 11, normal goat serum (NGS).

were analysed in combination with 2 *QO* alleles present at the other locus, only showed one α-chain. In all cases where one or two C4A variants were present, an α-chain with a MW of 96,000 was found whereas an α-chain with a MW of 94,000 was always found when one or two C4B variants were present. Since the typing of the variants in agarose gels (Fig. 2) was carried out with neuraminidase-treated samples we analysed all the phenotypes described above by SDS-PAGE after neuraminidase treatment. This resulted, as shown in Fig. 1 for the A3 and B1 variants, in a decrease in the apparent MW of 3,000 for both the C4A and C4B α-chains; the difference between the α-chains of the C4A and C4B variants remained (data not shown). When comparing the concentration in the gel of the C4A α-chains with the C4B α-chains (Fig. 4)

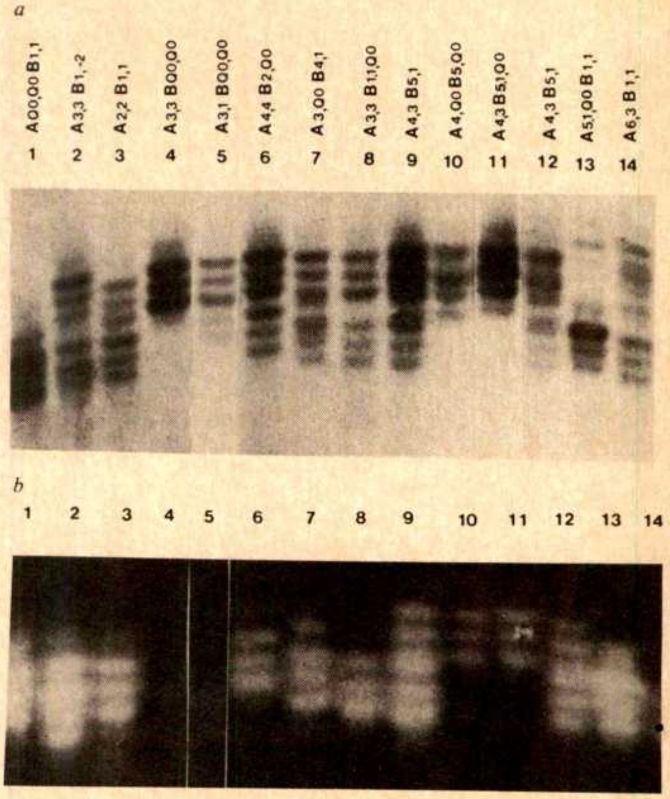

Fig. 2 Human C4 polymorphism as detected by agarose gel electrophoresis. EDTA–plasma samples were treated with neuraminidase (5 U per µl plasma; type VIII, Sigma) as described by Awdeh *et al.*[9]. Agarose gel electrophoresis was carried out according to the method of O'Neill *et al.*[8], on 20×20 cm glass plates covered with 2 mm 0.5% agarose (Litex HSA), for 5 h using a voltage gradient of 20 V cm^{-1} until the haemoglobin marker had migrated at least 10 cm from the origin (some variants may only be recognized in such extended runs); two plates were run in parallel. After completion, one plate was overlayed with goat anti-human C4 serum (Atlantic Antibodies) overnight, washed, dried and stained with Coomassie blue. The duplicate plate was covered with an agar overlay containing a haemolytic system with C4-deficient guinea pig serum as described previously[29]. The C4 variants were attributed to the *C4B* locus when they caused a lytic banding pattern in the functional overlay[9,14]. The individual *C4A* and *C4B* locus variants were identified by comparing the immunofixation banding patterns and lytic banding patterns with a reference set distributed by Dr G. Mauff to C4 typing laboratories in 1979 and the final designation of human C4A and B allotypes (A1, A2, ... B1, B2 ...) is in accordance with Awdeh *et al.*[9] and with a proposal of Drs G. Hauptmann, G. Mauff and C.R. (see also Fig. 3). The influence of silent alleles (*QO*) on the amount of C4A and C4B molecules present in the phenotypes was judged by comparing the relative strength of the *A* and *B* locus-encoded variants. In addition, in some cases, HLA-A, B, C, DR information (linkage disequilibrium) was also considered. Some variants could be followed in families by segregation[15]. *a*, Immunofixation banding pattern of 14 C4 phenotypes; *b*, haemolytic overlay banding pattern of the same samples.

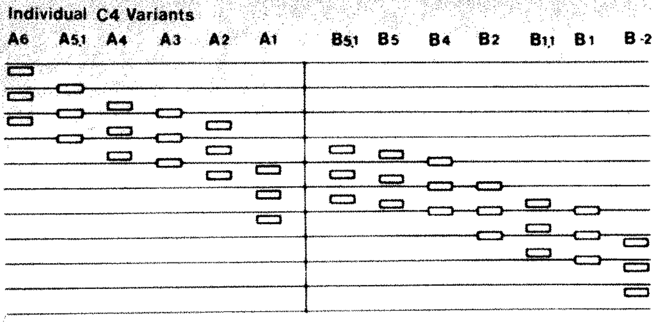

Fig. 3 Schematic representation of the C4 variants used in this study. These are all the variants that could be identified at present in the Bonn laboratory. Note the designation of the variants A5.1, B1.1, B5.1 and B-2.

sometimes a clear difference in the intensity of the α-chains was observed. Whether this represents the presence of a silent allele at the locus with the fainter band is under investigation[15].

Our results constitute the first evidence for a molecular difference between all C4A and C4B variants tested. All the C4A variants analysed contain an α-chain with an identical MW of 96,000 whereas all the analysed C4B variants contain an α-chain with an identical MW of 94,000. This indicates that the C4A and C4B variants differ structurally from each other even though some variants among both loci have very similar mobilities on agarose electrophoresis. The difference between C4A and C4B α-chains is another indication that the C4 structural genes are located in the *HLA* complex, and also provides a new analogy between human and mouse C4. In the mouse a different MW for the α-chains of C4 and the allotype Slp (sex limited protein) has been described[20,21] providing evidence that distinct structural *C4* and *Slp* loci are linked to the *S* region of the *H-2* complex. Another striking similarity between human and mouse C4 is the difference in functional activity between the products of the two loci. Human C4B variants possess a functional activity that is 10 times higher than that of the C4A variants[9,14]; in the mouse the *C4* locus produces a functionally active C4 molecule, while the *Slp* locus produces a molecule for which no functional C4 activity has been detected[21,22]. This could be a consequence of the structural difference between the α-chains of the two loci since the α-chains have been shown to be involved in the activation of C4[23].

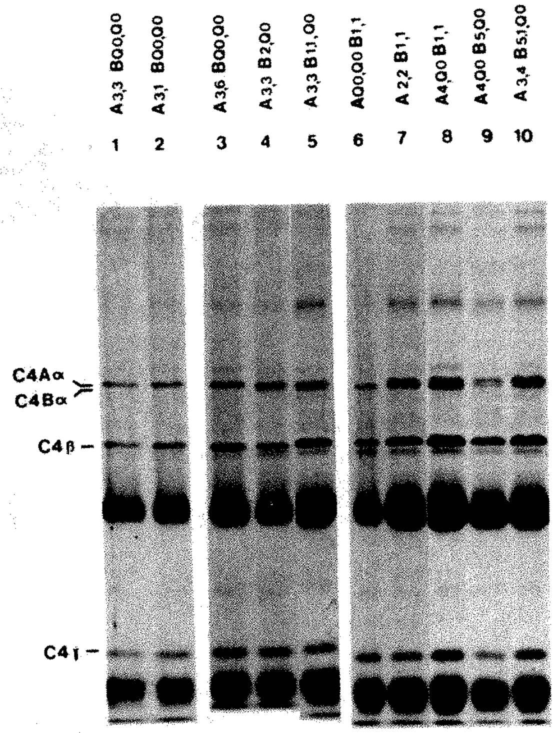

Fig. 4 Difference in MW of the *C4A* and *C4B* locus-encoded α-chains in 10 different phenotypes. Immunoprecipitation, SDS-PAGE and staining with Coommassie blue was performed as described in Fig. 1 legend. Lanes 1–10, analysis of 10 different phenotypes; lanes 3, 4, 5 are from a different gel. The total amount of C4 present in the samples in the gel is no indication of the level of C4 present in the plasma, as the C4 in the samples was adjusted to give clearly visible bands.

The antisera directed against the *HLA*-linked Chido and Rodgers blood group antigens[24,25] were shown previously to react specifically with the α-chains of the C4B and C4A variants, respectively, by the agglutination test and by inhibition of the antiglobulin test[17,18]. Our blotting method proved to be a new and sensitive way of analysing the reaction of the anti-Ch^{a} and anti-Rg^{a} sera with C4 α-chains of the A3 and B1 variants. Thus C4 variants, so far not found in a haplotype with a *QO* allele at the other *C4* locus and therefore considered to be Rodgers- or Chido-positive only by analogy or inference, can be analysed directly with our method for their reaction with anti-Rg^{a} or anti-Ch^{a} serum.

The removal of sialic acid from native C4 by neuraminidase affects the α-chains, as expected[12]. This result, together with the localization of both the Rg^{a} and Ch^{a} antigenic determinants[17,18] and the charge difference between the human C4 variants on the C4 α-chain[26], indicates that parts of the α-chain are exposed on the C4 molecule. However, the human C4 β- and γ-chains are not affected by neuraminidase, although the human C4 β-chain, in contrast to the murine C4 β-chain, also contained sialic acid[12,27] implying that at least the carbohydrate part of the β-chain is hidden inside the C4 molecule.

Our findings may open new ways for the biochemical characterization of the polymorphism of human C4 and of the genetic organization and structure of the human C4 genes. In addition, our results extend the homologies between *HLA* and *H-2* and may provide additional possibilities for investigation and understanding of the association of the early complement component genes with the MHC.

We thank Dr T. Meo for a gift of the C4-deficient serum and Drs C. Giles and R. Berger for the anti-Chido and anti-Rodgers sera and Mrs N. van Nuland-van Wijngaarde for secretarial assistance. This study was supported by the Queen Wilhelmina Foundation (Netherlands Cancer Foundation) and by the Deutsche Forschungsgemeinschaft (Ri 164-15-2).

Nucleotide sequence of the rat skeletal muscle actin gene

R. Zakut, M. Shani, D. Givol*, S. Neuman, D. Yaffe & U. Nudel

Departments of Cell Biology and *Chemical Immunology,
The Weizmann Institute of Science, Rehovot 76100, Israel

The actins constitute a family of highly conserved proteins found in all eukaryotic cells. Their conservation through a very wide range of taxonomic groups and the existence of tissue-specific isoforms make the actin genes very interesting for the study of the evolution of genes and their controlling elements. On the basis of amino acid sequence data, at least six different mammalian actins have been identified (skeletal muscle, cardiac muscle, two smooth muscle actins and the cytoplasmic β- and γ-actins)[1–5]. Rat spleen DNA digested by the *Eco*RI restriction enzyme contains at least 12 different fragments with actin-like sequences but only one which hybridized, in very stringent conditions, with the skeletal muscle cloned cDNA probe[6]. Here we describe the sequence of the actin gene in that fragment. The nucleotide sequence codes for two amino acids, Met-Cys, preceding the known N-terminal Asp of the mature protein. There are five small introns in the coding region and a large intron in the 5′-untranslated region. Comparison of the structure of the rat skeletal muscle actin gene with the available data on actin genes from other organisms shows that while the sequenced actin genes from *Drosophila* and yeast have introns at different locations, introns located at codons specifying amino acids 41, 121, 204 and 267 have been preserved at least from the echinoderm to the vertebrates. A similar analysis has been done by Davidson[7]. An intron at codon 150 is common to a plant actin gene and the skeletal muscle acting gene.

Act15 is a recombinant bacteriophage containing the coding region of the rat skeletal muscle actin gene and 11 kilobases (kb) of its 5′-flanking region[6]. A 3.7-kb *Eco*RI DNA fragment was subcloned in pBR322 (pAct15-2); the restriction map of the subclone and the strategy used for sequencing are shown in Fig. 1. The sequence of the entire coding region and the 3′-untranslated region is given in Fig. 2*a*.

The coding sequence begins with codons for two amino acids, methionine and cysteine, which are absent from the mature protein. They are followed by the codon for Asp (GAC), the known N-terminal residue of actin. It is of interest that in all six *Drosophila* actin genes, the same two codons precede the codon specifying the N-terminal amino acids[8]. The translation initiator codon ATG was found in all eukaryotic genes. The preservation of the cysteine codon in actin genes of such remote organisms suggests a functional role for this sequence. The primary mRNA translation product probably contains the Met-Cys residues, which are then cleaved off the polypeptide chain. Note, however, that the Cys codon is absent from the rat β-actin gene (U.N. *et al.*, unpublished).

The amino acid sequence deduced from the nucleotide sequence is identical to that of rabbit skeletal muscle actin. (The sequence of rat skeletal muscle actin has not been determined.)

A recombinant cDNA plasmid (p106) containing the entire nucleotide sequence of the 3′-untranslated region of the rat muscle actin mRNA was isolated and sequenced[9,10]. Comparison of the 3′ region of the Act15 insert with p106 showed that the Act15 insert contains 75 base pairs (bp) of the 3′-untranslated region of the structural gene and lacks the last 165 bp of the 3′ end. The only differences in the overlapping region were two additional thymines in p106 and one A/T replacement. These differences may have arisen from mistakes in the sequence of p106 or from polymorphism in the sequence of the 3′-noncoding region of this gene. As the sequence of the terminal 165 nucleotides of the 3′-untranslated region was deduced from a cDNA clone, the existence of an intron in that region cannot be excluded.

The skeletal muscle actin gene contains five introns in the coding region (Fig. 1*c*). The sequences of the splice sites are in accordance with the consensus sequence for splice sites suggested by Breathnach and Chambon[11] (Fig. 2*a*). At the codon specifying amino acid 150, the intron sequence shows another potential splice site (CAG/GTA), which is present 32 bp downstream from the CG/GT splice site at codon 150 (Fig. 2*a*). The sequence between the two splice sites encodes 11 amino acids. Thus, if this site were involved in mRNA splicing, it could add an additional peptide (Gly-Glu-Cys-Ser-His-Thr-Ala-His-Ser-Gly-Pro) after Thr 149, without changing the reading frame downstream. This would produce a protein having the exact sequence of skeletal muscle actin, with an insert of 11 amino acids. The existence of such a protein has not been reported so far.

We have previously demonstrated by electron microscopy that the rat skeletal muscle actin gene has a large intron, ~750 bp long, at its 5′ end[6]. The sequencing data (Fig. 2*a*) do not reveal such a large intron in the coding region, therefore it should be localized in the 5′-untranslated region. The 5′ and 3′ borders of this intron were determined by S_1 endonuclease mapping[12], and were assigned to nucleotides 250/251 and nucleotides 1,206/1,207, respectively (that is, the intron is located 12 nucleotides upstream from the initiator ATG). The sequence of the two splice sites is in agreement with the consensus splice site sequences[11] (Fig. 2*b*). The sequence data indicate the existence of a potential Goldberg–Hogness box, TATAAA[13], starting at nucleotide 161, and a potential

Table 1 Positions of introns in actin genes

Source and type of actin gene			Intron location*										
Dictyostelium (several genes)[18]								None					
Yeast[19,20]			4	—	—	—	—	—	—	—	—	—	—
Drosophila[7]	*DmA* 6			—							307		
	DmA 4			13							—		
	DmA 2	5′-UT (−8)		—							—		
Sea urchin gene J†				—	—	41	121	—	203	267	—	—	—
Chicken skeletal muscle‡		5′-UT (−12)		—	—	41	—	150	204	267	—	327	—
Rat skeletal muscle		5′-UT (−12)		—	—	41	—	150	204	267	—	327	—
Rat β-cytoplasmic§		5′-UT (−6)		—	—	41	121	—	—	267	—	327	—
Soybean[16]				—	20	—	—	150	—	—	—	—	355

* The numbers indicate the codons at which introns are localized. Numbers in parentheses indicate the position of introns in the 5′-untranslated (5′-UT) region (the number of nucleotides upstream from the initiator ATG). No introns were found in the sites indicated by dashes.

Fig. 1 The structure of the rat skeletal muscle actin gene. *a*, Restriction enzyme map of the rat DNA insert in the recombinant bacteriophage Act15. *b*, The strategy used to sequence the rat skeletal muscle actin gene. The 3.7-kb *Eco*RI DNA fragment was subcloned in pBR322 and the resulting recombinant plasmid pAC15.2 was sequenced using the restriction sites shown, in the directions indicated. Solid arrows indicate fragments sequenced by the method of Maxam and Gilbert[21]; broken arrows indicate fragments sequenced by the Sanger procedure[22]. The restriction enzymes used were: Ava, *Ava*I; B, *Bam* HI; Bgl, *Bgl*II; H, *Hin*dIII; Hin, *Hin*fI; Pst, *Pst*I; R, *Eco*RI; S, *Sac*I; Su, *Sau*3AI; X, *Xba*I. *c*, Structure of the rat skeletal muscle actin gene: the boxes represent exons and the solid lines introns. Open boxes, the 5′- and 3′-untranslated regions; solid boxes, the coding regions of the exons. The broken box represents the part of the gene which is absent from the genomic clone Act15 but present in the cDNA recombinant plasmid p106. The numbers above the exons indicate the location of the exon–intron junctions (numbered according to Vanderkerckhove and Weber[5]). The numbers beneath the introns indicate their sizes in bp.

transcription initiation site, ACAC[14], 30 nucleotides downstream from this box (Fig. 2*b*). The assignment of the transcription initiation site was verified by S_1 endonuclease mapping (data not shown).

Comparison of the sequences and location of introns in several gene families in the vertebrates (for example, genes for globin, ovalbumin and the immunoglobulins; for review see ref. 11) has indicated that whereas the nucleotide sequence of introns has changed rapidly during evolution, the location of introns in relation to the coding sequence has been highly conserved. On the other hand, the data on the actin genes offer a comparison of gene structure across a much greater evolutionary range, that is, from unicellular organisms to fungi, insects and vertebrates. From the available data, it is apparent that

Fig. 2 Nucleotide sequence of the rat skeletal muscle actin gene. *a*, The coding and 3′-untranslated regions of the skeletal muscle actin gene. The numbers in the coding region indicate the number of amino acids, as suggested by Vanderkerckhove and Weber[5]. The numbers in the 3′-untranslated region (italics) indicate the nucleotide number following the termination codon. The *Hae*III site at nucleotide 73 in the 3′-untranslated region is the end of the rat DNA insert in the bacteriophage Act15. (The recombinant bacteriophage Act15 was isolated from a *Hae*III partial digest rat gene library and thus ends at the *Hae*III site which is found in p106 at this position[6].) The sequence 3′ to the asterisk was deduced from the sequence of p106. *b*, Nucleotide sequence of the 5′-untranslated region of the skeletal muscle actin gene. Solid underlining indicates the splice sites. The nucleotide sequence of the intron is given in italics. The Goldberg–Hogness box (TATAAA) and the cap site (CACA) are underlined with broken lines. Restriction enzyme sites used for the S_1 nuclease mapping are indicated.

despite the great conservation of the amino acid sequence of actins, the number of introns and their positions vary greatly (Table 1).

Clearly, there is no similarity in the number and location of introns of actin genes between fungi, protostomes and the known actin genes of deuterostomes (except for the possible homology regarding the intron in the 5′-untranslated region of rat α- and β-actin genes and the *Drosophila* actin gene *DmA* 2)[8]. However, within the deuterostomes, all known intron positions in sea urchin actin genes (at codons 41, 121, 203 and 267) are found in the rat skeletal muscle actin gene or in the cytoplasmic actin gene, or in both. In addition, the vertebrate actin genes do contain introns which are not found in the known sea urchin actin genes (at codon 327 in α- and β-actin genes and at codon 150 in the α-actin gene). The locations of introns in the chicken muscle actin gene are identical to those in the rat muscle actin gene.

The great resemblances between the actins exclude the possibility of convergent evolution from different ancestral genes. It can be concluded, therefore, that the intron locations, although highly conserved when examined on a small evolutionary scale (that is, among the vertebrates), do change during evolution.

Despite the incomplete data, the homology of intron sites may be used as an indication of the evolutionary relatedness of actin genes. It seems that differences between intron locations in actin isogenes can be regarded as an indication of an ancient separation of these genes. Thus, the great differences in intron locations among the *Drosophila* actin genes suggest that these genes separated from one another very early in evolution. On the other hand, the available data (Table 1) on the intron locations in deuterostomes indicate that these actin genes evolved from a common ancestor more recently. Although all *Drosophila* actin genes apparently have been isolated and partially sequenced, it is of interest that the deduced amino acid sequence of all of them resembles that of the vertebrate cytoplasmic actins; no gene coding for amino acid sequences typical of vertebrate muscle actin has been found[8]. Thus, the known pattern of intron sites and the available amino acid data suggest that, despite their great similarity in specialization and function, the vertebrate muscle actin and the insect muscle actin genes evolved independently from non-muscle actin genes[15].

It has been suggested that split genes were assembled by rearrangement of several DNA regions containing coding sequences, into a new functional unit; noncoding flanking regions of these fragments formed the introns[16]. This would imply that the primordial actin gene was split in at least all those positions in which introns are found in the various actin genes, and that the variability in the location of introns was due to deletion of introns during evolution. However, without sufficient evidence, an alternative or additional mechanism should be considered also, namely that the variability in intron positions and numbers resulted from insertion and deletion of introns, possibly as transposable sequences. Studies on the structure of actin genes along the evolutionary track leading to the vertebrates may discriminate between these possibilities.

It was recently reported that a soybean actin gene contained introns at codons 20/21, 151 and 355/356 (ref. 17). When we aligned the codons of this gene with those of the rat skeletal muscle actin gene, we found that the plant actin gene intron at codon 151 and the rat skeletal muscle intron at codon 150 split the coding sequence at exactly the same position. Although we cannot exclude the possibility that the homology in intron sites in these two actin genes is coincidental, we consider this very unlikely. Thus, if these introns are evolutionarily related, the immediate conclusion is that the intron at codon 150 existed in the actin gene before the separation between the animal and plant kingdoms. Therefore, this intron cannot be considered a novel intron, specific to the skeletal muscle actin gene[7]; rather, the lack of an intron at this location in the known sea urchin actin genes and the rat β-actin gene is most probably due to a deletion. The data are compatible with the suggestion that a primordial actin gene common to plants and animals was split at all intron locations known in the actin genes and that the variability in intron sites was a result of deletion of introns.

We acknowledge the technical assistance of Ms Zehava Levy, and thank Drs L. L. Jagodzinsky, T. Sargent and J. Bonner for the rat gene libraries. This work was supported by NIH grant R01 GM 22767 and by grants awarded by the Muscular Dystrophy Association to D.Y. and U.N. U.N. holds an A. and E. Blum Career Development Chair in Cancer Research.

Structure of the human immune interferon gene

Patrick W. Gray & David V. Goeddel

Department of Molecular Biology, Genentech, Inc.,
460 Point San Bruno Boulevard, South San Francisco,
California 94080, USA

Sequence determination of cloned cDNAs and genes of the three classes of interferon (IFN-α, −β and −γ) has revealed more than a dozen members of the human IFN-α gene family[1–7] and a single gene for IFN-β[4,8–14]. These genes are found on chromosome 9 (ref. 15) and contain no introns[1,5–7,11–14]. We recently reported[16] that the 146-amino acid sequence of mature IFN-γ deduced from the nucleotide sequence of a cloned cDNA was quite unrelated to those of the other IFNs, and that the gene for IFN-γ contains at least one intron[16]. We now describe the isolation, characterization and DNA sequence of the human IFN-γ gene. It contains three introns, a repetitive DNA element, and is not highly polymorphic. All our evidence to date[16,17] and the present data suggest that this is the only gene for IFN-γ and that the resolution of IFN-γ into two components[18] is probably the result of post-translational processing of the protein.

A ^{32}P-labelled restriction fragment obtained from the IFN-γ cDNA clone p69 (ref. 16) was used as a hybridization probe to screen 10^6 plaques of a bacteriophage λ Charon 4A/human genomic library[19]. Six individual hybridizing plaques were isolated from the library, and DNA from each recombinant phage was isolated and mapped with five different restriction endonucleases (Fig. 1). The insert DNAs span a contiguous region of 33.5 kilobase pairs (kbp) of the human genome. Each phage DNA was analysed by Southern blotting[20] with the IFN-γ cDNA probe, after digestion with *Eco*RI, *Bam*HI, *Hin*cII and

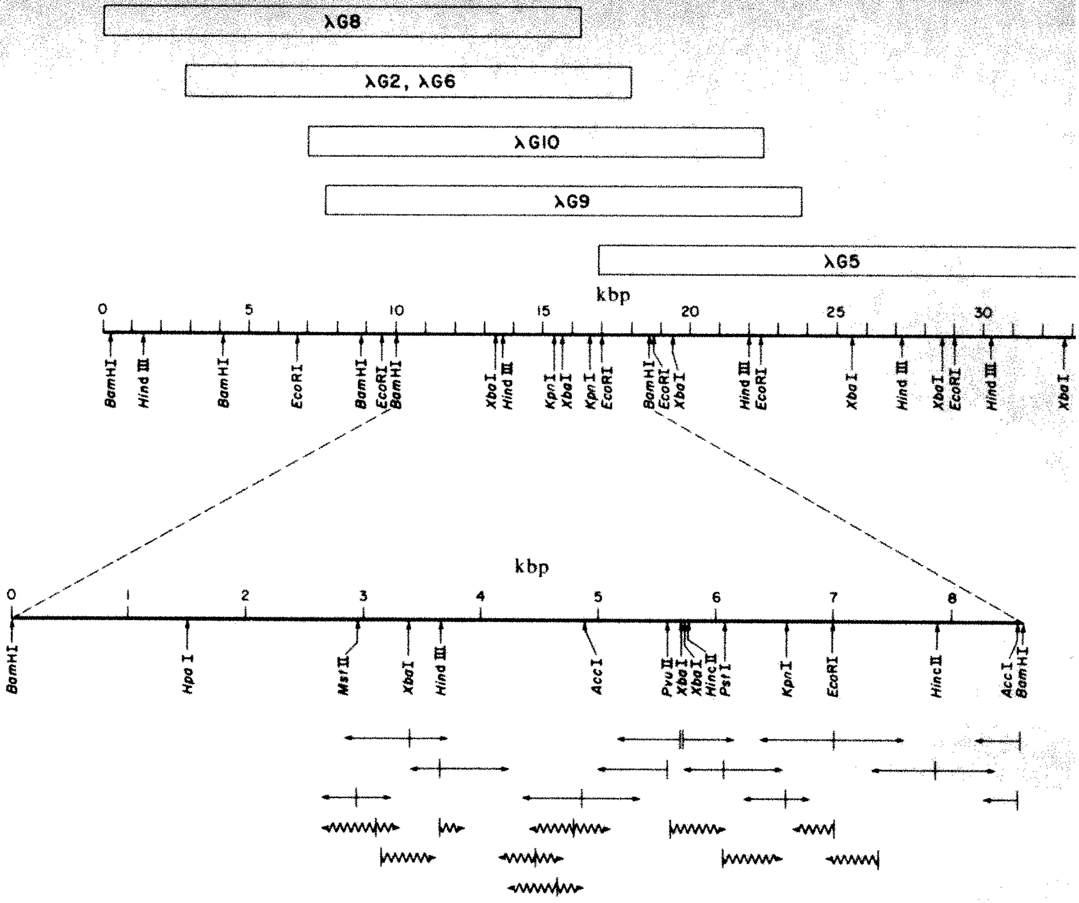

Fig. 1 Restriction endonuclease map of the IFN-γ gene region. The limits of each different phage DNA insert are shown at the top. Sites for *Eco*RI, *Bam*HI, *Hin*dIII, *Kpn*I and *Xba*I were determined by digestions of each individual phage DNA. Phage (10^6) from the recombinant human λ library described by Lawn *et al.*[19] were plated on to 10 15-cm plates and screened by the method of aniatis *et al.*[34] with 3 × 10^7 c.p.m. of ^{32}P-labelled[35] cDNA probe (887 bp *Sau*3A fragment, ref. 16). Plaques which hybridized positively with the probe were subjected to another round of plaque purification[34]. Individual hybridizing plaques were isolated and phage DNA was prepared[19,34] from 500-ml cultures. Each phage DNA was digested with *Eco*RI, *Bam*HI, *Hin*dIII, *Kpn*I and *Xba*I (either singly or in combination) and then electrophoresed on a 1% agarose gel. Gels were blotted on to nitrocellulose[20] and hybridized with the ^{32}P-labelled IFN-γ cDNA probe. The size of fragments was determined by comparison with *Hin*dIII λ molecular weight standards. The 8.6-kbp *Bam*HI fragment of λG9 was separated by electrophoresis through 1% agarose, electroeluted, and ligated into the *Bam*HI site of pBR322. One of the resultant recombinants, pB9KB-1, was extensively mapped with restriction endonucleases, and sequenced according to the strategy outlined below. Each sequence was determined from the marked positions and sequenced in the direction of the arrow; the length of each arrow corresponds to the length of sequence determined. Only those *Hin*cII sites which were used in sequencing are shown. Sequences determined by the Maxam–Gilbert method[36] are depicted with straight lines, while sequences determined by the dideoxy chain termination method[37] are represented by wavy lines. Synthetic single-stranded DNA primers, synthesized by the modified solid phase phosphotriester method[38], were used for dideoxy sequencing. The sequences of the primers were designed from the cDNA sequence[16]: dTCTCTCGGAAACG (found at nucleotides 97–109 of the cDNA), dGGTCATTCAGATG (229–241), dAATGCAGAGCCAA (309–321) and dCGAAAAGCTGACT (453–465). The reverse complements of the above primers were also used for sequencing in the 3′ to 5′ direction. In addition to the M13 *lac* primer[39], two other synthetic DNA primers were also used: dCTGCCAGGACCCA (174–186 of the cDNA) and dAAATATTGCAGGC (complementary to 620–632 of the cDNA). The templates for dideoxy sequencing were four restriction fragments (*Hpa*I–*Hin*dIII, *Hin*dIII–*Pvu*II, *Pvu*II–*Eco*RI and *Pst*I–*Hin*cII) which were subcloned in both orientations of the M13 vector mp7 (ref. 39).

*Pvu*II. Comparison of these hybridization patterns with those obtained earlier using human lymphocyte DNA[16] indicated that two phage DNAs (λG9 and λG10) appeared to contain the entire IFN-γ gene, as illustrated in Fig. 1. Clone λG9 was selected for further study. The region of λG9 hybridizing to the IFN-γ cDNA probe appeared to be contained entirely within an 8.6-kbp *Bam*HI fragment. This restriction fragment was subcloned into the *Bam*HI site of pBR322. The *Bam*HI insert from one of the resultant recombinants, pB9KB-1, was mapped with restriction endonucleases to allow DNA sequence analysis (Fig. 1).

Almost 6,000 contiguous base pairs (bp) of the IFN-γ gene region were determined by sequencing the majority of both strands (Fig. 1); these are shown in Fig. 2. The IFN-γ cDNA sequence previously determined[16] was aligned with the gene sequence as shown in Fig. 2. The two sequences matched completely except for a single base pair transition (4,712 of Fig. 2; position 588 of ref. 16) which changes the glutamine codon found at position 140 in the cDNA sequence to an arginine. However, we have subsequently sequenced five additional IFN-γ cDNAs which all contained arginine codons at this position[17].

There are three intervening sequences in the coding region of the gene. All three introns begin with a GT dinucleotide and end with an AG, sequences thought to be necessary for correct RNA splicing[21,22]. Intron 1 is 1,238 bp long; intron 2 is 95 bp, and intron 3 is 2,422 bp long. The four exons are less variable in length, coding for 38, 23, 61 and 44 amino acids, respectively. Each intron interrupts the reading frame precisely betwee codons.

Although there is no obvious overall amino acid homolog between IFN-γ and either IFN-α or IFN-β[16], a pattern c single amino acid homology between IFN-γ and IFN-α ha been reported[42], and the first exon of IFN-γ codes for tw groups of amino acids which have homology with IFN-α. Th four identical amino acids, Ser-Leu-Gly-Cys, are found at th junction between the signal peptide and mature interferon (where Cys is the first amino acid of the mature proteins)[4 Another homology with the first exon of IFN-γ is found neare the carboxy-terminus of IFN-α_2 (refs 2, 3):

	130	131	132	133					134	135	136
IFN-α	Tyr–	Leu–	Lys–	Glu–					Lys–	Lys–	Tyr
IFN-γ	Tyr–	Val–	Lys–	Glu–	Ala–	Glu–	Asn–	Leu–	Lys–	Lys–	Tyr
	7	8	9	10	11	12	13	14	15	16	17

If amino acids 11–14 of IFN-γ are neglected, six of seven amin acids are identical (17 of 21-nucleotide homology). Thi homology may be significant as the IFN-α sequence was foun to be highly conserved in this region when 11 different IFN- sequences were compared[4,5]. Furthermore, this region is pro posed to be highly α-helical[23]; the insertion of four amino acid would increase the length of the helix by one turn, but shoul not disturb the relative position of amino acids on the helix which is particularly important in a postulated helix of this typ with hydrophobic side chains on one side and hydrophilic side chains on the other.

The determination of the complete nucleotide sequence of the IFN-γ gene allows comparison of sequences thought to be important in gene regulation. One such sequence is the Goldberg–Hogness box[24,25], located ~30 bp upstream from the 5′ end of the site of RNA initiation. This sequence, 5′ $\mathrm{TATA}^{T}_{A}\mathrm{A}^{T}_{A}$ 3′, is thought to be important in determining the specificity of the initiation of RNA synthesis by RNA polymerase II[26–28]. Such a sequence, TATAAATA, is found in the IFN-γ gene 28 bp upstream from the 5′ end of the mRNA[17]. Interestingly, this same sequence is found in a comparable position in the IFN-β gene[13,14], although there is little further homology with IFN-β sequences in the 5′ extragenic region. However, seven different members of IFN-α contain the significantly different sequence, TATTTAA[6].

Another sequence which is relatively conserved at the 5′ end of many genes is the consensus sequence $\mathrm{GG}^{C}_{T}\mathrm{CAATCT}$[29], located ~80 bp upstream of the cap site. This sequence is thought to modulate transcription by RNA polymerase II[26] and has been shown to be necessary for efficient transcription of the rabbit β-globin gene *in vivo*[30]. A similar sequence, GTCACCATCT, found 89 bp upstream from the 5′ end of IFN-γ mRNA, is not detected in either the IFN-α genes or the IFN-β gene[6,13,14].

IFN-α and IFN-β have extensive homology in the 5′-flanking regions[13,14] which is not shared by IFN-γ. Perhaps it is not surprising that sequences potentially involved in the induction of IFN-γ gene transcription differ from those of IFN-α and IFN-β as the inducers and kinetics of induction of IFN-γ are quite distinct from those of the other interferons.

The coding region of the IFN-γ gene consists of unique, single-copy DNA, as shown by Southern[20] hybridization of a labelled cDNA probe to genomic human DNA[16]. To determine whether introns or flanking regions of the IFN-γ gene contained repetitive DNA sequences, probes from individual regions of the gene were prepared and hybridized with Southern blots of human genomic DNA. As shown in Fig. 3, all but one of the probes hybridized to unique human DNA fragments. The sizes of the hybridizing bands correspond to the lengths predicted from the map derived from the phage DNAs (Fig. 1). The first intron contains DNA which hybridizes to DNA throughout the blot, typical of repetitive sequences. We conclude therefore, that the IFN-γ gene consists of predominantly unique sequence DNA, but also contains a repetitive DNA element in the first intron.

The human genome contains more than 300,000 copies of a family of related sequences termed *Alu* sequences[31] which are ~300 bp long and for which no known function has been demonstrated. A computer comparison of the IFN-γ gene sequence (Fig. 2) with the *Alu* family repeat consensus sequence[32] failed to detect significant homology. Furthermore, an *Alu* family repeat probe (BLUR8; ref. 32) failed to hybridize with the first intron, but did hybridize with six different regions of the 33.5-kbp IFN-γ gene region, five of which are 'clustered' in 13 kbp upstream from the start of the IFN-γ gene (Fig. 4). Such a clustering of *Alu* family repeats has been observed in other human DNA regions[33] and in IFN-α genomic clones[6].

In six different IFN-γ cDNA clones, obtained using mRNA from four different individuals, only one nucleotide variation was observed[17], which suggests that the coding region of IFN-γ may be relatively consistent for all individuals. To determine if the IFN-γ gene sequence is conserved in a broader segment of the human population, we conducted a limited search for restriction fragment length polymorphisms. Genomic DNA isolated from lymphocytes of nine individuals of various ethnic backgrounds was cleaved with a series of restriction endonucleases (*Pvu*II, *Hin*cII, *Xba*I, *Pst*I, *Hin*fI, *Eco*RI and *Rsa*I) and analysed by Southern blotting using the IFN-γ cDNA probe. No detectable differences in mobility of hybridizing fragments were seen (data not shown), suggesting that the IFN-γ gene and surrounding DNA sequences are relatively conserved.

Fig. 2 Sequence of the human IFN-γ gene region. Only the sense strand is shown. The coding sequences of the exons have been translated. The CCAAT box[29], Goldberg–Hogness box[24,25] and polyadenylation site sequence (AATAAA)[40], have been underlined. The start of RNA transcription[20] is marked with a star, as is the position of polyadenylation. Restriction endonclease sites used in sequencing or Southern hybridizations are also shown.

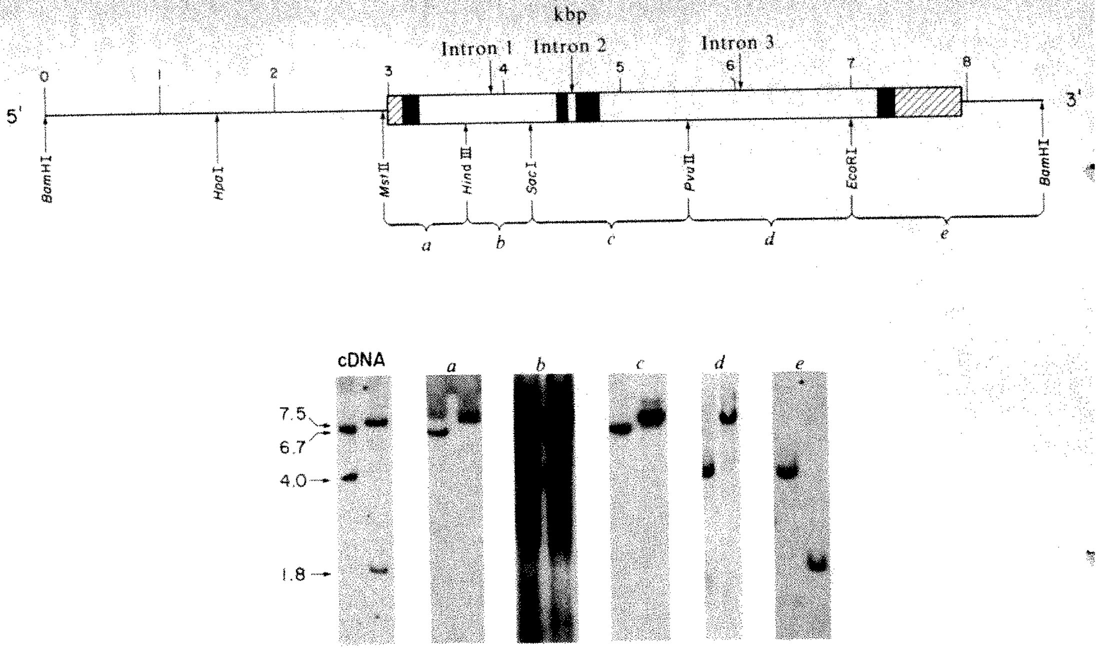

Fig. 3 The IFN-γ gene region contains a repetitive element. The cloned IFN-γ gene sequence was digested with the restriction endonucleases shown and the resulting fragments (*a–e*) were isolated on 5% polyacrylamide gels, electroeluted and used to synthesize ^{32}P-labelled probes by the calf thymus primer method[35]. The individual probes were hybridized with *Pvu*II (left) and *Eco*RI (right) digests of human genomic lymphocyte DNA (isolated by the method of Blin and Stafford[41]), separated on 1% agarose gels and transferred to nitrocellulose by the method of Southern[20]. Four of the probes (*a, c, d* and *e*) hybridized only to the single *Pvu*II or *Eco*RI fragments from which they were derived. Probe *b* hybridized throughout the genomic DNA. The 5'- and 3'-untranslated regions of the IFN-γ gene are shown as cross-hatched boxes and coding regions of exons are represented by solid boxes.

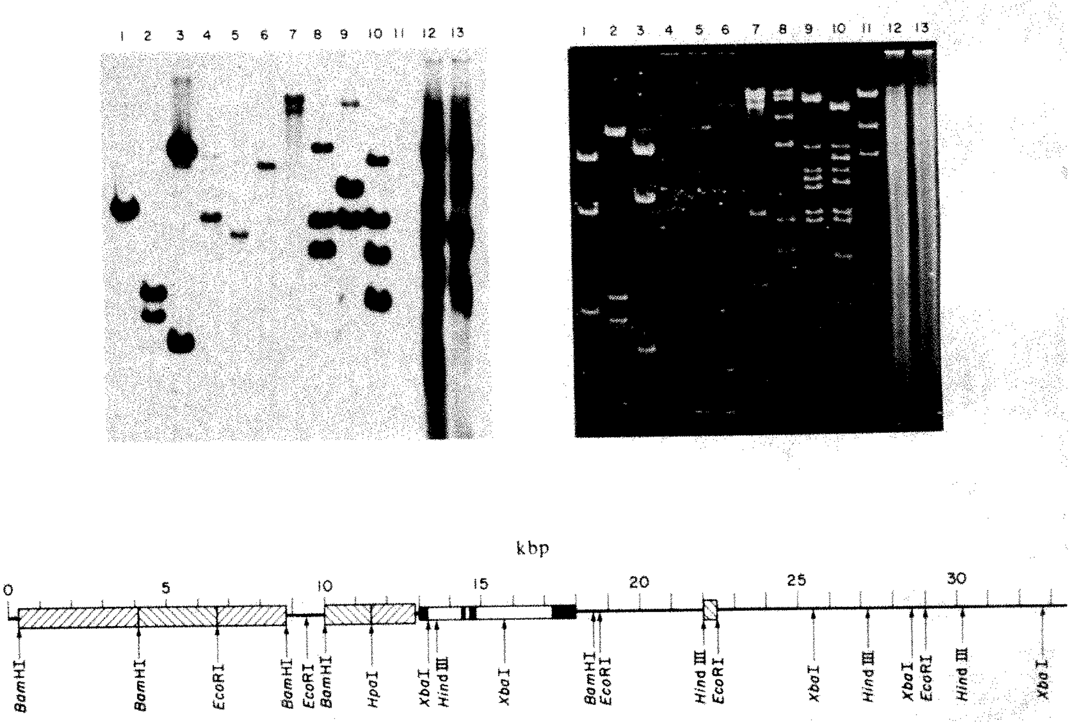

Fig. 4 Hybridization of the *Alu* family repeat probe to the IFN-γ gene region. The ^{32}P-labelled probe was prepared[35] from a 300-bp *Bam*HI fragment of pBLUR8 (provided by C. Houck and R. Lawn) which contains *Alu* family repeat DNA[32]. Electrophoresis in 1% agarose gel is shown on the right; lane 1, *Hin*dIII + *Sac*I digest of pB9KB-1; 2, *Hin*dIII + *Hpa*I digest of pB9KB-1; 3, *Bam*HI + *Hpa*I digest of pB9KB-1; 4, *Eco*RI digest of λ G5; 5, *Xba*I + *Hin*dIII digest of λ G5; 6, *Xba*I digest of λ G5; 7, *Xba*I digest of λ G9; 8, *Eco*RI digest of λ G6; 9, *Bam*HI digest of λ G8; 10, *Eco*RI + *Bam*HI digest of λ G8; 11, *Hin*dIII digest of λ DNA (size markers); 12, *Pvu*II digest of human genomic DNA; 13, *Eco*RI digest of human genomic DNA. The gel was transferred to nitrocellulose[20] and hybridized with 3×10^6 c.p.m. of probe (10^7 c.p.m. per μg DNA), shown on the left. Four different hybridizing signals are observed in λ G8 (lane 10). The signal in the subclone pB9KB-1 was shown to consist of two separate parts (lanes 2, 3). Only a single hybridizing signal was observed in the 3' region (λ G5, lanes 4–6). Mapping of these hybridizing regions (cross-hatched) is shown below on the map originally presented in Fig. 1. The IFN-γ gene region is represented by a smaller box with solid bars for exons and open bars for introns.

We thank Mark Vasser for deoxyoligonucleotide synthesis, Dr Ellson Chen for preparation of templates for dideoxy sequencing and Dr Richard Lawn for providing the human λ DNA library.

DNA precursors in chemical mutagenesis: a novel application of DNA sequencing

Michael D. Topal*, Clyde A. Hutchison III† & Mary S. Baker*

Departments of *Pathology, †Bacteriology and Immunology, and the *Cancer Research Centre, University of North Carolina Medical School, Chapel Hill, North Carolina 27514, USA

Recently, we have shown that deoxyribonucleoside residues in the cellular DNA precursor pool are generally more susceptible to methylation than are residues within the DNA duplex[1]. The N-1 position of adenosine, for example, was found to be at least 13,000 times more susceptible to methylation by *N*-methyl-*N*-nitrosourea (MNU) than the same site in the DNA. These results suggest that potential sites for alkylation in the double-strand duplex are relatively inaccessible to direct alkylation *in vivo*. Many of these sites are probably protected from alkylation not only by their position in the interstices of the DNA helix[2,3], but also by further *in vivo* 'packaging' of the DNA in chromatin[4–8]. We have now used DNA sequencing to demonstrate the incorporation properties of products of the reaction of MNU with dATP and of deoxy-N^4-hydroxycytidine triphosphate during DNA replication *in vitro* by phage T4 DNA polymerase and the 'Klenow' fragment of *Escherichia coli* pol I. The results suggest that DNA precursor nucleotides due to their greater availability for alkylation, may offer routes for the introduction of alkylated residues into double-stranded DNA.

To investigate the ability of DNA polymerase to use products from the interaction of chemical mutagens with DNA precursors, we reacted MNU with dATP. The products were separated by chromatography on QAE-Sephadex. Chromatographic and enzymatic analyses (to be described elsewhere) revealed N-1 and N-3MedATP in an approximate ratio of 7:1, N-1/N-3MedATP, dADP with one methyl group associated with its terminal β-phosphate, mP$^{\beta}$-dADP, and dATP with one methyl group associated with its terminal γ-phosphate, mP$^{\gamma}$-dATP.

We investigated the incorporation of these products into DNA using a novel application of the 'plus and minus' DNA sequencing method[9]. A plus reaction with a modified dNTP, dN*TP, as substrate provides information about the incorporation properties of dN*TP when bands generated on an analysing gel by products of the reaction are compared with those generated on the same gel by products of control reactions from the same sequence (Fig. 1*a*). The incorporation properties of dN*TP can be determined also from minus reactions using dN*TP instead of the missing triphosphate. If dN*TP can substitute for the missing dNTP, then synthesis proceeds beyond those sites that are blocked in the control reaction because of the need for the missing dNTP. Incorporation of the methylated precursor eliminates bands in the gel (see Fig. 1*b*).

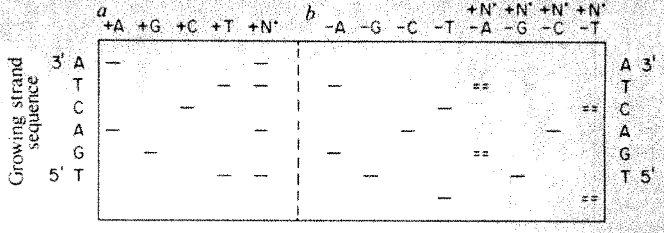

Fig. 1 Representation of a gel containing the products of: *a*, plus reactions; and *b*, minus reactions for the DNA sequence TGACTA. The gel bands indicated are the products of plus and minus reactions in the presence of a hypothetical modified triphosphate, dN*TP (N*), which incorporates as dATP and TTP (that is, against T and A template residues). Note the appearance of bands in the +N* slot that correspond to bands in the +A and +T but not the +G or +C slots. In minus reactions, bands in slots that analyse the products of −A and −T reactions with N* have decreased in intensity or are absent (indicated by pairs of dotted lines) compared with bands from −A and −T reactions without N*. No such effect was seen when the products of −G and −C reactions in the presence and absence of N* were compared.

N^4-hydroxy-dCTP (OH-dCTP; IUPAC numbering) was studied as a control in both plus and minus reactions (Fig. 2) because it may be able to act as both dCTP and TTP as suggested by studies of the incorporation of OH-rCTP into RNA[10,11]. As expected, OH-dCTP incorporated sometimes as dCTP and sometimes as TTP but never as dATP or dGTP. In a plus reaction, however, OH-dCTP incorporated opposite less than half of the available A and G sites (Fig. 2*a*) whereas in minus reactions containing OH-dCTP, almost all A and G template sites were used (Fig. 2*b*). This apparently different ability to incorporate in plus as opposed to minus reactions is probably related to the heavy dependence of plus reactions on the exonuclease and synthetic activities of the DNA polymerase. Once a residue (correct or incorrect) is incorporated during a minus reaction it may escape repeated scrutiny by the proofreading exonuclease through incorporation of the next residue. Analysis of OH-dCTP incorporation in plus reactions (Table 1) suggests

Table 1 Incorporation of OH-dCTP as T and C during plus reactions

a Four sites incorporate OH-dCTP at:			Two do not incorporate OH-dCTP at:	
Amount of incorporation	Site	ΦX174 coordinate	Site	ΦX174 coordinate
(m)	CT C GG	(4,683)	AG C AA	(4,677)
(s)	CC C TC	(4,685)	$_{5'}$GG C GT	(4,710)
(w)	GC C TT	(4,694)		
(w)	$_{5'}$TA C TG$_{3'}$	(4,724)		
***b* Two sites incorporate OH-dCTP at:**			**Five do not incorporate OH-dCTP at:**	
Amount of incorporation	Site	ΦX174 coordinate	Site	ΦX174 coordinate
(w)	CC T CG	(4,684)	CT T GC	(4,692)
(m)	$_{5'}$AC T GA$_{3'}$	(4,723)	AT T AG	(4,698)
			TG T GA	(4,706)
			CG T GT	(4,708)
			$_{5'}$GA T AG$_{3'}$	(4,720)

a, Six C sites and *b*, seven *T* sites tested for incorporation. The site of incorporation is indicated by the ΦX174 *am*3*cs*70 plus strand DNA sequence coordinate[18] shown next to each sequence. The minus (daughter) strand site of incorporation is indicated by the ΦX174 *am*3*cs*70 plus strand DNA sequence neighbours and next-nearest minus strand neighbours are also shown. A semi-quantitative measure of the ability of OH-dCTP to incorporate at the site indicated is represented by w, m or s (weak, moderate or strong), a measure of the effect on band intensity.

that the extent to which OH-dCTP can replace dCTP or TTP during DNA synthesis *in vitro* varies with sequence position; OH-dCTP apparently preferentially incorporates as dCTP when at least one of its nearest neighbours is T and as TTP when at least one of its nearest neighbours is C. The presence of purine residues on both sides of C or T sites inhibits OH-dCTP incorporation opposite those G or A template sites.

Analysis of the products of reaction of MNU with dATP by the plus reaction method (Fig. 3*a*) indicates that N-1/N-3MedATP, mP$^{\gamma}$-dATP and mP$^{\beta}$-dADP are incorporated into DNA by bacteriophage T4 DNA polymerase opposite T template residues but not opposite A, C or G template residues (not shown) at the concentration used. Incorporation of mP$^{\beta}$-dADP opposite T is suspect, however, for two reasons. First, it is believed that diphosphates cannot be incorporated by DNA polymerase. Second, this product chromatographs very closely to unreacted dATP, and so is possibly contaminated by dATP. All of the products were therefore re-purified until the diphosphate analogue no longer incorporated into DNA. Repurification did not alter the ability of products other than mP$^{\beta}$-dADP to pair as dATP. Use of repurified methylation products in minus reactions confirms that N-1/N-3MedATP and mP$^{\gamma}$-dATP preferentially incorporate opposite T template residues. Generally, mP$^{\beta}$-dADP at 10, 102 and 1,020 μM did not incorporate opposite any template residues (Fig. 3*b*); this result serves as a control against contamination by dATP. The slight incorporation at 1,020 μM suggests very low levels (< 4 nM) of dATP contamination. Yet lower levels of dATP contamination are expected for the other products as they chromatographed even further away from the unreacted dATP.

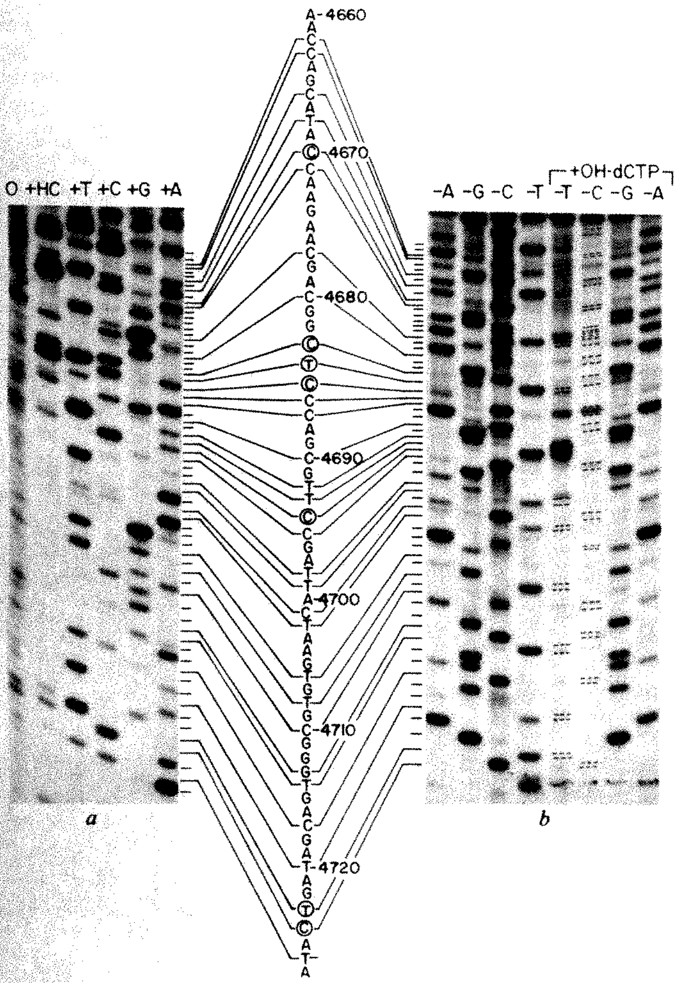

Fig. 2 Incorporation of OH-dCTP (HC) during: *a*, plus and *b*, minus sequencing reactions. OH-dCTP was synthesized according to published procedures[19], shown to be pure by HPLC, and identified by UV absorbance. Plus strand ΦX174 *am*3 *cs*70 DNA annealed with the *Hae*III restriction fragment Z9 (prepared as described elsewhere[20]) was incubated at 37 °C for 20 min with 0.4 μg of bacteriophage T4 DNA polymerase in the presence of 0.2 mM dNTP for plus reactions, or 10.0 μM dNTP for minus reactions. OH-dCTP (500 μM) was used where indicated. *a*, Products of normal plus reactions and products of a plus reaction in the presence of OH-dCTP are analysed on this gel. The sequence of the minus strand (growing strand) is shown. Sites at which OH-dCTP incorporated during plus reactions are indicated by circled bases in the sequence. Only those sites where incorporation was unambiguously assigned are indicated. Caution is required analysing this gel because the bands slant downwards as you proceed from left to right across the gel. *b*, Products of normal minus reactions and products of four extra minus reactions in the presence of OH-dCTP. Bands that have been diminished in intensity by the presence of OH-dCTP during minus reactions are indicated by pairs of dotted lines. The control slot, labelled O, contains the protein-free products of the asynchronous extension of template-primer (by Klenow pol I) in the absence of phage T4 DNA polymerase. All sequence sites are represented by radiolabelled primer extensions. These extended primers are either hydrolysed or elongated by DNA polymerase during plus and minus reactions, respectively.

N-1/N-3MedATP incorporates into DNA *in vitro* at T template sites (Fig. 3*b*) but not at A, G or C sites (not shown) at the concentrations used. Incorporation at some T template sites was noted at 10 μM and efficient incorporation was attained at 1,010 μM as demonstrated by the conversion of lower to higher molecular weight DNA fragments. In contrast, dATP incorporates at some sites at 4 nM and incorporates efficiently at 500 nM. This suggests that one N-1MedATP will incorporate for every 100–1,000 dATPs if both are present at equal concentrations during DNA replication. The use of chemically synthesized N-1MedATP in minus A reactions (unpublished results) indicates that it completely mimics the action of the N-1/N-3MedATP mix in a minus A reaction. Whether or not N-3MedATP can incorporate as dATP therefore remains unknown. mP$^{\gamma}$-dATP incorporates well opposite T (Fig. 3*b*) but not opposite A, G or C residues (not shown). Incorporation of mP$^{\gamma}$-dATP caused a shift of almost all the lower molecular weight DNA fragments, formed because of the absence of dATP during DNA synthesis, to higher molecular weight even at 10 μM—behaviour similar to that found with 10 μM dATP. Thus, the presence of a methyl adduct on the terminal phosphate of dATP does not interfere significantly with incorporation of this precursor.

In a preliminary report we suggested that some unpurified and unidentified products of the reaction of MNU with dATP incorporate as dGTP and dCTP as well as dATP at high concentrations[12]. The data presented here show that at much greater purity, those products that we have been able to isolate and clearly identify incorporate preferentially opposite T template residues.

Alkylation of DNA precursors may result in nucleotide pool imbalances, inhibition of nucleotide binding enzymes, and incorporation of modified residues into double-stranded DNA *in vivo*. The plus and minus DNA sequencing technique has proved a valuable tool in elucidating the third possibility. The technique requires only microgramme quantities of modified dNTP, does not require radiolabelling of the modified dNTP of interest, and allows us to locate specific sites where modified dNTPs are incorporated into DNA. By using this technique we have shown that N-1MedATP incorporates as dATP during replication of single-stranded DNA (ssDNA) *in vitro* by phage T4 DNA polymerase. Preliminary studies in our laboratory further indicate that the Klenow fragment of *Escherichia coli* pol I also incorporates N-1MedATP opposite T template residues. Similar *in vivo* conversion of N-1MedATP to N-1MedAMP template residues could be mutagenic as such template residues have been shown to cause misincorporation of C, G, U and A residues during 'transcription' of RNA with RNA polymerase[13]. Indeed, alkylation of unpaired DNA residues in the form of precursors and possibly single-strand

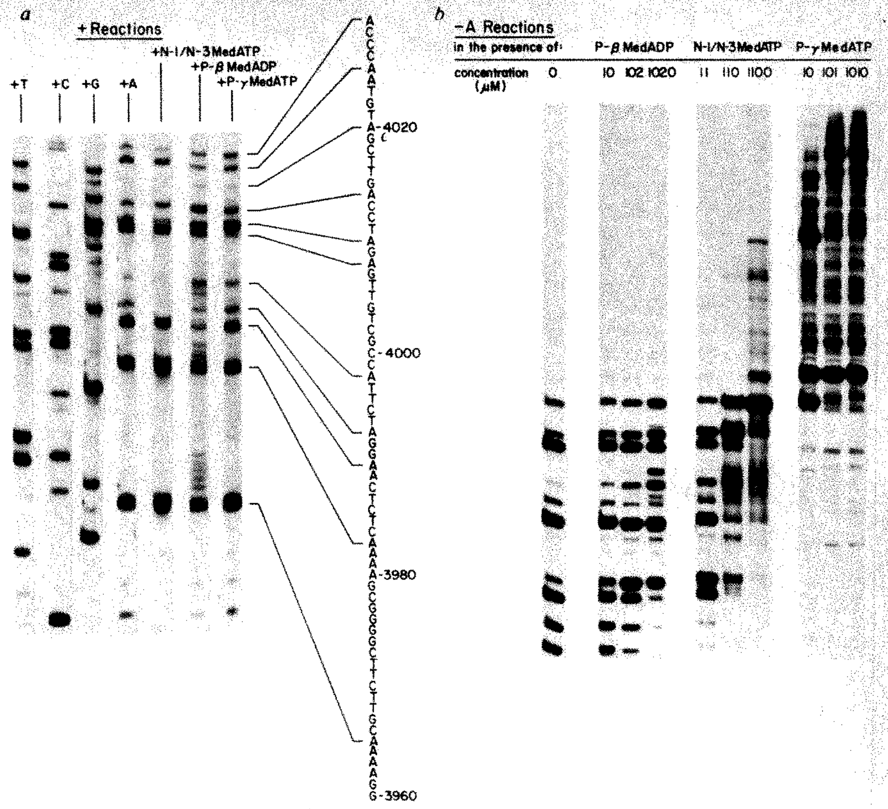

Fig. 3 Incorporation properties of products from the reaction of MNU with dATP during: *a*, plus and *b*, minus reactions. The template-primer is a synthetic oligodeoxyribonucleotide (P-L Biochemicals) complementary to positions 3,466 to 3,477 (pCAATAAACCAGC) of the pBR322 insert of R208, a pBR322/f1 chimaera[21], annealed to R208 ssDNA. The replicating daughter-strand sequence shown agrees with the published sequence for pBR322 (ref. 22). Reaction conditions are as described in Fig. 2 legend. *a*, Plus reactions: the concentrations of modified precursors were all 1.0 mM. All three products incorporated as dATP, as shown by the appearance of bands corresponding to A sites in the sequence (denoted by lines connecting bands with sequence sites). On further purification of the products, mP$^{\beta}$-dADP(P-βMedAP) lost its ability to incorporate. The other repurified products continued to incorporate as dATP, however, making the diphosphate analogue a good control against dATP contamination. These further purified products were used in minus reactions. *b*, The template-primer and reaction conditions were the same as for *a*. Note the increased shifting of bands to higher positions in the gels as you proceed from the control gel slot on the left to the highest concentration of mP$^{\gamma}$-dATP(P-γMedATP) at the extreme right. This shifting of bands indicates incorporation into DNA opposite T template residues.

residues at the replication fork, may offer a direct explanation for the S-phase dependence of both mutation[14] and neoplastic transformation[15] of cells in culture and of the chromosome replication point specificity of alkylating agents in bacteria[16,17].

Antifreeze effect of thermal hysteresis agents protects highly supercooled insects

Karl Erik Zachariassen & Jon Arve Husby

Department of Zoology, University of Trondheim, 7055 Dragvoll, Norway

Insects that are cold-hardy but sensitive to freezing survive at low temperatures due to their capacity for supercooling—their supercooling points are below −25 °C. In addition to polyols, these insects produce proteinaceous thermal hysteresis antifreeze agents reported to prevent growth of ice crystals down to ~−10 °C, thus stabilizing the supercooled insects down to this temperature[1,2]. We report here that in the beetle *Rhagium inquisitor* the ability of thermal hysteresis agents to prevent growth of ice crystals increases substantially when the crystal size is diminished. Thus, supercooled insects may be protected against growth of embryo ice crystals over their whole supercooling range, that is, they may be protected against freezing even during prolonged exposures to temperatures as low as −30 °C. The present observations are in accord with the prevalent theories for the action of antifreeze agents.

Thermal hysteresis factors (THF) have been found in polar fish[3,4], molluscs[5] and insects[1,2]. They appear to act by causing a separation of melting point and freezing point (thermal hysteresis) of frozen samples of body fluid, so that ice crystals are prevented from growing on cooling until a temperature several degrees below the melting point is reached. At this temperature (the freezing point) a rapid growth of ice crystals is observed. Thermal hysteresis factors are present in cold-hardy freeze-sensitive beetles of many species, giving their body fluid freezing points down to ~−10 °C. However, all these beetles have supercooling points below −20 °C, suggesting that THF are of no protective value to the insects in the critical, highly supercooled state.

Preliminary experiments revealed that diminution of ice crystals was accompanied by a more pronounced thermal hysteresis effect. To investigate the exact relationship between ice crystal size and thermal hysteresis, experiments were done on haemolymph from cold-hardy freeze-sensitive cerambycid beetles, *R. inquisitor*. These beetles hibernate at the adult stage and incorporate accumulated glycerol and THF, thus depressing body fluid melting points to below −5 °C and supercooling points of intact animals to below −25 °C. Our experiments revealed (Fig. 1*a*) that there is a linear relationship between the freezing points and the logarithm of the ice crystal size over the whole range of the measurements, the freezing point corresponding to the smallest ice crystal tested being about −9 °C.

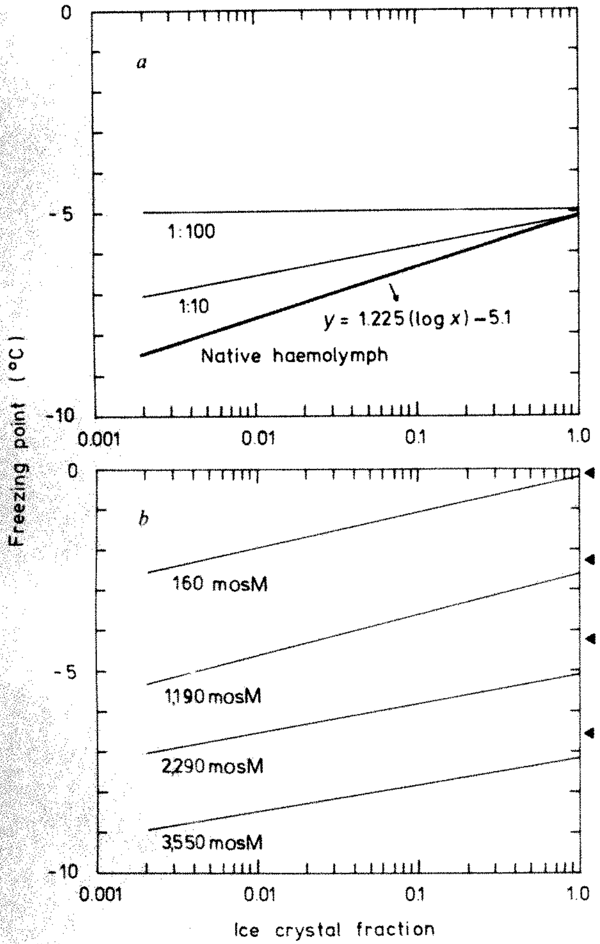

Fig. 1 *a*, Freezing point of native haemolymph of *R. inquisitor* beetles (thick line) and of haemolymph diluted 10-fold and 100-fold in isosmotic (2,290 mosM) glycerol solution (thin lines) as a function of ice crystal size. *b*, Freezing points of haemolymph of *R. inquisitor* beetles diluted 10-fold in four different concentrations of glycerol solution as a function of ice crystal size. The crystal size is expressed as the ice crystal fraction of the whole (2 nl) fluid sample. Assuming that the osmotic coefficients remain constant during freezing, the fraction of unfrozen water in a partly frozen sample is given by t_m/t_i, where t_m is the melting point of the fluid sample and t_i the temperature at which the ice crystal is stabilized. Thus, the ice crystal fraction has been calculated as $1 - t_m/t_i$. The linear regression lines were each calculated from ~75 individual points. The correlation coefficients range from 0.53 to 0.77, and the s.d. about the regression lines is about ±0.6 °C; the comparatively large s.d. may, at least in part, be due to the fact that the ice crystals were not ideal spheres. The experiments were carried out with a Clifton nanolitre osmometer, where 2 nl fluid samples could be observed through a microscope, while the temperature was regulated to within ±0.001 °C between 0 °C and −9.5 °C. The beetles were collected in the vicinity of Trondheim in January 1981. The dilutions were carried out with the haemolymph and glycerol solutions sandwiched between two layers of paraffin oil inside glass capillaries. Fluid was transferred between the capillaries and to the osmometer by means of a microsyringe.

Even the smallest ice crystal used in these experiments was large compared with the aggregates of water molecules present in the body fluid of a highly supercooled insect. Figure 1*a* indicates that the freezing points will continue to decrease with further diminution of the ice crystal. Hence, THF may be able to prevent ice crystal growth and thus stabilize supercooled insects at considerably lower temperatures than those tested experimentally. Unfortunately, the available techniques for temperature control do not allow stabilization of ice crystals at a smaller size. However, some information can be obtained by extrapolating the regression line representing pure haemolymph in Fig. 1 to smaller crystal sizes. The haemolymph used in the experiment was 2,290 mosM. *R. inquisitor* beetles with this haemolymph osmolality have supercooling points of ~−25 °C (ref. 6). Extrapolation of the regression line to this temperature reveals that the corresponding ice crystal fraction is $\sim -10^{-16}$, that is, an ice crystal radius of 3.6×10^{-17} mm (fluid sample volume = 2 nl). According to Chalmers[7], the critical crystal radius for nucleation by embryo ice crystals at −25 °C is 1.5×10^{-16} mm. The aggregations of water molecules in a supercooled insect are probably smaller than this critical size. The extrapolated regression line indicates that THF have the ability to prevent growth of embryo ice crystals of this size. Thus, THF seem to have considerably more efficient antifreeze effects at low temperatures than previously thought. They may in fact be able to stabilize supercooled insects over their whole supercooling range. Thus, the presence of THF probably explains why many hibernating insects can endure exposure to extreme cold for long periods without freezing.

The influence of varying concentrations of THF on the thermal hysteresis was investigated in another series of experiments, in which the concentration of THF was varied by diluting *R. inquisitor* haemolymph 10-fold and 100-fold in isosmotic (2,290 mosM) glycerol solution. These studies revealed (Fig. 1*a*) that even after 10-fold dilution there was still a pronounced thermal hysteresis effect, but this was absent following 100-fold dilution. Seasonal variations in the levels of THF may influence the freezing points in accordance with the varying slopes of the regression lines in Fig. 1*a*.

The fact that a pronounced thermal hysteresis was still present after 10-fold dilution of the haemolymph was used to investigate the relationship between glycerol concentration and thermal hysteresis (Fig. 1*b*). The results reveal that increasing glycerol concentrations cause a parallel displacement of the regression lines to lower freezing points, the freezing point depressions being greater than the corresponding melting point depressions. Thus, glycerol seems to act by extending the temperature range within which the THF performs its stabilizing antifreeze effect.

As THF appear to be unable to mask the effect of ice nucleating agents[8], their antifreeze function at very low temperatures is restricted to insects which have no nucleating agents in their body fluids[6,9,10].

The present results are in agreement with the model proposed by Raymond and DeVries[11,12] to describe the mechanism of the THF antifreeze effect. This model is based on the assumption that THF molecules are adsorbed to the ice crystal surface, thus confining ice growth to the spaces between adjacent THF molecules. The resulting increase in ice front curvature will displace ice growth to lower temperatures. When the ice crystal size is diminished as in the present experiments, more THF molecules may be adsorbed per unit ice surface area. The subsequent increase in ice front curvature will therefore cause a further decrease in the freezing points, as observed.

E. coli F_1-ATPase interacts with a membrane protein component of a proton channel

John E. Walker, Matti Saraste & Nicholas J. Gay

Laboratory of Molecular Biology, MRC Centre, Hills Road,
Cambridge CB2 2QH, UK

The ATP synthases of bacteria, mitochondria and chloroplasts, which use the energy of a transmembrane proton gradient to power the synthesis of ATP, consist of an integral membrane component F_0—thought to contain a proton channel—and a catalytic component, F_1. To help investigate the way F_0 and F_1 are coupled, we have sequenced the b-subunit of the *Escherichia coli* F_0, which seems to be the counterpart of a thermophilic bacteria F_0 subunit thought to be essential for F_1 binding[1]. We report here that its sequence is remarkable, being hydrophobic around the N-terminus and highly charged in the remainder. We propose that the N-terminal segment lies in the membrane and the rest outside. The extramembranous section contains two adjacent stretches of 31 amino acids where the sequence is very similar: in the second of these stretches there is further internal homology. These duplicated stretches of the polypeptide probably fold into two α-helices which have many common features able to make contact with F_1 subunits. Thus protein b occupies a central position in the enzyme, where it may be involved in proton translocation. It is possibly also important in biosynthetic assembly.

The organization of the genes coding for ATP-synthase subunits in the *unc* operon is shown in Fig. 1. The three genes for F_0 polypeptides a, c and b are grouped together at the promoter-proximal end and are followed by the five F_1 genes. Gene b encodes a protein of molecular weight 17,212, which is not modified by post-translational processing[2]. The amino acid sequence of this product (Fig. 2) falls into two distinct parts. With the exception of single threonine and cysteine residues and one charged residue, Lys 23, residues 1–33 are hydrophobic. It is proposed that this section of the protein forms a single transmembrane α-helix (see below). Other transmembrane α-helices in bacteriorhodopsin also contain buried threonine residues[3]. The hydroxyl group can form a hydrogen bond with the main-chain polypeptide backbone, as can the thiol of cysteine. Buried charges are also proposed in bacteriorhodopsin but in protein b the side chain of Lys 23 could be near the membrane surface. In contrast, the rest of the sequence of protein b is highly polar, containing 26 basic and 26 acidic residues; this charged section of the protein has internal repeats (Fig. 3). Thus, residues 52–82 are homologous with residues 85–105 (Fig. 4). In addition, within the latter but not the former sequence, a shorter repeat is found, residues 85–99 being homologous to residues 100–115. It is of particular interest that the residues identical in the short repeat consist largely of those that are not conserved (10/14) in the long repeat (see Fig. 4). Thus it seems that part of the charged segment arose by duplication of a 31-amino acid stretch which itself was formed in an earlier event involving duplication of 15 amino acids.

Further information about the structure of protein b can be obtained from the secondary structure predicted from the amino acid sequence (Fig. 1). It is highly probable (probability >0.6) that the protein is almost entirely α-helical. Breaks in α-helices may occur at three points, around residues 27–28 (Pro–Pro), 83–86 (between the long repeats) and near residue 136. A weakening of α-helicity is also noted at residues 43–44. Thus the structure of the protein breaks down into two clear α-helical domains, the first of which (residues 1–20) is highly hydrophobic and could yield an α-helix spanning the membrane once. This helix presumably makes hydrophobic interactions with a and c, the two other constituents of F_0. It is hinged to the second highly charged region by residues 21–28, including the sequence Pro–Pro. The highly charged region appears to consist of at least two connected α-helices, with related sequences, and presumably presenting α-helical surfaces with many identical features able to interact with F_1 subunits. A clue to the nature of the interactions between the proposed α-helical structure of b and F_1 comes from a study of observed helix–helix interactions in proteins[4], which showed that Ala, Val, Leu, Ile and Phe constitute 50% of all residues involved in these interactions, and Asn, Gln, Glu, Asp, Lys and Arg a further 25%, in contrast to the residues involved in helix–α-sheet interactions[5]. The proposed extramembranous α-helical region of b consists mainly of Ala, Val, Leu and Ile (44%) and acidic and basic amino acids (39%). Thus, if the rules of protein–protein interactions are the same as found in proteins to date, it seems likely

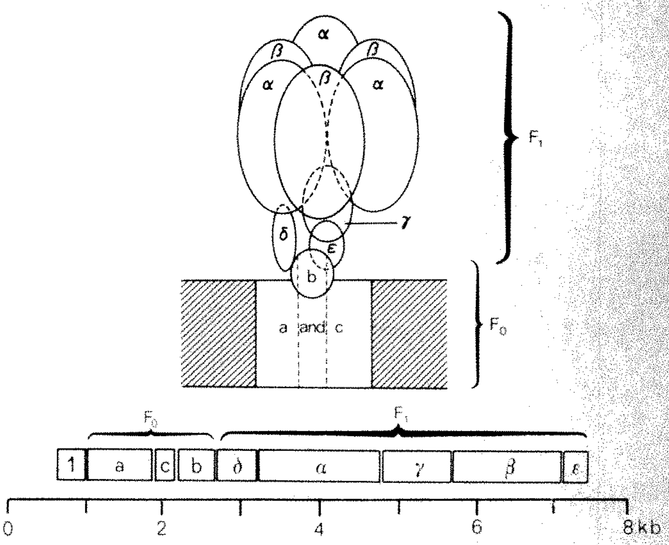

Fig. 1 Organization of polypeptides in the ATP-synthase complex and of their corresponding genes in the *unc* operon. The enzyme (upper panel) is bound to the inner membrane of *E. coli*. F_1 protrudes into the cytoplasm and is depicted with alternating α- and β-subunits although other arrangements have been proposed[13,18]. The hydrophobic F_0 subunits, a and c, are buried in the membrane. It is proposed here that a and c interact with the hydrophobic amino-terminal region of the third F_0 subunit, b. The rest of b is very polar and lies outside the lipid bilayer, making helix–helix contacts with the δ and ε subunits thus binding F_1 to the membrane. All three F_0 subunits are required to make a transmembrane proton channel (dotted line) linking the membrane proton potential to ATP synthesis in F_1. The genes encoding the ATP-synthase subunits are organized in the *unc* operon as shown in the lower panel. The order of genes was determined by DNA sequence analysis[16,19,20]. Gene a was identified by homology with mitochondrial ATPase-6 genes[21], c from total amino acid sequence[22]; b and δ from their molecular weight and charge[16] and N-terminal sequences[2]; α, γ, β and ε by sequence analysis of the *E. coli* proteins[23] and, in the case of α and β also from highly homologous beef proteins (M. J. Runswick, V. L. J. Tybulewicz and J.W., unpublished work). The presence of an active promoter preceding gene 1 and the transcription start point have been established by experiments *in vitro* (N.J.G., unpublished work). Parts of the sequence corresponding to genes a, c, b, δ and α have also been sequenced independently[2,24–26]. Gene 1 does not encode a structural protein of ATP-synthase, but may be involved in regulation of assembly[16].

that the interactions of b with F_1 proteins will be predominantly helix–helix.

The binding of F_1 to F_0 is mediated by δ and ε subunits[6–9]. In thermophile PS3 enzyme, which is very similar to the *E. coli* enzyme[10], both are required to bind the $\alpha\beta\gamma$ subcomplex to F_0 (ref. 7). Smith and Sternweis showed also that in *E. coli*, δ is involved in attachment of F_1 to F_0 (ref. 7). The δ protein in particular could make helix–helix interactions with b; it has a high α-helical content (65%) as estimated by circular dichroism spectroscopy of the PS3 protein[11]. In the same study ε and γ were estimated to contain 33% and 49% α-helix respectively, in general agreement with α-helix contents of 83%, 31% and 67% for δ, ε and γ, respectively, derived from secondary structures predicted from the *E. coli* protein sequences (J.W. and M.S., unpublished work).

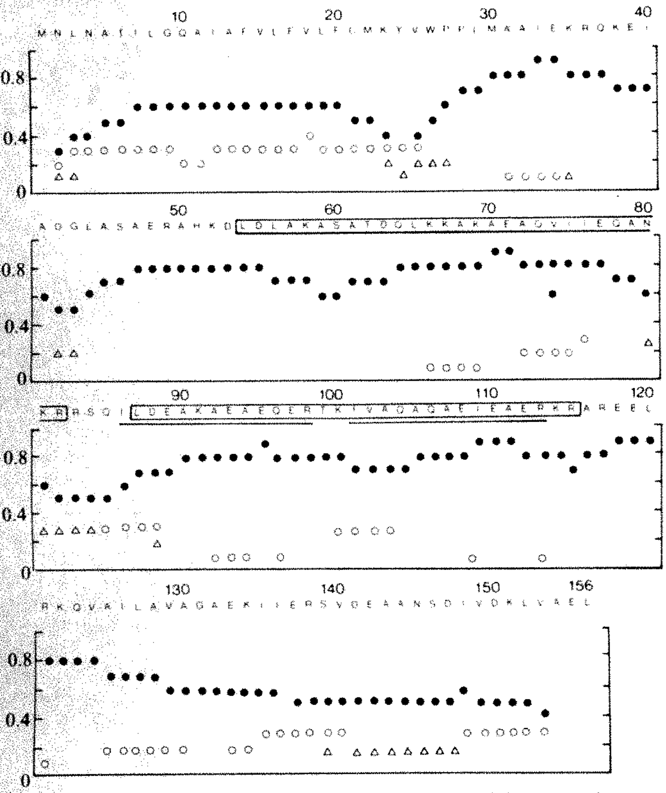

Fig. 2 Amino acid sequence of subunit b, and its secondary structure, predicted from the primary sequence using a program described by McLachlan[27]. The graphs beneath the sequence show probabilities (ordinate scale) of residues forming an α-helix (●), β-sheet (○) or β-bend (△). Boxed sequences represent related sequences (the long repeat); underlined segments are also related to each other (the short repeat, see Fig. 4).

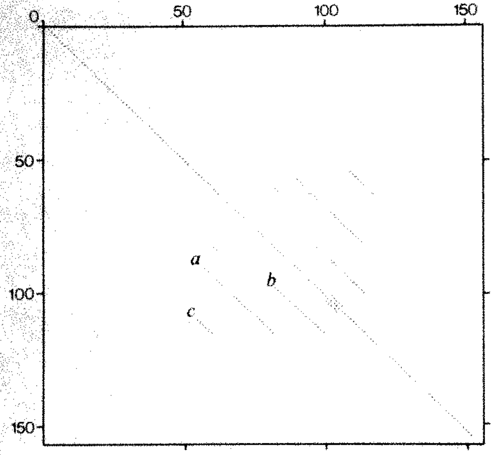

Fig. 3 Matrix of comparison of b with itself, performed with the interactive computer program DIAGON (R. Staden, unpublished work) adapted from earlier procedures[28]. Scoring is based on a mutation matrix calculated from observed changes in homologous proteins. The scoring level in the matrix shown corresponds to a double matching probability of 1.2×10^{-3}, that is, in a random sequence of the same composition only about one sequence in a thousand should reach this scoring level. The span used in the comparison was 25. Each point (midpoints of the span) has a score less than the 'cutting level'. The diagonal is b aligned with itself; *a* and *b* correspond to the long and short repeats, respectively (see Fig. 4), and *c* corresponds to alignment of residues 57–61 (A K A S A) with residues 103–107 (A Q A Q A), which is probably trivial.

Fig. 4 Alignment of repeated sequences in protein b. *a*, The long repeats; *b*, the short repeats. Identities are boxed. In *a*, the 14 residues conserved in *b* are encircled; of these four residues are conserved in both *a* and *b*.

The stoichiometry of subunits in F_1 is $3\alpha:3\beta:1\gamma:1\delta:1\varepsilon$[12] with an estimated one or two copies of b per enzyme complex[13]. Thus it remains unclear whether two or four roughly equivalent α-helical segments in b are available in each F_0 to bind F_1, also how many complementary α-helices would be required in δ and ε.

As it occupies a central position providing an important structural link between the membrane and F_1, it seems likely that b will be involved directly in proton translocation with some of its charged residues contributing to the process. This is supported by the finding that mutants in b have drastically reduced proton translocation[1]. The γ-subunit has also been proposed to participate in this process by gating the proton channel[14]. Like protein b it appears to interact with δ and ε although not directly with F_0[9,14] and therefore not with b.

Biosynthetic assembly of ATP-synthase is poorly understood. It is clearly desirable to assemble the enzyme in a controlled manner to avoid open H^+ channels. Open H^+ channels would 'de-energize' the membrane leading to breakdown of several essential functions driven by the membrane proton potential[15]. The location of b in the enzyme complex, the *in vitro* assembly of F_1 from subunits and reassociation of F_1 and F_0 suggest that b will be important here also. In addition, the order of genes in the *unc* operon (Fig. 1) is striking: the genes for the hydrophobic components of F_0 (a and c) are followed by the gene for protein b, and then those for F_1, suggesting that insertion of F_0 polypeptides may occur early in assembly. This notion is not in accord with a study of *unc* mutants by Cox *et al.*[15], who proposed that α and β must bind to membranes containing a and c before b can enter the lipid bilayer to complete F_0 (although b was not shown to be present in the cytoplasm of these mutants). However, these studies did not take account of gene 1 (Fig. 1) which may encode a pilot protein to regulate the assembly process[16]. Indeed, identification of the role of this gene may be the key to understanding assembly of bacterial ATP-synthase.

Recently Hoppe *et al.*[17] have reported that *E. coli* protein b in F_1-depleted membranes is very sensitive to proteolytic degradation. Also F_1 protects b in these membranes from proteolysis. Additionally a photoactive hydrophobic phospholipid derivatives reacts with Cys-21. These experiments strongly support the structure of b proposed above.

We thank A. D. McLachlan and R. Staden for help with computer analyses and R. Hendersen and J. Deatherage for helpful comments. M.S. is supported by an EMBO fellowship and N.J.G. by an MRC studentship.

University of Pennsylvania School of Medicine,
Philadelphia, Pennsylvania 19104, USA

The origin of the differences in oxygen binding energy in various haemoglobins and myoglobins has long been debated. Perutz[1] proposed that the haem-coordinated histidine (proximal histidine) strains the haem iron in low affinity globins but relaxes it in high affinity globins. The existence of such tension in T-structure deoxyhaemoglobin (deoxyHb) was recently confirmed by electron paramagnetic resonance (EPR)[2,3], resonance Raman[4,5] and NMR[6] spectroscopy. Although its contribution to the free energy of cooperativity is insignificant in the deoxy state, the tension at the haem is considered to be ~1 kcal mol^{-1} for the ligated form in which the haem iron moves into the porphyrin plane[7]. The remaining free energy is probably stored in other parts of the molecule. Therefore, a study of the stabilization mechanisms of the oxygenated form became increasingly important. A hydrogen bond between the bound oxygen and the distal histidine has been proposed by Pauling[8]; this would be expected to stabilize the oxy form of the protein and could contribute to the regulation of the oxygen affinity through the oxygen dissociation rate. A series of EPR and functional studies on various cobalt-substituted monomeric haemoglobins and myoglobins suggested the presence of such hydrogen bonding[8–12] and it has recently been established in crystals of oxy iron myoglobin (oxyFeMb)[13] and in oxyhaemoglobin[14]. Here we present resonance Raman spectra of the oxy forms of cobalt–porphyrin-substituted myoglobin and haemoglobin (CoMb and CoHb) recorded in buffered H_2O and D_2O solutions at 406.7 nm excitation. Only the Raman lines corresponding to the O—O stretching mode of the bound oxygen[15], appearing near 1,130 cm^{-1}, are shifted (2–5 cm^{-1}) on replacement of H_2O by D_2O; no other vibrations, including the Co—O_2 stretching mode, exhibit any frequency shifts. This indicates that the bound oxygen in oxyCoMb and in both subunits of oxyCoHb interacts with the adjacent exchangeable proton, and confirms the formation of a hydrogen bond between the bound oxygen and the distal histidine[9].

The IR active vibrational frequencies of the bound dioxygen stretching modes in haemoglobin have been detected in the 1,100–1,160 cm^{-1} frequency range[16]. Resonance Raman spectroscopy probes the vibrational frequencies of the porphyrin chromophore and electronically associated ligands. Tsubaki and Yu[15] demonstrated by $^{16}O_2$–$^{18}O_2$ isotopic substitutions, that the dioxygen stretching mode of the bound oxygen of oxyCoMb and oxyCoHb, located near 1,130 cm^{-1}, was resonance-enhanced on excitation at 406.7 nm (ref. 15). In contrast, the spectra of oxyFeMb and oxyFeHb revealed no oxygen isotope-dependent frequencies in this region. Tsubaki and Yu[15] proposed that the dioxygen stretching mode is enhanced by coupling to a charge transfer transition in the cobalt-substituted haem that is absent from the iron haem. The O—O stretching frequency should be a sensitive probe of hydrogen bonding to the dioxygen molecule, therefore we investigated the frequency of the O—O stretching mode of oxyCoMb and oxyCoHb on deuterium substitution of the exchangeable protons.

CoMb, CoHb and iron–cobalt hybrid haemoglobins ($\alpha(Fe)_2\beta(Co)_2$ and $\alpha(Co)_2\beta(Fe)_2$) were prepared as described previously[2,17] and oxygenated in 50 mM Tris-HCl buffer *p*H (or *p*D) 9.0, except for the *p*H variation studies. The Raman spectra were recorded using the difference spectrometer described previously[18], the accuracy of the detected difference in the frequency was ~0.2 cm^{-1} and that of the absolute frequency ~ ±1 cm^{-1}.

Typical H_2O–D_2O difference spectra for oxyCoHb and oxyCoMb in the 1,000–1,250 cm^{-1} region are shown in Fig. 1*a*, *b*. The spectrum of oxyCoHb in H_2O (Fig. 1*b*) is in agreement with the reported spectrum in which Raman lines near 1,133 and 1,146 cm^{-1} were found to be $^{18}O_2$ isotope-sensitive[15]. These two lines show no frequency shift between *p*H 5.3 and 10.4. On replacing the H_2O by D_2O, however, the 1,133 cm^{-1} component exhibits a frequency shift of 5 cm^{-1} to 1,138 cm^{-1} (Fig. 1*b*). There may be a shift in the 1,146 cm^{-1} line also (see the difference spectrum) but its magnitude is obscured by the shift of the more intense line. In contrast to this behaviour in the cobalt haemoglobin, no frequency differences were detected on deuteration of iron haemoglobin. This was expected as the only Raman-active modes in the 1,050–1,150 cm^{-1} region of oxyFeHb, are porphyrin modes. Thus, the hydrogen bonding is probably present in the iron haems also but it is not spectroscopically detectable in our conditions. Figure 1*a* shows the spectra of oxyCoMb in which the H_2O–D_2O shift is from 1,134 to 1,136 cm^{-1}. In oxyCoMb the higher frequency component (~1,146 cm^{-1}) has been shown to be weaker than in oxyCoHb[15], thus obscuring any possible shift in frequency in this line.

The iron–cobalt hybrid haemoglobins were also examined. The absence of any H_2O–D_2O dependence in oxyFeHb allows determination of the relative contributions from the individual subunits in the hybrids as any shift must result from the cobalt subunit. The size of the shift and shape of the line on deuteration in the α- and β-subunits are depicted in Fig. 1*c*, *d*. The α-subunit gave a smaller shift (2 cm^{-1}) than the β-subunits (4 cm^{-1}). The magnitude of shift for each subunit was less than that of fully cobalt-substituted oxyHb. This is expected as the presence of Raman modes from the iron subunits of the hybrids that do not shift in this frequency region should dilute the contribution from the cobalt subunits. The frequency difference between the $\alpha(Fe)_2\beta(Co)_2$ and $\alpha(Co)_2\beta(Fe)_2$ oxyHbs, both in H_2O, is small. Therefore the frequency difference that we observe between the α- and β-subunits occurs in the deuterated form. A shape difference in this mode between the subunits is also noted in the deuterated form; the 1,136 cm^{-1} line of the

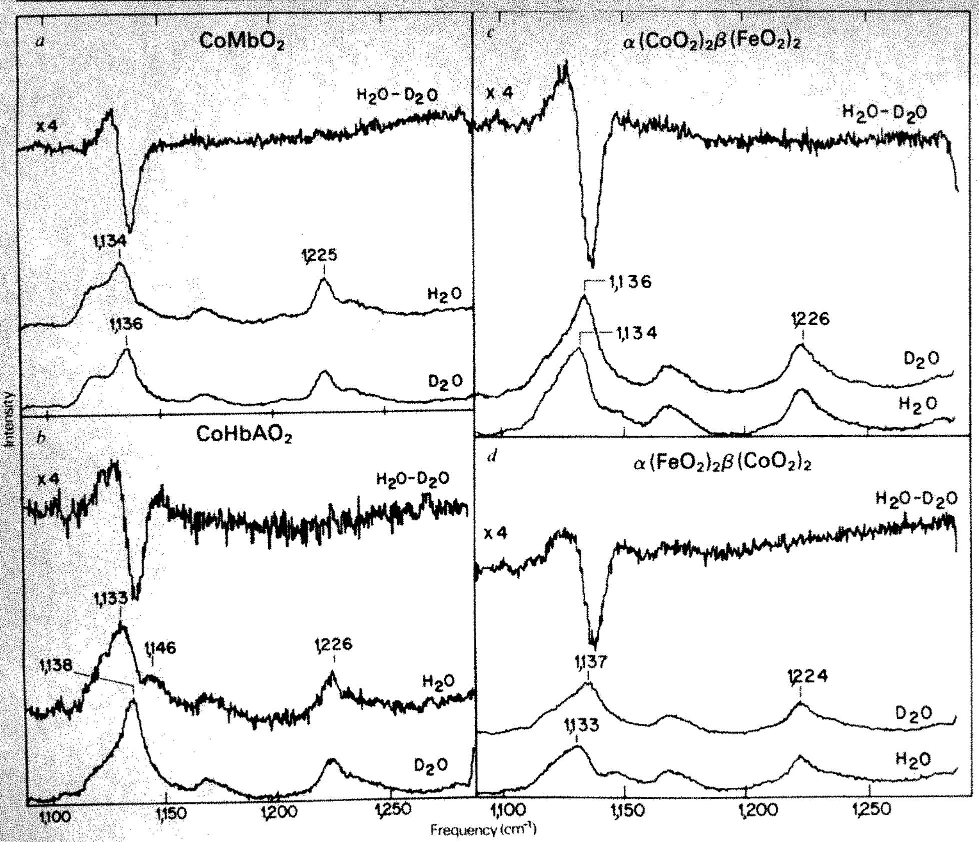

Fig. 1 Resonance Raman spectra of *a*, oxyCoMb; *b*, oxyCoHb; *c*, oxy $\alpha(Co)_2\beta(Fe)_2$; and *d*, oxy $\alpha(Fe)_2\beta(Co)_2$ in H_2O and D_2O. In each case the difference spectrum is plotted at the top with a sensitivity four times as high as the individual spectra. Excitation frequency 406.7 nm, laser power ~100 mW, spectral slit width ~4 cm^{-1}.

$\alpha(Co)_2\beta(Fe)_2$ oxygenated hybrid is narrower than that of the complementary hybrid.

Figure 2 shows the H_2O-D_2O difference spectrum of oxyCoMb in the Co—O_2 stretching region. The Raman line of oxyCoMb at 538 cm^{-1} was assigned previously to the Co—O_2 stretching mode[15]. Unexpectedly, this line did not show any frequency difference (<2 cm^{-1}) in the H_2O and D_2O solutions despite the clear shift of the O—O stretching mode.

Deuterium substitution of exchangeable protons of haemoglobin has been reported to stabilize the protein against thermal denaturation and auto-oxidation[19]. Thus, the hydrogen bonding in haemoglobin is presumably stronger in D_2O than in H_2O as expected on the basis of a lower zero point energy. Therefore, a resulting change of tertiary structure due to the deuterium substitution could alter a state of the Co—His (proximal) bond or a degree of charge delocalization between the haem and the bound dioxygen. This seems unlikely, however, because the Fe—His stretching mode of deoxyFeHb is not shifted by more than 1 cm^{-1} on deuterium substitution; nor is any frequency shift detected on deuteration for any of the porphyrin skeletal vibrations of oxyCoHb, and the Co—O_2 mode is unaffected by deuteration. In addition, Phillips and Shoenborn, using neutron diffraction[13], observed no significant difference between the tertiary structures of myoglobin in H_2O and D_2O. Therefore, the differences we have detected in the O—O stretching frequency in D_2O must result from a specific interaction between the oxygen and the apoprotein on the distal side of the haem.

Recently, Phillips and Schoenborn[13] made a direct observation of a hydrogen bond in crystals of oxyFeMb and reported that the N_ϵ—O^2 distance is 2.97 Å. According to a recent X-ray analysis[14] of crystalline oxyFeHb, the N_ϵ—O^2 distance is 2.7 Å and 3.4 Å for the α- and β-subunits, respectively. Furthermore, the N_ϵ—O^2 distance in crystals of oxyCoMb has also been shown to be compatible with hydrogen bonding[20]. The data reported here, obtained in solution, confirm the existence of hydrogen bonds in oxyCoMb and in both subunits of oxyCoHb. It is probable that the entire H_2O—D_2O shift of the O—O stretching frequency is caused by the change from the hydrogen—oxygen bond to the deuterium—oxygen bond. It is also possible, however, that a change in position of the distal histidine due to tertiary structural changes in the protein contributes to our observed frequency differences. The hydrogen bond to the distal histidine is (approximately) perpendicular to the O—O bond axis[13], therefore it seems reasonable that the Co—O_2 stretching frequency is less sensitive to the changes caused by deuteration than the O—O stretching frequency. More information is required to correlate the size and direction

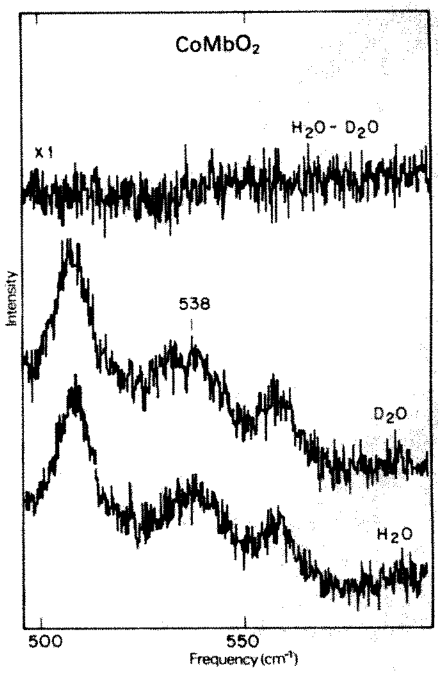

Fig. 2 Resonance Raman spectra of oxyCoMb in the region of the Co—O_2 stretching frequency (538 cm^{-1}). The absence of a significant shift on deuteration in this mode may be seen by examination of the difference spectrum plotted at the top. Excitation frequency 441.6 nm, laser power ~20 mW, spectral slit width ~4 cm^{-1}.

of the frequency shift with the strength of the hydrogen bond or with conformational changes. Analysis of the O—O stretching mode in oxyCoHbs in which a quaternary structure change can be induced should elucidate whether any free energy of cooperativity is localized in the hydrogen bonding interaction.

Myosin phosphorylation, agonist concentration and contraction of tracheal smooth muscle

Primal de Lanerolle, John R. Condit Jr, Mark Tanenbaum & Robert S. Adelstein

Laboratory of Molecular Cardiology, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

Myosin phosphorylation plays an important part in excitation–contraction coupling in smooth muscle. Phosphorylation by a Ca^{2+}, calmodulin-dependent kinase stimulates the actin-activated Mg^{2+}-ATPase activity of smooth muscle myosin[1–5], suggesting that myosin phosphorylation regulates smooth muscle contraction (see refs 5, 6 for discussions of alternative hypotheses). This hypothesis is supported by evidence that myosin is phosphorylated during contraction and dephosphorylated during relaxation of intact smooth muscles stimulated with a single agonist concentration[7–9]. However, there is little information regarding the response to stimulation with various agonist concentrations. As the dose–response relationships for phosphorylation and tension should be similar if myosin phosphorylation does, in fact, regulate smooth muscle contraction, we studied myosin phosphorylation in tracheal smooth muscle stimulated with a broad range of concentrations of the cholinergic agonist, methacholine. The results of these experiments are consistent with the hypothesis that myosin phosphorylation regulates smooth muscle contraction but they indicate a relatively complex relationship between myosin phosphorylation and the generation of isometric tension.

Canine tracheal smooth muscles were obtained and treated as previously described[8] except that: (1) muscles were maintained in the muscle baths as flat sheets in order to minimize non-uniform rates of agonist diffusion to receptor sites; (2) individual smooth muscle strips were maintained at a length of 2 cm, as defined by their *in vivo* length, from the time they were removed from the cartilaginous rings of the trachea until the end of the experiment; (3) muscle strips were kept in the muscle baths for 45 min before initiating contractile responses.

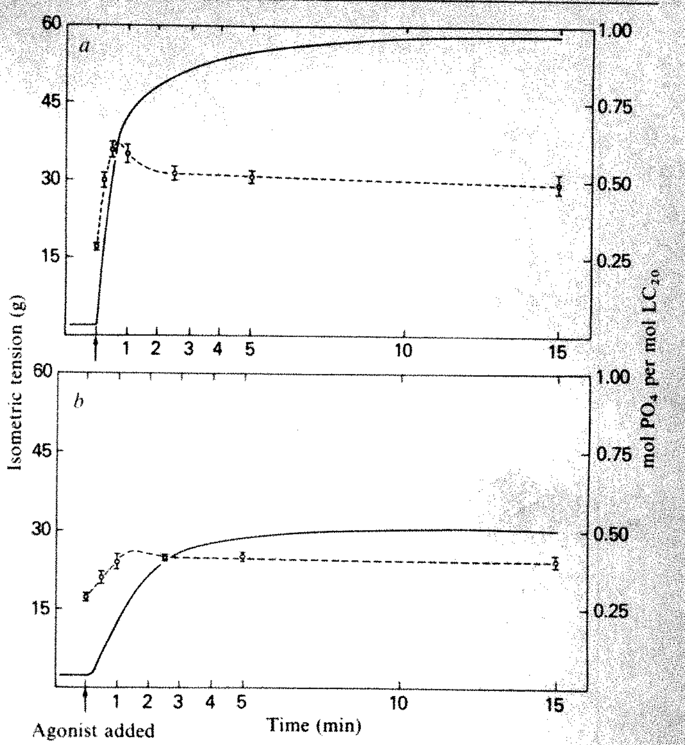

Fig. 1 Myosin phosphorylation and tension generated by tracheal smooth muscle contracted with 10^{-4} M (*a*) or 2×10^{-7} M (*b*) methacholine. Tracheal muscle from six consecutive tracheal rings was isolated and mounted in six myobaths. The data at 15 min in *a* were obtained from separate experiments. The solid lines represent tension generated by representative muscles contracted for 15 min; broken lines represent the phosphate content of muscles frozen at the times indicated. Error bars indicate the s.e.m. for phosphate determinations on at least five different pieces of tissue. Experiments on smooth muscles have demonstrated that a specific subunit of the myosin molecule, with a molecular weight of 20,000 (LC_{20}), is phosphorylated. A maximum of 1 mol PO_4 can be incorporated per mol LC_{20}. As there are 2 mol LC_{20} per mol myosin, the maximal level of myosin phosphorylation is 2 mol PO_4 per mol myosin. We have chosen to present the data as mol PO_4 per mol LC_{20} because this was the experimentally determined value.

The myosin phosphate content was quantitated using an immunoprecipitation–isoelectric focusing method as described previously[8].

Phosphate analyses on resting (unstimulated) tracheal muscle demonstrated 0.29 mol of phosphate incorporated per mol LC_{20}. (LC_{20} is a subunit of myosin—see Fig. 1 legend.) On stimulation with 10^{-4} M methacholine (Fig. 1*a*), the myosin phosphate content rose rapidly, reaching a peak of 0.62 mol PO_4 per mol LC_{20}, before the muscle generated maximal tension. The myosin phosphate content then decreased slightly, while the muscle was still contracting, to a stable level of 0.49 mol PO_4 per mol LC_{20}. Stimulation of tracheal muscle with 2×10^{-7} M methacholine (Fig. 1*b*), a concentration previously determined to produce half-maximal tension, contracted muscles more slowly than stimulation with 10^{-4} M methacholine (maximal rates of contraction were 31 and 129 g min^{-1}, respectively). Myosin was phosphorylated at a much slower rate, and the maximal and steady-state levels of phosphorylation were lower for muscles stimulated with 2×10^{-7} M methacholine (Fig. 1*b*) than for those stimulated with 10^{-4} M methacholine (Fig. 1*a*).

We have also determined the relationship between the steady-state level of myosin phosphorylation, tension and agonist concentration (Fig. 2). Muscles were stimulated with various concentrations of methacholine, then frozen 15 min after addition of the agonist and assayed to determine the myosin phosphate content. (Muscles were frozen at 15 min because the experiments in Fig. 1 indicated that tension and phosphorylation had reached a plateau by 10 min.) Myosin phosphorylation and active tension were expressed as a percentage of the

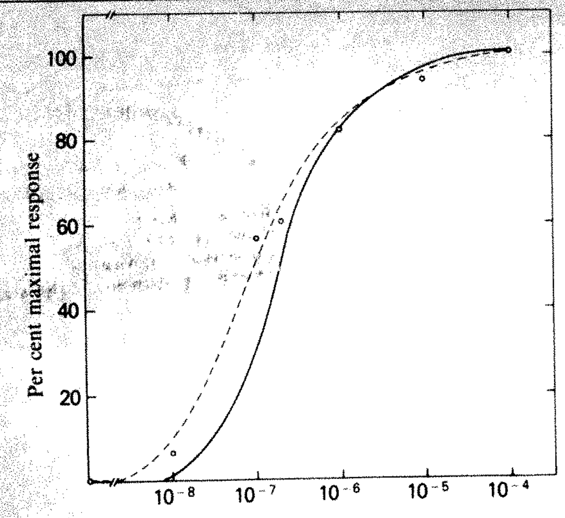

Fig. 2 The dose–response relationship for myosin phosphorylation and isometric tension in tracheal smooth muscle stimulated with methacholine. Myosin phosphorylation was determined on tracheal smooth muscle contracted for 15 min using the agonist concentration shown. The phosphorylation and tension data were expressed as per cent maximal increase using the equation $X - R/M - R$ where X = myosin phosphate content or tension at 15 min of muscles stimulated with various methacholine concentrations; R = the resting phosphate content (29%) or resting tension; and M = the myosin phosphate content (49%) or tension at 15 min of muscles stimulated with 10^{-4} M methacholine. The solid line represents the rise in tension after stimulation at each agonist concentration; the broken line represents the increase in myosin phosphorylation at each agonist concentration. Each point represents the mean from phosphate assays on at least five different pieces of tissue.

maximum (see Fig. 2 legend). These data, plotted as a function of log agonist concentration (Fig. 2), demonstrated similar agonist concentration–response relationships for both phosphorylation and tension. Analysis of variance indicated statistically significant differences ($P < 0.001$) between successive points on each dose–response curve. However, there were no statistically significant differences between the two curves at any given agonist concentration, indicating that the phosphorylation and tension data define superposable curves.

The data on myosin phosphorylation presented here argue against a simple relationship between the processes of myosin phosphorylation and tension generation by tracheal smooth muscle. Three major aspects of the phosphorylation data require comment—the resting myosin phosphate content, the overshoot in myosin phosphorylation and the steady-state level of myosin phosphorylation. Each of these may have a bearing on the manner in which tracheal muscle generates tension and will be discussed separately.

First, it should be noted that a substantial fraction of the myosin (29%) is phosphorylated in unstimulated tracheal smooth muscle. There is a low level of tension (2–5 g) in these muscles but this resting tension seems to be generated by passive elastic elements as a reduction in the myosin phosphate content does not decrease the resting tension[8]. It is possible that a high level of myosin phosphorylation is unique to tracheal smooth muscle because lower levels of myosin phosphorylation have been reported in resting[10,11] and pharmacologically relaxed[12] smooth muscles. Nevertheless, one explanation for this observation is that these represent monophosphorylated myosin molecules. Recent experiments[13] on the relationship between smooth muscle myosin phosphorylation and acto-myosin ATPase activity indicate the apparent requirement that both myosin heads be phosphorylated in order for the myosin to be activated by actin. Thus, it is possible that myosin molecules involved in generating tension in tracheal smooth muscle are monophosphorylated in resting conditions and do not begin to hydrolyse ATP and generate tension until the second head is phosphorylated.

Second, what is the significance of the overshoot in myosin phosphorylation seen in muscles maximally stimulated with methacholine (Fig. 1*a*)? Recent studies on intracellular calcium levels during contraction of smooth muscle cells[14,15] and stimulation of non-muscle cells[16] have demonstrated that intracellular calcium levels rise sharply, peak and then decay after stimulation of these cells. Furthermore, peak levels of intracellular calcium are reached before the smooth muscle cells generate maximal tension. As myosin kinase requires Ca^{2+}-calmodulin for activity[3], the activation of this enzyme probably follows the calcium transient. In fact, the overshoot in myosin phosphorylation may be a reflection of the redistribution of the intracellular calcium levels in response to stimulation of muscarinic receptors[17].

Finally, the most direct relationship between myosin phosphorylation and tension appears to be between the steady-state level of myosin phosphorylation and maximal isometric tension generated at a given agonist concentration. The data in Fig. 2 support this hypothesis as they demonstrate that both myosin phosphorylation and isometric tension are coupled to stimulation of muscarinic receptors. Uncoupling of either process, or a shift in the phosphorylation curve in relation to the tension curve, would have indicated a complex relationship between tension and steady-state myosin phosphorylation. The generation of superposable dose–response curves for phosphorylation and tension suggests that the active isometric tension maintained by tracheal smooth muscle is directly related to the steady-state level of myosin phosphorylation. The data also suggest that the myosin phosphorylation–dephosphorylation reaction can be regulated in tracheal smooth muscle so as to maintain defined levels of phosphorylation which, in turn, seem to determine the tension generated by the muscle.

In contrast to the data presented above, myosin phosphorylation does not remain elevated in hog carotid artery smooth muscle contracted with KCl[10]. In this case the myosin phosphate content decreased to a level slightly above the resting level after the carotid artery muscle had generated maximal tension, which suggested that smooth muscles can maintain tension through the formation of a special, non-cycling acto-myosin cross-bridge, termed a 'latch' bridge[10]. It is possible that latch bridges are formed only when carotid artery smooth muscles are stimulated by KCl, as the myosin phosphate content remains elevated in the same muscles contracted with histamine[11]. Although the presence of latch bridges in smooth muscles contracted with pharmacological agents cannot be discounted, the demonstration that the rise in both tension and myosin phosphorylation is related to the level of agonist stimulation (Fig. 2), and the observation that myosin phosphorylation remains elevated when smooth muscles are stimulated with pharmacological agonists (Fig. 1; and ref. 11), suggest that the steady-state level of myosin phosphorylation may be the major determinant of the tension maintained by a smooth muscle.

Thus, the data presented here support, but do not prove, the hypothesis that myosin phosphorylation regulates muscle contraction, and also demonstrate a relatively complex relationship between myosin phosphorylation and the process of tension generation by tracheal smooth muscle.

But is man a worm?

J. S. Jones

Darwin to DNA, Molecules to Humanity. By G. Ledyard Stebbins. Pp.491. Hbk ISBN 0-7167-1331-4; pbk ISBN 0-7167-1332-2. (W. H. Freeman: 1982.) Hbk $25, £21.80; pbk $12, £10.50.

THE most difficult thing in writing a book about evolution is to know what to leave out. Almost any biological observation can be discussed in Darwinian terms: indeed, the very universality of the theory of evolution is the main philosophical obstacle to subjecting it to scientific test. In the past few years we have had books dealing with, for example, evolutionary biochemistry, the evolution of animal behaviour and the mathematics of the evolutionary process, together with a mass of popular (or at least unscientific) works which purport to explain human behaviour and social organization in terms of evolutionary theory. In the rush to explain such complex matters in simple terms there has often been a danger of losing sight of the biological wood through the evolutionary trees. What interested Darwin was, of course, the diversity of living organisms. It is therefore surprising how small a part the variety of animals and plants plays in most of these volumes.

Here we have a book, aimed both at undergraduates and at a general audience, which sets out not only to describe the mechanisms and results of evolutionary change in a range of species from cycads to cephalopods but attempts also to apply such patterns to the evolution of human behaviour and the course of human history. Such attempts — and there are many of them — imply that man is indeed little more than a remarkably well-developed worm; the same rules which govern the evolution of amphibia from fish or of *Homo sapiens* from *Ramapithecus* have been responsible for the change from tribe to nation state or from feudalism to capitalism. How well does G. Ledyard Stebbins, an eminent plant evolutionist, succeed in establishing a seamless transition from the primordial slime to the Reagan administration?

It is immediately obvious that Stebbins is far better qualified to attempt this task than are most of his recent predecessors. Instead of the usual facile discussions of human society in terms of carefully selected anecdotes of animal behaviour, we have in the first two-thirds of the book a greatly compressed but remarkably complete account of modern evolutionary biology.

Courtesy *Punch*

The results of this compression are sometimes alarming; for example, Chapter 9 takes us "From Worms to Primates" in 31 pages of text. There is nevertheless much more insight into the process of evolution here than in many books claiming a far higher level of technical sophistication. Many of these insights are attractively phrased: thus Stebbins illustrates the inevitable incompleteness of the fossil record by pointing out that no one has seen the fossilized remnants of a passenger pigeon, although these birds flourished in millions in North America only a hundred years ago. There is even room for a few poetic touches, as when he talks of the oppressive silence of the Carboniferous forests before the evolution of animals capable of making sounds.

Stebbins illustrates the changes in the fortunes of Darwinism over the past century by recalling disparagingly that in his Harvard days in 1926 the theory outlined in the *Origin of Species* was described as having been long ago abandoned. The recent resurgence of anti-Darwinian models of speciation by "punctuated equilibrium" from the same institution shows how rapidly the pendulum of evolutionary fashion can swing. Stebbins himself considers that the pattern of change of animals and of societies does indeed show stability followed by relatively rapid change, although he is careful to point out that the enormous time scale of evolution in comparison to the brief generation interval of living organisms means that this can easily be accommodated in the Darwinian model.

Only three years after the publication of the *Origin*, Marx wrote to Engels:

> It is remarkable how Darwin recognizes among beasts and plants his English society with its division of labour, competition, opening up of new markets, inventions, and the Malthusian "struggle for existence".

Darwin was himself well aware of the possible application of his theory to human history but steadfastly refused to be drawn into discussion on the subject. Such restraint has scarcely been a characteristic of his successors. Indeed it is now almost an occupational hazard for elderly and distinguished biologists to produce biological overviews of human society. Stebbins is no exception, and it is in the last third of his book — "Human Evolution: Biological and Cultural" — that the clarity of his arguments begins to falter.

Although Stebbins criticizes some of the particularly inane statements of geneticists about history (such as Darlington's equation of the success of the Normans with their acquisition of genes both for horse-riding and for seamanship) he is not inhibited from discussing patterns of historical change — including such unjustifiably neglected episodes as the Revolt of the Red Eyebrows in first-century China — in genetic terms. This does provide occasional brilliant insights into human history. For example, the lack of speciation in the hominid line compared to that in other primates is ascribed to the development of tools, which themselves underwent adaptive radiation. However, for much of the time he is drawn onto the wilder shores of speculation as, for instance, when he discusses the presumed coincidence of nut-eating with the beginnings of intelligence, or of mental alertness with the idle ruminations of prehistoric night-watchmen by their newly-discovered fires and the favours bestowed on them by females as rewards for their wakefulness.

Stebbins is too good a scientist to draw simple lessons from the faulty and imperfect evidence of human history. As a result, he often reaches conclusions so broad as to be almost lacking in content:

> A safe generalization is that genetic templates transmit potentialities and capacities rather than adult behavioural traits . . . . In humans, cultural fitness, based to a large extent on a desire for approval by society, has both a genetic and a cultural basis. Is *Homo sapiens* just another species of animal that has evolved in the same way as have the various species of monkeys and apes? The answer to this question is a qualified 'no'.

In general, a large part of his answer to the question posed throughout — Can the evolution of man and society be explained in terms of the evolutionary rules affecting lower organisms? — is a similarly resounding "perhaps". The book therefore ends in a curiously flatfooted way: "Is the evolutionist better equipped than anyone else to recommend what is best for human society? Perhaps not". This conclusion is an honest one, but betrays the excellence of Stebbins's treatment of the evolutionary process. *Darwin to DNA* is fine; *Molecules to Humanity* could be considerably edited with little loss. □

Naked protoplasm and synchronous nuclei

Michael Carlile

Cell Biology of Physarum and Didymium. Vol. 1, *Organisms, Nucleus and Cell Cycle.* Edited by Henry C. Aldrich and John W. Daniel. Pp.444. ISBN 0-12-049601-1. (Academic: 1982.) $55, £36.40.

THE myxomycete plasmodium is a remarkable object. A mass of protoplasm not subdivided into cells it can, in the most intensively studied species *Physarum polycephalum,* attain the size of a dinner plate and contain hundreds of millions of nuclei which divide synchronously, at least twice a day in a well-nourished plasmodium.

A handful of enthusiasts for "naked protoplasm" have studied myxomycete plasmodia for over a century and since 1961, when workers at the McArdle Laboratory for Cancer Research at Madison grew plasmodia of *P. polycephalum* in pure culture on soluble media, many molecular, developmental and cell biologists have carried out work on this organism. A second species, *Didymium iridis,* has also been the subject of ultrastructural and genetical studies, but here biochemical investigation has been limited through failure to grow plasmodia in pure culture.

In spite of the wide interest in *Physarum* plasmodia, however, reviewing activity has been limited. Two recent works are now remedying this deficiency. In 1980 *Growth and Differentiation in* Physarum polycephalum, edited by W. F. Dove and H. P. Rusch, was published by Princeton University Press (for review see *Nature* **288,** 307; 1980). Now a different group of authors have contributed to the first of two volumes edited by Henry Aldrich, a leading student of myxomycete ultrastructure, and John Daniel, who with Howard Rusch was responsible for the crucial 1961 paper on pure culture.

The introductory section of the first volume consists of a chapter on the morphology and taxonomy of myxomycetes by Alexopoulos and one on *D. iridis* by Collins and Betterley, leading authorities on this organism. Subsequent pages are effectively confined to *P. polycephalum.* Tyson deals with periodic phenomena — not only synchronous nuclear division and other periodic events of the nuclear cycle, but also the control of the protoplasmic streaming that occurs in well-defined channels in the plasmodium at rates of up to a millimetre a second with reversals in the direction of flow taking place at approximately one minute intervals. The plasmodium is capable of rapid migration and among the sensory systems guiding migration is chemotaxis, which is being intensively studied in Japan and is reviewed here by Ueda and Kobatake. Protoplasmic streaming and its control is further considered by Kessler.

The difficult subject of *Physarum* genetics is dealt with ably by Jennifer Dee, the founder of the subject. Two chapters by Mohberg and Babcock then clarify in a succinct way the confusing topics of ploidy and of the genealogy of the strains of *P. polycephalum* in current use. The final four chapters of the first volume deal with nuclear organization (Lafontaine and Cadrin), chromosomal organization (Matthews and Bradbury), DNA (Evans) and RNA (Braun and Seebeck), the important topics of differentiation, metabolism and methodology being deferred to Vol. 2.

This first volume is lucidly written and admirably illustrated. I suspect — and hope — that the two-volume work will do much to promote work on myxomycetes and publicize the results among other biologists. □

Michael Carlile is Senior Lecturer in the Department of Pure and Applied Biology, Imperial College, University of London.

Putting the forams in order

John W. Murray

Foraminifera. By John R. Haynes. Pp.433. ISBN 0-333-28681-2. (Macmillan Press/Halsted: 1982.) £50, $79.95.

FORAMINIFERA are tiny animals that build themselves a test or shell. Their fossil remains occur in astronomical numbers from the Cambrian to the present day in sediments accumulating in estuaries, seas and oceans. These attributes, together with their great diversity, have made them of use to geologists both for correlating rocks of similar age (biostratigraphy) and for determining the environments of deposition of their enclosing sediment (palaeoecology). In addition, as foraminiferal tests survive the process of drilling boreholes, they are especially useful in the exploration for petroleum.

A sound taxonomic basis is an essential prerequisite for all such studies and Dr Haynes has taken this as the main theme of his book. In particular, his thorough account of how to write the description of a species and the compilation of a synonymy will prove invaluable to postgraduate students and researchers.

The main thrust of the volume is the introduction of a revised suprageneric classification. As the study of Foraminifera has progressed over the past 200 years, the importance of certain morphological features as criteria for grouping or dividing the species into genera, superfamilies and so on have varied. The revised classification follows previous ones in using the wall structure of the test as the primary means of grouping and subdivision but it takes into account the new information amassed from electron microscopy. Greater importance is attached to details of the aperture than is customarily the case.

Nine orders and thirty-two superfamilies are described. For each order there is discussion of the range of morphology observed, possible evolutionary relationships, an appraisal of their stratigraphic value, comments on their ecology and palaeoecology, and a summary of the classification. The latter includes diagnoses of the superfamilies and of the important genera.

The book is described in the preface as a general text which lays stress on the stratigraphical application of Foraminifera. This aim it achieves admirably with a synthesis of knowledge from more than 1,000 publications, but, in addition, it contains much original work. All those involved in the study of Foraminifera will find it both instructive and stimulating reading. □

J. W. Murray is Professor of Geology and Head of the Geology Department at the University of Exeter.

Extra genes, in and out of chromosomes

Joseph G. Gall

Gene Amplification. Edited by Robert T. Schimke. Pp.339. ISBN 0-87969-151-4. (Cold Spring Harbor Laboratory: 1982.) $35 (US), $42 (elsewhere).

WHEN mammalian tissue cultures are treated with gradually increasing concentrations of methotrexate (MTX), cell lines can be selected that are resistant to very high concentrations of the otherwise toxic drug. The basis of resistance may be decreased permeability of the cells to the drug or decreased binding between the drug and the target enzyme, dihydrofolate reductase (DHFR). In a significant number of lines, however, resistance is due to compensatory production of the enzyme, which itself is related to increased synthesis of the mRNA and ultimately to differential replication or amplification of the gene coding for DHFR.

These surprising facts were first reported four years ago in elegant experiments by Robert Schimke and his colleagues at Stanford University. Progress in the field has been rapid since then, and late last year Schimke organized a small symposium at Cold Spring Harbor to summarize that progress. This volume, *Gene Amplification*, contains 42 short papers based on presentations at the symposium.

Many of the papers are concerned with the chromosomal and molecular state of the amplified genes. It became evident early on that two unusual cytological phenomena could be associated with amplified cell lines: first, the presence of small acentric chromosomes, which, because they often occur in pairs, are called double minutes; and second the appearance of long chromosome segments with little evidence of G-banding, referred to as homogeneously staining regions. Amplified genes have now been demonstrated in both regions by *in situ* nucleic acid hybridization. There is a good but not perfect correlation between stability of the amplified condition (when MTX is removed) and the physical location of the amplified genes — homogeneously staining regions being characteristic of stable lines, double minutes of unstable ones. It is possible, therefore, that amplified gene copies appear first as small extrachromosomal elements that later become stably integrated into one or more chromosomes. The size of the amplified region has been measured by hybridizing DNA from amplified lines with genomic sequences that flank the DHFR gene. The amplified segment may be up to 100 kb in length, considerably longer than the coding region itself (31 kb counting its five introns).

Almost nothing is known about the initial molecular events of amplification in tissue cultures. A model discussed in the book by Botchan and by Spradling involves multiple rounds of replication at a single origin of replication, giving rise to an "onion-skin" configuration. An attractive feature of this model is the ease with which it can be applied to the chorion genes of *Drosophila*, whose amplification in the follicle cells of the oocyte has been analysed in detail by Spradling. In this case the chorion genes are more highly amplified than surrounding sequences, the level of amplification falling off progressively on both sides of the genes. This is just what one would expect if multiple replication forks move away from an origin of replication in or near the genes.

Several other specific amplifications have been induced in tissue cultures, of which the best characterized involve resistance to *N*-(phosphonacetyl)-L-aspartate or to the cadmium ion. These cases involve overproduction of the multifunctional protein "CAD" and of metallothionein-1 respectively. Several other likely cases are discussed in the book, and it seems probable that many genes can be amplified if a suitable inhibitor of enzyme activity is available. An interesting possibility is that random genomic fragments regularly detach from chromosomes and require only a selective force to undergo differential replication.

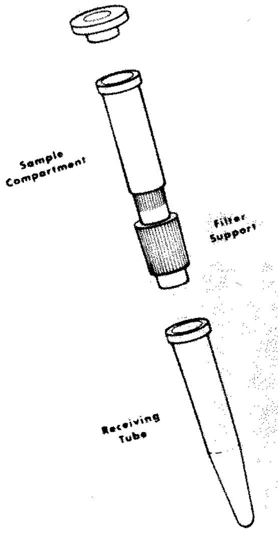
All 42 articles in the volume are short; indeed some are little more than expanded abstracts. The quality is variable, and since many are rather specialized the general reader will have to pick and choose to avoid getting bogged down in cytological and molecular detail. In addition, the title *Gene Amplification* is somewhat misleading. Schimke's major interest is drug-induced gene amplification in cultured cells, and that is what the book really covers. Gene amplification as a general biological phenomenon is touched upon, but readers unfamiliar with the field would not guess that naturally occurring gene amplification, particularly of rDNA, has been investigated extensively during the past 15 years in a variety of vertebrates, insects and protozoa. For a broader introduction to the topic one should begin with Adrian Bird's review article, "Gene reiteration and gene amplification", published in Vol.III of Prescott and Goldstein's *Cell Biology* (Academic, 1980).

Nevertheless this volume summarizes a large amount of work on an important topic. Like the much larger 1980 Cold Spring Harbor Symposium on movable genetic elements, it emphasizes the plasticity of the eukaryotic genome, a subject of great current interest. Because the book was published just six months after the meeting itself, the articles are timely and will prove useful to a wide audience. □

Joseph G. Gall is Professor of Biology, Molecular Biophysics and Biochemistry at Yale University.

Centrifugal Microfilters

Bioanalytical Systems introduces a centrifugal microfilter for membrane filtration of small volumes using the force of a conventional bench top centrifuge. Ideal for LC sample preparation, extraction of TLC spots, and many other applications.



- minimize loss and contamination
- no vacuum or pressure required
- solvent resistant polyalomar
- filter many samples simultaneously
- a variety of filter materials are available
- reusable

Send for details...

Meteoritics as petrography

John A. Wood

Meteorites: A Petrologic–Chemical Synthesis. By Robert T. Dodd. Pp.432. ISBN 0-521-22570-1. (Cambridge University Press: 1982.) £35, $69.50.

METEORITES are complex, ancient, enigmatic rock fragments from somewhere beyond Mars. They were formed at the same time as the Solar System, and they retain a cryptic record of the events of that time. In the 30 years since Harold Urey and Harrison Brown unleashed the techniques and concepts of post-War geochemistry on these objects, meteoritics has burgeoned into an important scientific subdiscipline. Many studies have been carried out and as many papers published; a number of important insights have been gained; and several riddles are still with us, more prickly and intractable than ever.

The field has always needed a good reference book, the more so as its literature has expanded to a scale greater than any one person can assimilate. Several books about meteorites have been written at a professional level in the past decade, but none can be said to fill the need. Robert Dodd's *Meteorites: A Petrologic–Chemical Synthesis* is the latest candidate. It is important to include the subtitle, because the emphasis of the book is very strongly on the petrology (or, to be more precise, the petrography) and chemistry of meteorites, Dodd's own speciality. (Petrography is the descriptive study of the microstructures and component mineralogies of rocks.)

Many good things can be said about the book. Dodd writes in a readable, straightforward style. His coverage of petrography and chemistry is comprehensive, scholarly and exhaustively referenced. Material is rationally organized, most of the chapters dealing with discrete subclasses of meteorites. (Two exceptions are a chapter on radiometric studies of meteorites, and one on the asteroid-sized parent bodies that they once resided in.) He strikes an appropriate balance between descriptions and interpretive discussions. In the latter, he is as objective as can reasonably be expected of a mortal in this contentious field. Each chapter is preceded by a précis that maps out for the reader the ground to be covered. There is an excellent index, and the illustrations are more than adequate in number and quality.

However, I fault the book for presenting a narrow view of meteoritics, that is, one largely limited to petrographic and geochemical studies. Perhaps it is unreasonable to expect Dodd, or anyone, to cover the whole marvellously diverse field of meteoritics as comprehensively as the author has treated meteoritic petrography and chemistry. The book would be twice as long and would cost Dodd far more than twice the labour, since he would have to venture beyond his field of experience.

But the book as it stands unfortunately presents the study of meteorites as an end in itself rather than as a means to a greater end: an understanding of the origin of the Solar System. The stage on which this drama occurred was the solar nebula, a giant accretion disk of gas and dust where the properties of the meteorites and, ultimately, the planets, were established. Dodd cannot avoid making repeated references to the nebula, the context in which everything happened; but he eschews any systematic discussion of astrophysical models of the nebula because they are "varied and changeable". Lacking such a framework, he cannot put the properties of meteorites to work in clarifying our view of the nebula.

"Nebula" does not appear in the index of the book; nor does "Solar System, origin"; nor does "FUN inclusions". The latter, the subject of intensive isotopic research which gives us a fascinating view of pre-Solar System events, are touched on only momentarily, and then not by the name "FUN". It is regrettable that the non-petrographic aspects of meteorites are given such short shrift: the most inspiring aspects of meteoritics are the grand vista it examines, and the close collaboration of researchers from many diverse disciplines in attacking the problem. *Meteorites: A Petrologic–Chemical Synthesis* exposes only a near-sighted and parochial view of the goals of this field. It is, however, a useful and excellent reference work within the unfortunately restrictive boundaries it has erected. ☐

John A. Wood is an Associate Director of the Harvard–Smithsonian Center for Astrophysics, Cambridge, Massachusetts.

Welcome to theoretical particle physics

P.V. Landshoff

Gauge Theories in Particle Physics: A Practical Introduction. By Ian J.R. Aitchison and Anthony J.G. Hey. Pp.341. Pbk ISBN 0-85274-534-6. (Adam Hilger/Heyden: 1982.) £14.50, $36.

THERE are still very few books on the topics that now excite the interest of particle theorists — the electroweak theory that brings together electromagnetism and the weak nuclear interaction, and quantum chromodynamics, the candidate theory of the strong nuclear interaction. So this book, which sets out to be a compact introduction to these subjects, will be warmly welcomed, especially for the attention it gives to the distinctive properties of the gauge symmetry underlying the new theories.

Quantum electrodynamics is the prototype gauge theory and is described by Aitchison and Hey as "the best theory we have". Its best test is the magnetic moment of the electron, whose calculated and measured values agree to within one part in 10^{10}. Electrodynamics is a gauge theory because its physical predictions are invariant under certain transformations of the electromagnetic potentials. Only this gauge invariance makes it possible to remove unphysical infinities from the quantized version of the theory (renormalization).

Quantum electrodynamics is based on Maxwell's equations, the first description of the electric and the magnetic force in the same set of equations. A century later, Glashow, Salam and Weinberg enlarged the theory so as to incorporate the weak interaction (responsible, for example, for neutron β-decay). Their unified electroweak gauge theory is steadily accumulating an impressive list of successes.

Another gauge theory, chromodynamics, seems to give a good description of the nuclear force. Attempts to unify this with the electroweak theory have led to the prediction that protons are unstable, with a lifetime of about 10^{31} years. Four candidate proton-decay events have recently been observed, but the data are not yet a sufficient test.

Quantum electrodynamics itself is far from easy, but the electroweak theory and chromodynamics are less accessible to most physicists because the groups of gauge transformations are not Abelian (which implies that the underlying gauge transformations do not necessarily commute with each other). This book sets out to make the theories as simple as possible. Everything is here, from the elements of relativistic quantum mechanics to a mention of proton decay in grand unified models, with renormalization and even a brief discussion of the quark–parton model on the way.

Inevitably in a short book of wide scope nothing is treated very fully. In places plausibility arguments replace proper derivations. But experimentalists especially will find it helpful in providing an understanding of the essential ideas behind what the theorists are talking about, while neophyte theorists will find it a valuable introduction to the more advanced texts. The second half of the book will be the most useful, for the painless insight that it gives into non-Abelian physics. ☐

Peter Landshoff is Reader in Mathematical Physics at the University of Cambridge.

LAST REMINDER

Can Europe stay in the biotechnology race?

An international conference organised by The Economist at the Amstel Hotel, Amsterdam on 7-8 October 1982

e Economist, one of the first to recognise the ommercial potential of developments in otechnology, is now organising a conference discuss the present state and future of otechnology in Europe. The speakers are:

GER WHITTENBURY
fessor of Biological Sciences
niversity of Warwick, UK

BOB RABIN
Professor of Biochemistry
University College,
London, UK

ROB MARGETTS
General Manager, 'Pruteen'
ICI Agricultural Division, UK

ROBERT FILDES
President
Biogen Inc, USA

J SCHELL
Professor of Genetics
Laboratorium voor Genetica,
Belgium

VIVIAN MOSES
Professor of Microbiology
Queen Mary College, London,
UK

MICHAEL ROSE
Group Manager Biosciences
ICI Corporate Bioscience Group,
UK

R S CRESPI
Patents Controller
British Technology Group, UK

R E CAPE
Chairman
Cetus Corporation, USA

J D BU'LOCK
Wolfson Biomass Unit
University of Manchester, UK

PETER LAING
Manager
N M Rothschild
Asset Management
Limited, UK

GUNNAR WESSMAN
President
Fortia/Pharmacia, Sweden

SCOTT KING
Vice-President
Research Division
F Eberstadt & Co Inc, USA

B M RICHARDS
Vice-President
UK Preclinical Research & Development
G D Searle & Co Limited, UK

JOHN ASHWORTH
Vice-Chancellor
Salford University, UK

J A WOLHOFF
Board member of Dutch companies
Netherlands

If you are interested in the latest financial, commercial, legal or scientific developments in biotechnology, simply complete the coupon below now.

☐ Please send me further details.
☐ Please register me as delegate.
☐ Please send invoice (fee £275.00).

Please return to: The Economist Conference Unit, 25 St. James's Street, London SW1A 1HG. Telephone: 01-839 7000. Telex: 24344.

A NEW QUARTERLY JOURNAL...

JOURNAL OF ATMOSPHERIC CHEMISTRY

Editors:
P.J. CRUTZEN, *Max-Planck-Institute for Atmospheric Chemistry, Mainz, F.R.G.*
D.H. EHHALT, *Institute for Atmospheric Chemistry, Kernforschungsanlage Jülich, F.R.G.*

The Journal will be devoted to the study of the chemistry of the Earth's atmosphere with emphasis on the region below about 100 km. Submission of original work on the following is welcome:
- composition and physico-chemical processes (excluding air pollution problems of only local importance);
- the role of the atmosphere in biogeochemical cycles;
- laboratory studies of transformation processes;
- novel instrumentation of direct importance for field measurements.

The first issue will appear in March 1983. Contributions should be submitted in triplicate to either of the above editors (for the first issue, by the end of September 1982). Further information can be obtained from the publisher.

Subscription rates:
Institutional: Dfl. 185,– / US $ 74.00. *Private:* Dfl. 85,– / US $ 34.00 (prices include postage and handling).

D. Reidel Publishing Company.
P.O. Box 17 3300 AA Dordrecht The Netherlands

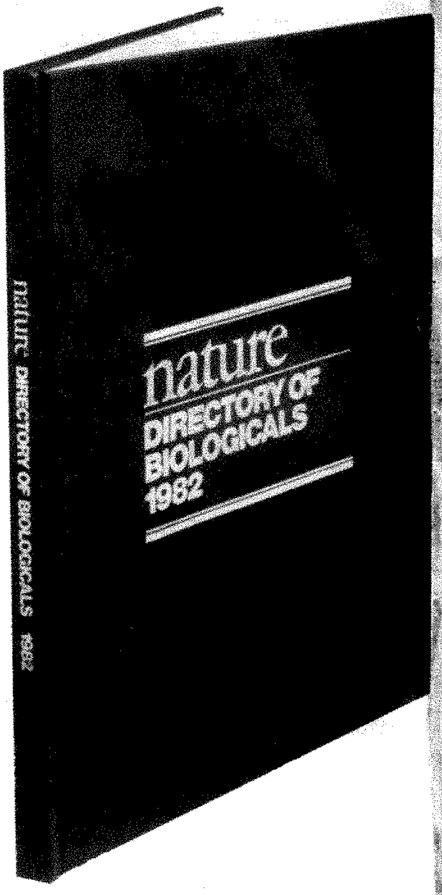
"A unique guide to biological laboratory products."



The Directory of Biologicals offers life scientists a comprehensive listing of what is on the market and where researchers can order these materials for their work. Designed to meet the day-to-day needs of active biologists searching for the right product to use in the laboratory, its simple alphabetical listings cover all of modern life science research. Clear and easy to use, it lists more than 2,000 products commercially available, with the names and addresses of companies throughout the world that offer them for sale. Telex and telephone numbers give users direct access to sales offices in your area. Company entries also briefly describe each supplier's specialization. A separate section lists products by trade name or registered trademark, keyed to the companies in the guide.

Helpful essays on how to use the directory, safety procedures, how to purchase biological materials, and the future of modern biology, make this the most useful directory ever published for biological research workers.

All subscribers to *Nature** automatically receive a handsome paperbound version of the directory. **But if you think you need a copy to stand up against constant use in your laboratory or your library, or if you are not a subscriber, you can purchase the deluxe hardcover edition.** (No paperback editions will be available after subscribers receive their free copy.) To order a hardcover edition, all you need do is fill out the form and mail it today.

297x210mm
232 pages
ISBN: 0 333 33233 4

U.S. and Canada: *Nature*, 15 East 26th Street, New York, NY 10010
U.K. and Rest of World: *Nature*, Canada Road, Byfleet, Surrey KT14 7JL, England.

☐ **Send me______copies of the deluxe, hardcover edition of the Directory of Biologicals @ $45/£22.50 each. (P&P free).** (Tax: N.Y. State Residents, please add sales tax.) (I understand that as a subscriber to *Nature* I will receive a free copy of the paperbound edition as part of my subscription.*)
